Methylprednisolone	125–500 mg oral/IV every 6 hours for total of four doses	N/A	
Cannabinoids			
Dronabinol	Oral: 5–15 mg/m^2 every 2–4 hours as needed	Use adult dose with caution and adjust based on response	Most common: Drowsiness, euphoria, somnolence, vasodilation, vision changes, dysphoria
Nabilone	Oral: 1–2 mg two to three times a day as needed	N/A	Less common: Diarrhea, flushing, tremor, myalgia
Benzodiazepines			
Lorazepam	Oral/IV: 0.5–2 mg prior to chemotherapy	Oral/IV: 2–15 years old: 0.05 mg/kg (up to 2 mg) prior to chemotherapy	Most common: Sedation, amnesia Rare: Respiratory depression, ataxia, blurred vision, hallucinations
Alprazolam	Oral: 0.5–2 mg three times a day prior to chemotherapy	N/A	
Serotonin Antagonists			
Dolasetron	*CINV*: Contraindicated due to dose-dependent QTc prolongation *PONV*: 12.5 mg IV 15 min before end of anesthesia or at onset of N/V or 100 mg PO within 2 hours before surgery	*CINV*: Contraindicated due to dose-dependent QTc prolongation *PONV*: 0.35 mg/kg IV (max 12.5 mg) or 1.2 mg/kg PO (max 100 mg) within 2 hours before surgery	Most common: Headache, QT prolongation Less common: Constipation, asthenia, somnolence, diarrhea, fever, tremor or twitching, ataxia, lightheadedness, dizziness, nervousness, thirst, muscle pain, warm or flushing sensation on IV administration, serotonin syndrome (with ondansetron when used with serotonergic agents) Rare: Transient elevations in hepatic transaminases Granisetron may be degraded by light. Cover patch application site (eg, with clothing) if risk of exposure to sunlight or sunlamps during use and for 10 days after removal
Granisetron	*CINV*: 10 mcg/kg IV prior to chemotherapy; or 1 mg orally 1 hour before chemotherapy and 1 mg 12 hours after first dose, or 2 mg 1 hour before chemotherapy *PONV*: 1 mg IV before induction of anesthesia or immediately before reversal of anesthesia, or at onset of N/V	*CINV*: 2–16 years: Use adult dosing IV or PO regimen *PONV*: Not recommended for pediatric patients	
Granisetron	*CINV*: 1 patch 24–48 hours before chemotherapy; may wear for up to 7 days	N/A	
Ondansetron	*CINV*: Oral: 24 mg single dose prior to chemotherapy, or 8 mg prior to chemotherapy, repeat every 12 hours IV: 0.15 mg/kg, not to exceed 16 mg/dose, for three doses. Give the first dose 30 min prior to chemotherapy. Repeat dose 4 and 8 hours after the first dose *PONV*: 4 mg IV/IM before anesthesia induction or at onset of N/V; 16 mg orally once given 1 hour before anesthesia induction	*CINV*: Oral: 4–11 years, 4 mg 30 min prior to chemotherapy, repeat at 4 and 8 hours and every 8 hours for 1–2 days after chemotherapy completion IV: 6 months to 18 years: 0.15 mg/kg, not to exceed 16 mg/dose, for three doses. Give the first dose 30 min prior to chemotherapy. Repeat dose 4 and 8 hours after the first dose *PONV*: 1 month–12 years: 4 mg IV/IM before anesthesia induction for over 40 kg and 0.1 mg/kg IV for under 40 kg Oral recommendations not available	
Palonosetron	*CINV*: 0.25 mg IV 30 min before chemotherapy; 0.5 mg orally 1 hour before chemotherapy *PONV*: 0.075 mg IV before anesthesia induction	*CINV*: 20 mcg/kg (maximum 1.5 mg) IV 30 min before chemotherapy	

(*Continued*)

Table 21–2

Antiemetic Agents: Usual Doses for Adults and Children and Adverse Effects (*Continued*)

Drug	Adult Dosing	Pediatric Dosing	Adverse Effects[a]
Neurokinin-1 Antagonist			
Aprepitant	*CINV*: 150 mg IV (fosaprepitant) 30 min before chemotherapy on first day of chemotherapy only; or 125 mg orally on day 1, 1 hour prior to chemotherapy followed by 80 mg on days 2 and 3 *PONV*: 40 mg orally 3 hours prior to anesthesia induction	*CINV*: 12 years and older: 125 mg PO on day 1, 1 hour prior to chemotherapy followed by 80 mg on days 2 and 3 6 months to 12 years: 3 mg/kg (max 125 mg) day 1, then 2 mg/kg (max 80 mg) day 2 and 3	Most common: Fatigue, hiccups Less common: Dizziness, headache, insomnia Rare: Transient elevations in hepatic transaminases
Rolapitant	*CINV*: 180 mg PO on day 1, 1–2 hours prior to chemotherapy	N/A	
Netupitant	*CINV*: Netupitant 300 mg plus palonosetron 0.5 mg combination product on day 1, 1 hour prior to chemotherapy	N/A	
Other			
Doxylamine/ pyridoxine	Oral: 10 mg/10 mg tablets, 2 tablets PO at bedtime, titrate to a maximum of 4 tablets daily for persistent symptoms; or 20 mg/ 20 mg tablets, 1 tablet at bedtime on day 1; if symptoms persist on day 2, increase to 1 tablet in the morning and at bedtime (maximum of 2 tablets/day)	N/A	See adverse effects for antihistamines above.
Olanzapine	*CINV*: 10 mg PO daily, days 1–4 of highly emetogenic chemotherapy	N/A	Sedation

[a] Most common, greater than 10%; less common, 1% to 10%; rare, less than 1%. Based on US FDA-approved labeling and generalized to drug class.

CINV, chemotherapy-induced nausea and vomiting; EPS, extrapyramidal symptoms; IM, intramuscularly; Inj, injectable dosage form for IV or IM use; N/A, not available; PO, orally; PONV, postoperative nausea and vomiting; TD, transdermal; Supp, rectal suppository.

▶ *Cannabinoids*

Cannabinoids have antiemetic and appetite stimulant activity when used alone or in combination with other antiemetics.[27] Oral dronabinol and nabilone are used for preventing and treating refractory or delayed CINV.[14,27] Cannabinoids are thought to exert their antiemetic effect centrally, although the exact mechanism of action is unknown.[27] Sedation, euphoria, hypotension, ataxia, dizziness, and vision difficulties can occur. Medical marijuana is an area of increased interest, but current evidence is insufficient to recommend its use for this indication.[3,27]

▶ *Benzodiazepines*

Benzodiazepines, especially lorazepam, are used to prevent and treat CINV.[8,14] Lorazepam is used as an adjunct to antiemetic agents.[14] Sedation and amnesia are common side effects. Respiratory depression can occur with high doses or when other central depressants such as alcohol are used concomitantly.

▶ *Serotonin Antagonists*

Serotonin is a neurotransmitter synthesized in neurons in the CNS and in enterochromaffin cells of the GI tract. Chemotherapeutic agents release 5-HT, which is a predominant mediator in nausea and vomiting.[28] This increase in 5-HT concentrations stimulates the visceral vagal nerve fibers and CTZ, thereby triggering nausea and vomiting. Selective 5-HT_3 receptor antagonists (ondansetron, granisetron, dolasetron, and palonosetron) prevent and treat nausea and vomiting due to stimulation of these receptors, especially for CINV and PONV.[3,4,29] These agents are well tolerated; the most common adverse effects are headache, somnolence, diarrhea, and constipation.[14] Dose-related QT changes (including torsades de pointes) have been reported, and ECG monitoring is recommended for patients with risk factors for QT prolongation who will receive ondansetron or dolasetron.[29] Although the labeling for granisetron and palonosetron does not include a recommendation for ECG monitoring, patients may still be at risk for QT changes.

Palonosetron is the first 5-HT_3 antagonist to be approved for preventing both acute and delayed CINV.[14] Compared to other 5-HT_3 antagonists, palonosetron has a longer serum half-life (40 hours compared to 4–9 hours) and a higher receptor-binding affinity, which may contribute to its efficacy in preventing delayed CINV.[30]

▶ *Neurokinin-1 Receptor Antagonists*

Substance P is a neurokinin neurotransmitter that binds to NK_1 receptors in the GI tract and the brain and is believed to mediate both acute and delayed nausea and vomiting.[3,31] Aprepitant was the first NK_1 receptor antagonist antiemetic and is effective for preventing acute and delayed CINV when used with a 5-HT_3 antagonist and a corticosteroid.[32] It is also effective for preventing

PONV.[4,33] Aprepitant has numerous drug interactions because it is an inhibitor and substrate of the CYP 3A4 metabolic pathway.[33]

Netupitant is the second NK$_1$ receptor antagonist; it is available only as a combination product with palonosetron (Akynzeo) for preventing acute and delayed CINV following moderately or highly emetogenic chemotherapy.[3] Rolapitant is the third NK$_1$ receptor antagonist.[34] It is available as an oral formulation that may be used in place of aprepitant or netupitant and is given as a single dose due to its long elimination half-life and does not have the same concerns for drug interactions associated with aprepitant and netupitant. None of the NK$_1$ antagonists are renally eliminated.

▸ *Olanzapine*

Olanzapine is an antipsychotic agent that has effects at D$_2$, 5-HT$_{2c}$, and 5-HT$_3$ receptors, among others. Current guidelines recommend the addition of olanzapine to combination therapy for prevention of CINV in patients receiving highly emetogenic chemotherapy.[3] When used for short-term treatment in this way, olanzapine is well tolerated with sedation on day 2 of chemotherapy the only reported significant adverse effect.

Chemotherapy-Induced Nausea and Vomiting

CINV is classified as (a) acute (within 24 hours after chemotherapy); (b) delayed (more than 24 hours after chemotherapy); or (c) anticipatory (prior to chemotherapy when acute or delayed nausea and vomiting occurred with previous courses).[3,8,14] Risk factors for CINV include poor emetic control with prior chemotherapy, female sex, low chronic alcohol intake, and younger age.[35]

Chemotherapeutic agents are classified according to their emetogenic potential, which aids in predicting CINV.[3,8] Cisplatin, high-dose cyclophosphamide (1.5 g/m^2 or more), or cyclophosphamide combined with an anthracycline are examples of highly emetogenic chemotherapeutic regimens. Lower doses of cyclophosphamide, ifosfamide, and carboplatin are examples of moderately emetogenic agents. Risk factors for anticipatory nausea and vomiting include poor prior control of CINV and a history of motion sickness or NVP.[3,14]

KEY CONCEPT A combination of antiemetics with different mechanisms of action is recommended to prevent acute CINV for patients receiving moderately or highly emetogenic chemotherapy (Table 21–3).[3,8,14] Patients receiving chemotherapeutic agents with low emetogenic potential should receive a single dose of a 5-HT$_3$ antagonist or an 8-mg dose of dexamethasone as CINV prophylaxis, and those receiving chemotherapy with minimal emetogenic risk do not require prophylaxis.

Delayed nausea and vomiting is more difficult to prevent and treat. It occurs most often with cisplatin- and cyclophosphamide-based regimens, especially if delayed nausea and vomiting occurred with previous chemotherapy courses.[8] Patients who had poorly controlled acute CINV in the past are at greatest risk for delayed CINV.[3,8,35]

Oral and IV antiemetics can be equally effective for CINV, depending on patient characteristics such as ability to take oral medications, dosage form availability, and cost.[3,14] Patients undergoing chemotherapy should have antiemetics available to treat breakthrough nausea and vomiting even if prophylactic antiemetics were given.[3,14] A variety of antiemetics may be used, including lorazepam, dexamethasone, methylprednisolone, prochlorperazine, promethazine, metoclopramide, 5-HT$_3$ antagonists, dronabinol, and olanzapine. If breakthrough CINV occurs despite prophylaxis, treatment with an antiemetic with a different mechanism of action is recommended.

Table 21–3

Recommended Drug Regimens for Prevention of CINV Based on Emetogenic Risk[3]

Emetogenic Risk	Acute CINV (Day 1)	Delayed CINV (Days 2–4)
Minimal	None	None
Low	Dexamethasone OR 5-HT$_3$ antagonist	None
Moderate[a,b]	5-HT$_3$ antagonist + dexamethasone	Dexamethasone (days 2 and 3) for agents with known risk for delayed nausea and vomiting
High (includes AC regimens)	NK$_1$ receptor antagonist + 5-HT$_3$ antagonist + dexamethasone[b] + olanzapine	If aprepitant[c] is used, continue days 2 and 3 Continue dexamethasone days 2–4 for non-AC highly emetogenic regimens Olanzapine (days 2–4)

[a] Add NK$_1$ receptor antagonist if using carboplatin and area under the curve is ≥ 4 mg/mL/min.

[b] If rolapitant is the NK$_1$ receptor used, use full dose (20 mg) dexamethasone on day 1. If aprepitant, fosaprepitant, or netupitant are used, dose-adjust dexamethasone (12 mg) on day 1.

[c] If fosaprepitant, netupitant/palonosetron combination or rolapitant are used as the NK$_1$ receptor antagonist on day 1, no subsequent doses required.

AC, anthracycline (daunorubicin, doxorubicin, epirubicin, or idarubicin) plus cyclophosphamide; CINV, chemotherapy-induced nausea and vomiting.

The best strategy for preventing anticipatory nausea and vomiting is to prevent acute and delayed CINV by using the most effective antiemetic regimens based on the emetogenic potential of the chemotherapy and patient factors. CINV should be aggressively prevented with the first cycle of therapy. If anticipatory nausea and vomiting occurs, benzodiazepines and behavioral therapy such as relaxation techniques may be tried.[8,14]

Postoperative Nausea and Vomiting

PONV is a common complication of surgery that can lead to delayed discharge and unanticipated hospitalization.[4] The overall incidence of PONV is 25% to 30%, but it can occur in 70% to 80% of high-risk patients.[4,5] Risk factors for PONV include patient factors (female sex, nonsmoking status, and history of PONV or motion sickness), anesthetic factors (volatile anesthetics, nitrous oxide, especially when administered for longer than one hour, or intraoperative or postoperative opioids), and surgical factors (duration and type of surgery).[4,5] Risk scores such as the Apfel simplified risk score allow practitioners to easily predict a patient's risk of experiencing PONV.[4] The Apfel risk score is based on four factors, each resulting in one point: (a) female sex, (b) history of PONV and/or motion sickness, (c) nonsmoking status, and (d) postoperative opioid use. A score of 0 to 1 corresponds to 10% to 20% risk of PONV (low risk), a score of 2 corresponds to 40% risk (medium risk), and a score of 3 to 4 corresponds to an 80% risk (high risk).

Patient Encounter 1

A 37-year-old man is having laparoscopic inguinal hernia repair surgery today.

PMH: GERD, hypertension, inguinal hernia

SH: Smokes five cigarettes/day, occasional alcohol, negative for illicit drugs

FH: Hypertension, dyslipidemia

Current meds: Lansoprazole 15 mg once daily, hydrochlorothiazide 25 mg once daily

VS: BP 124/84 mm Hg, HR 75 beats/min, RR 16 breaths/min, T 98.6°F (37.0°C)

Labs: All within normal limits
EKG shows normal sinus rhythm and a borderline QTc of 446 ms
General analgesia is planned for surgery and includes thiopental 4.5 mg/kg, atracurium 0.5 mg/kg, and fentanyl 0.05 mg followed by tracheal intubation. Postoperative orders include opioid analgesics for pain control.

What risk factors does this patient have for developing PONV?

What pharmacologic or nonpharmacologic PONV prevention or treatment options are recommended for this patient?

What treatment options would be recommended if he experiences PONV?

Patient Encounter 2

A 30-year-old woman who is 11 weeks pregnant with nausea and vomiting of pregnancy seeks your advice. She complains of frequent nausea and vomiting. She denies increased thirst or changes in urine output. She has not gained weight since her last appointment. She is tolerating small sips of water throughout the day to maintain hydration. She has been taking prenatal vitamins since before her pregnancy and has tried avoiding provoking stimuli, eating frequent small meals, and avoiding spicy and fatty foods. The patient's PUQE score is 7.

What type of nausea and vomiting is this patient experiencing?

What nonpharmacologic and pharmacologic treatment options may help prevent and treat this patient's nausea and vomiting?

Should this patient seek additional medical attention for her symptoms?

The first step in preventing PONV is reducing baseline risk factors when appropriate.[4,5] For example, the incidence of PONV may be less with regional anesthesia than general anesthesia, and nonsteroidal anti-inflammatory drugs may cause less PONV than opioid analgesics. Preventative antiemetic agents are administered based on a patient's risk for PONV.[4] A patient at low risk may not require prophylactic antiemetic medications, those at medium risk would benefit from one or two antiemetic agents, and those at high risk should receive a combination of two or more antiemetic agents as PONV prophylaxis.

KEY CONCEPT Some agents should be administered at induction of anesthesia (aprepitant, palonosetron, dexamethasone), whereas others are more effective when administered at the end of surgery (droperidol, 5-HT$_3$ receptor antagonists). Scopolamine should be administered the evening prior to surgery or 2 hours prior to surgery.[1,4] Aprepitant prevents PONV, but it is not more effective than other agents and is costly.[4,23] Combinations of antiemetics are recommended to prevent PONV for high-risk patients.[23] A 5-HT$_3$ antagonist plus droperidol or dexamethasone is an effective combination.[4,23] If PONV occurs despite appropriate prophylaxis, it should be treated with an antiemetic from a pharmacologic class not already administered.[23] If no prophylaxis was used, a low-dose 5-HT$_3$ antagonist should be used.[23]

Nausea and Vomiting of Pregnancy

KEY CONCEPT Nausea and vomiting affect the majority of pregnant women; the teratogenic potential of the therapy is the primary consideration in drug selection, followed by severity of the nausea and vomiting.[6] Risks and benefits of any therapy must be weighed by the health-care professional and the patient. The Pregnancy-Unique Quantification of Emesis and Nausea (PUQE) is a thee-question assessment tool used to determine the severity of NVP. A score of 6 or less is classified as mild, 7 to 12 as moderate, and 13 or more as severe NVP.

Pyridoxine (vitamin B$_6$) 10 to 25 mg four times daily alone or in combination with an antihistamine such as doxylamine is first-line pharmacotherapy for NVP.[6,11] Combination products are available (Diclegis 10 mg/10 mg and Bonjesta 20 mg/20 mg) with a recommended dose of 20 mg/20 mg at bedtime. Pyridoxine is well tolerated, but doxylamine and other antihistamines may cause drowsiness.

Ondansetron has been used to treat severe NVP. Ondansetron readily crosses the human placenta during the first trimester. There is mixed evidence demonstrating the efficacy of ondansetron vs metoclopramide in preventing severe nausea and vomiting symptoms, and quality data on fetal safety are sparse. Although the safety of anticholinergics and metoclopramide have been established, data demonstrating efficacy are lacking.[6]

In rare instances (0.3%–3% of pregnancies), NVP progresses to hyperemesis gravidarum.[6] Enteral or parenteral nutrition might be used if oral liquids cannot be tolerated or if dehydration occurs. A corticosteroid such as methylprednisolone may be considered.

Patient Encounter 3

A 70-year-old man who presents to your practice is planning a 10-day Mediterranean cruise. He has a past medical history significant for benign prostatic hyperplasia and hypertension for which he takes tamsulosin 0.4 mg daily and lisinopril 10 mg once daily. He has experienced nausea and vomiting during boat rides in the past and states that a friend recommended he purchase "a patch" at his local pharmacy to prevent nausea and vomiting.

What recommendations for nonpharmacologic interventions would you give this patient to help prevent motion sickness?

What are the pharmacologic options for this patient to prevent or treat nausea and vomiting?

What potential adverse effects would you counsel this patient about?

Because methylprednisolone is associated with oral clefts in the fetus when used during the first trimester, corticosteroids should be reserved as a last resort and should be avoided during the first 10 weeks of gestation.[6,11]

Motion Sickness and Vestibular Disturbances

Nausea and vomiting can be caused by disturbances of the vestibular system in the inner ear because of infection, trauma, neoplasm, or motion.[16] Patients may experience dizziness and vertigo in addition to nausea and vomiting. If a patient is susceptible to motion sickness, preventive measures include minimizing exposure to movement, restricting visual activity, ensuring adequate ventilation, reducing the magnitude of movement, and taking part in distracting activities.[16]

KEY CONCEPT Because the vestibular system is replete with muscarinic type cholinergic and histaminic (H_1) receptors, anticholinergics and antihistamines are the most commonly used agents to prevent and treat motion sickness. Oral medications should be taken prior to motion exposure to allow time for adequate absorption. Once nausea and vomiting due to motion sickness occur, oral medication absorption may be unreliable, making the therapies ineffective. Transdermal scopolamine may be considered as a first-line option for patients who cannot tolerate oral medications or who require treatment for a prolonged period.[16] Drowsiness and reduced mental acuity are the most bothersome side effects of antihistamines and anticholinergics. Visual disturbances, dry mouth, and urinary retention can also occur.

OUTCOME EVALUATION

- The symptoms of simple nausea and vomiting are self-limited or relieved with minimal treatment. Monitor patients for adequate oral intake and alleviation of nausea and vomiting.
- Patients with complex nausea and vomiting may have malnourishment, dehydration, and electrolyte abnormalities.
- If the patient has weight loss, assess whether enteral or parenteral nutrition is needed.
- Assess for dry mucous membranes, skin tenting, tachycardia, and lack of axillary moisture to determine if dehydration is present.
- Obtain blood urea nitrogen (BUN), serum creatinine (SCr), calculated fractional excretion of sodium (FeNa), serum electrolytes, and arterial blood gases.
- Ask patients to rate the severity of nausea.
- Monitor the number and volume of vomiting episodes.
- Ask patients about adverse effects to the antiemetics used. Use this information to assess efficacy and tailor the patient's antiemetic regimen.

Abbreviations Introduced in This Chapter

CINV	Chemotherapy-induced nausea and vomiting
CTZ	Chemoreceptor trigger zone
D_2	Dopamine type 2 receptor
EPS	Extrapyramidal symptoms
FeNa	Fractional excretion of sodium
GERD	Gastroesophageal reflux disease
H_1	Histamine type 1 receptor
5-HT_3	5-Hydroxytryptamine (serotonin) type 3 receptors
NK_1	Neurokinin type 1 receptors
NVP	Nausea and vomiting of pregnancy
PONV	Postoperative nausea and vomiting

Pharmacist's Patient Care Process

Collect Information:

- Obtain a thorough patient history including the prescription, nonprescription, and herbal medications being used. Identify any substances that may be causing or worsening nausea and vomiting.

Assess the Information:

- Assess the patient to determine whether the nausea and vomiting is simple or complex and whether patient-directed therapy is appropriate.
- Determine which treatments for nausea and vomiting have been used in the past and their degree of efficacy.

Develop a Care Plan:

- Eliminate the underlying cause of nausea and vomiting if possible.
- Develop a treatment plan with the patient and other health-care professionals if appropriate.
- Choose treatments based on the underlying cause of nausea and vomiting, duration and severity of symptoms, comorbid conditions, medication allergies, presence of contraindications, risk of drug–drug interactions, and adverse-effect profiles.
- Use the oral route for mild nausea with minimal or no vomiting. Seek an alternative route (eg, transdermal, rectal, parenteral) if the patient is unable to retain oral medications due to vomiting.

Implement the Care Plan:

- Counsel the patient to avoid known triggers.
- Provide patient education regarding causes of nausea and vomiting, avoidance of triggers, potential complications, treatment options, medication adverse effects, and when to seek medical attention.
- Educate the patient about nonpharmacologic measures such as stimulus avoidance, dietary changes, acupressure or acupuncture, and psychotherapy.

Follow-up: Monitor and Evaluate:

- To assess efficacy, ask the patient whether nausea or vomiting is resolving with therapy. Assess whether treatment failure is due to inappropriate medication use or the need for additional or different treatments and proceed accordingly.
- Assess adverse effects by asking the patient what he or she has experienced. Patient observation or examination is also useful for diagnosing adverse effects such as EPS.

Constipation, Diarrhea, and Irritable Bowel Syndrome

Beverly C. Mims

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify the causes of constipation.
2. Compare the features of constipation with those of irritable bowel syndrome (IBS) with constipation (IBS-C).
3. Recommend lifestyle modifications and pharmacotherapy for treatment of constipation.
4. Differentiate acute and chronic diarrhea.
5. Compare diarrhea caused by various infectious agents.
6. Appraise medication causes of diarrhea.
7. Construct pharmacotherapeutic strategies for treating diarrhea.
8. Identify the signs and symptoms of IBS with constipation (IBS-C), diarrhea (IBS-D), or mixed (IBS-M).
9. Compare and contrast the features of IBS-C, IBS-D, and IBS-M.
10. Establish treatment goals for IBS.
11. Evaluate the effectiveness of pharmacotherapy for IBS.

INTRODUCTION

Constipation, diarrhea, and irritable bowel syndrome (IBS) are disorders of the gastrointestinal (GI) tract that have various causes and symptoms. A thorough patient assessment is required to accurately identify the underlying causes and implement safe and effective treatment. Functional gastrointestinal disorders (FGIDs) have received increasing attention in recent years.[1] FGIDs are characterized by persistent and recurring GI symptoms due to abnormal GI tract function but without structural or biochemical abnormalities. As a result, many diagnostic tests (eg, X-rays, endoscopic examinations) are often negative. The Rome IV Foundation provides evidence-based definitions, diagnostic criteria, and classification of FGIDs.[1] This chapter is focused on the evaluation and management of constipation, diarrhea, and IBS.

CONSTIPATION

KEY CONCEPT Constipation, when not associated with symptoms of IBS-C, is characterized by the occurrence of fewer than three spontaneous stools per week. There may also be straining on defecation, lumpy or hard stools, sensation of incomplete evacuation, and the need to use manual maneuvers to facilitate defecation. Occasional constipation usually does not require medical evaluation or treatment. *Functional constipation* (FC) is defined as infrequent (fewer than three stools per week) or difficult passage of stools or both that lasts for 12 weeks or more and is accompanied by onset of symptoms at least 24 weeks prior to diagnosis. *Chronic idiopathic constipation* (CIC) is defined as continuing constipation with no known cause or known contributory illness.[2]

EPIDEMIOLOGY AND ETIOLOGY

Constipation affects people of all ages and occurs in approximately 16% of all adults and in one-third of adults aged 60 and older. In 2019, US sales of nonprescription laxative products totaled more than $1.4 billion.[3] It is estimated that CIC affects 9% to 20% of adults in the United States. A population-based survey determined that 37.6% of respondents had discussed their constipation symptoms with a primary care provider, gastroenterologist, or emergency room physician.[4] About 48% of respondents reported that they treated constipation with medication, with 93.5% of those using nonprescription medications alone, 1.3% using prescription medications alone, and 5.2% using both nonprescription and prescription medications.[4]

Constipation can be due to primary and secondary causes (Table 22–1). *Opioid-induced constipation* (OIC) is defined as a change from baseline bowel habits and patterns of defecation after initiating opioid therapy that is characterized by reduced bowel movement frequency, development or worsening of straining to pass bowel movements, a sense of incomplete bowel evacuation, or the patient's perception of stress related to bowel habits.[5] OIC can overlap with and worsen FC. OIC is associated with significant economic burden. In cancer patients taking opioids for pain, the incidence of OIC constipation approaches 94%.[5] Constipation is associated with significant socioeconomic costs and considerable quality-of-life ramifications.[5,6] Physiological, environmental, and demographic factors may play roles in the development of constipation. Some diseases and many medications are associated with constipation.[7,8]

Table 22–1

Some Causes of Constipation

Primary Causes

Normal-transit constipation
Slow-transit constipation (disturbances of neurogastroentero- and brain–gut interactions, inadequate caloric intake)
Defecatory or colonic/rectal evacuation disorders

Secondary Causes

Endocrine/metabolic conditions (diabetes mellitus, hypercalcemia, hypokalemia, hypomagnesemia, hypothyroidism, uremia)
Myopathies (amyloidosis, scleroderma)
Neurogenic conditions (brain trauma, stroke, Parkinson disease, multiple sclerosis, spinal cord injury, or tumor)
Mechanical obstruction (colon cancer, lesion compression, stricture, rectocele)
Medications (analgesics, anticholinergics, antidiarrheals, antihistamines, some antipsychotics and antidepressants, aluminum-containing products, calcium channel blockers, calcium-containing products, clonidine, diuretics, iron-containing supplements, ondansetron, phenothiazines)
Other (autonomic neuropathy, cardiac disease, cognitive impairment, diet, volume depletion, immobility, laxative abuse, postponing urge to defecate, deliberate suppression of defecation, psychological distress, perceptions about bowel frequency)

PATHOPHYSIOLOGY

Primary or idiopathic constipation is categorized as normal-transit constipation (NTC), slow-transit constipation (STC), or dyssynergic defecatory disorders (DD). In NTC, colonic motility is unchanged, and patients experience hard stools despite normal movements. In STC, motility is decreased or caloric intake is inadequate, resulting in infrequent, harder, and drier stools. All three conditions result in prolonged rectal storage of fecal residue and incomplete expulsion of feces from the rectum. Causes of DD may include inadequate relaxation of muscles or paradoxical contractions of the pelvic diaphragm, perineal membrane and deep perineal pouch (the pelvic floor), and the external anal sphincter during defecation.[2,9,10] Chronic constipation without an identifiable cause is often referred to as CIC.

Physiologic changes associated with OIC occur when opioids activate GI tract G-protein–coupled opioid μ, κ, and δ receptors. Activation of these receptors reduces acetylcholine release, which contributes to physiologic changes such as decreased propulsive activity; increased nonpropulsive contractions; decreased pancreatic, biliary, and gastric secretions; and increased anal tone. All of these changes may contribute to constipation.[11]

CLINICAL PRESENTATION AND DIAGNOSIS

A medical history is important to ascertain the frequency and character of bowel movements and the duration of symptoms (see accompanying box for the clinical presentation of constipation). It is important to understand the symptoms that the patient considers to constitute constipation. Dietary, hydration, and physical activity habits should also be determined to identify potential contributing factors. Family history should be assessed for the presence of inflammatory bowel disease (IBD) and colon cancer. A complete record of prescription medications, over-the-counter products, and dietary supplements is mandatory to identify drug-related causes.

KEY CONCEPT The diagnosis of constipation is based on clinical history (frequency of stools per week, consistency of stools, straining on defecation, sensation of incomplete evacuation, sensation of blockage or obstruction, and the need to apply manual maneuvers to facilitate passage of stool), physical examination, minimal laboratory tests, colonoscopy or other procedures, and specific tests to evaluate underlying pathophysiology.

Endoscopy is required to exclude cancer or strictures, especially in patients older than 50 years with weight loss greater than 10 pounds in 3 months, rectal bleeding, or anemia. Anorectal examination, manometry, radiography, colonoscopy, and other procedures may be useful in certain circumstances.

In most cases, the physical examination is normal, and no underlying cause of constipation is identified. However, evaluation may reveal one or more of the following conditions: (a) IBS-C; (b) STC with normal pelvic floor function and evidence of slow transit; (c) a defecatory disorder; (d) a combination of IBS-C and STC; (e) organic constipation (mechanical obstruction or adverse drug effect); and (f) secondary constipation (due to a metabolic disorder).[8]

Clinical Presentation and Diagnosis of Constipation

Symptoms of Constipation

- Infrequent bowel movements (fewer than three per week); straining; lumpy or hard stools; painful or difficult defecation; abdominal pain or distention; bloating; sensation of incomplete evacuation, anorectal obstruction, or blockage; and the need for manual maneuvers to facilitate defecations.
- Alarm (or "red flag") findings include worsening of constipation, sudden change in bowel habits after age 50, rectal bleeding in the absence of documented hemorrhoids or anal fissures, unintentional weight loss (more than 10% within 3 months), family history of colon cancer or family polyposis syndromes, anemia, or recent constipation onset without explanation. These findings require prompt medical evaluation and appropriate intervention.

Physical Examination

- The presence of central nervous system (CNS) or spinal cord lesions may suggest an underlying cause.
- Abdominal examination findings may include distention, hard stool in a palpable colon, or abdominal mass.
- Rectal examination may indicate fecal impaction, anal stricture, or rectal mass.

Laboratory Tests (to Identify Secondary Causes)

- Thyroid-stimulating hormone (hypothyroidism)
- Serum calcium (hypercalcemia)
- Glucose (diabetes mellitus)
- Serum electrolytes (dehydration, volume depletion)
- Urinalysis (dehydration)
- Complete blood count (anemia)

Other Tests

- Screening colonoscopy and other specialized tests may be conducted based on presenting signs and symptoms.

TREATMENT

Desired Outcomes

The primary goals for treating constipation are to: (a) educate the patient, (b) identify underlying causes, (c) treat or remove secondary causes, (d) relieve symptoms, and (e) restore normal bowel function.[1,8] Treatment of constipation depends on the characteristics, severity, and causes of symptoms.

Nonpharmacologic Therapy

KEY CONCEPT Nonpharmacologic measures including lifestyle and dietary modifications should usually be employed before recommending pharmacotherapy. The patient should be educated about possible causes of constipation and the appropriate use of nonpharmacologic measures. Medication use should be evaluated to identify possible contributing factors. Patients should be encouraged to schedule routine bathroom time after the morning or evening meal. It may be helpful to elevate the feet with a stool during defecation because that assists pelvic relaxation.

Increased dietary fiber intake or fiber supplementation (total 20–30 g/day) can improve NTC, whereas patients with STC or drug-induced constipation are unlikely to respond to increased fiber. High-fiber foods include beans, whole grains, bran cereals, fresh fruits, and vegetables such as asparagus, brussels sprouts, cabbage, and carrots.

There are two types of fiber: soluble and insoluble. Soluble fiber is dissolved by water and forms a gel that slows digestion. Some sources of soluble fiber include lentils, apples, nuts, flaxseed, and psyllium. Methylcellulose (eg, Citrucel with SmartFiber) is a soluble fiber. It is nonfermentable and less likely to cause bloating and gas. Calcium polycarbophil (eg, FiberCon) is mainly a soluble fiber. Wheat dextrin, a manufactured by-product of wheat (eg, Benefiber) contains only soluble fiber. Because Benefiber contains less than 20 parts per million of gluten, it is labeled as a gluten-free product. Psyllium is made from seed husks of the plantago ovata plant (eg, Metamucil). Psyllium contains 70% soluble fiber and some insoluble fiber.

Insoluble fiber does not dissolve in water and remains mostly intact as it decreases the time for food and feces to traverse the intestines. Insoluble fiber adds bulk to the diet and helps prevent constipation. Some food sources of insoluble fiber include whole wheat, corn bran, couscous, dark leafy green vegetables, and the skins of root vegetables such as potatoes. The beneficial effects of bulk-forming and osmotic products can be expected within 24 to 72 hours.

Adequate fluid intake is important, especially in patients with evidence of volume depletion. Adult men aged 19 years and over should ingest 3.7 L and women aged 19 and over should ingest 2.7 L of water daily. The thirst mechanism changes with age; keeping a daily intake diary may assist patients who need to be reminded to drink fluids. Increased exercise may improve symptoms of constipation.[1]

Biofeedback-aided pelvic floor training may be useful; patients are guided to demonstrate the ability to coordinate abdominal and pelvic floor motion during evacuation.

Surgery may be considered after all other approaches have failed and activities of daily living are compromised. Colectomy and ileorectal anastomosis may be considered in select patients with STC.

Pharmacologic Therapy

Table 22–2

Dosage Recommendations for Treatment of Constipation

Agent	Adults and Children Ages 12 and Over	Children Ages 6–11 Years
Agents That Cause Softening of Feces in 1–3 Days		
Bulk-forming agents/osmotic laxatives		
Methylcellulose	4–6 g/day PO	0.45–1.5 g PO per dose up to 3 g/day
Polycarbophil	4–6 g PO daily	On advice of practitioner
Psyllium	Varies with product	On advice of practitioner
Emollients		
Docusate sodium	50–360 mg PO daily	50–100 mg PO daily
Docusate calcium	50–360 mg PO daily	On advice of practitioner
Lactulose	15–30 mL PO daily	7.5 mL (5 g) PO daily
Mineral oil	15–30 mL PO daily	5–15 mL PO daily
Agents That Result in Soft or Semifluid Stool in 6–12 Hours		
Bisacodyl (oral)	5–15 mg PO daily	5–10 mg (0.3 mg/kg) PO daily
Bisacodyl Pico (sodium picosulfate)	5–10 mg (2–4 caps) PO at bedtime	Age 4–10: If recommended by MD
	5mg/5mL oral solution	2.5–5 mg PO at night Age under 4 years: not recommended
Senna	Dose varies with formulation	6–25 mg PO once or twice daily
Agents That Cause Watery Evacuation in 1–6 Hours or Less		
Magnesium citrate	120–300 mL PO	100–150 mL PO
Magnesium hydroxide	30–60 mL PO (15–30 mL of concentrate PO)	2.5–5 mL PO up to four times
Magnesium sulfate	10–30 g PO	5–10 g PO
Bisacodyl (suppository)	10 mg rectally	5 mg rectally (1/2 suppository)
Sodium picosulfate, magnesium oxide, anhydrous citric acid (Clenpiq)	Split-dose regimen: First dose during the evening before the colonoscopy. Second dose the next day in the morning prior to colonoscopy. Additional liquids must be consumed	Safety not established in children

KEY CONCEPT Oral laxatives are the primary pharmacologic intervention for relief of most forms of constipation, including OIC; several different drug classes are available (Table 22–2). Patients with OIC who are refractory to traditional laxatives should be treated with the peripherally-acting μ-opioid receptor-antagonists naldemedine, naloxegol, or methylnaltrexone.[11]

▶ *Bulk Producers*

These agents are either naturally derived (psyllium), semisynthetic (polycarbophil), or synthetic (methylcellulose) fiber supplements. They act by swelling in intestinal fluid, forming a gel that aids in fecal elimination and promoting peristalsis. They may cause flatulence (less commonly with methylcellulose), bloating, distention, and abdominal cramping. Fiber supplements may result in less improvement in patients with delayed colon transit constipation and/or obstruction. Bulk-forming or fiber laxatives must be taken with sufficient water (240 mL/dose) to avoid becoming lodged in the esophagus and producing obstruction or worsening constipation. Hypersensitivity reactions may occur and rarely may be manifested as an anaphylactic reaction.

▶ *Osmotics*

Lactulose, sorbitol, and glycerin are osmolar sugars. These products cause water to enter the lumen of the colon and may stimulate peristalsis. Lactulose acidifies colonic contents, increases water content of the gut, and softens the stool. Glycerin causes local irritation and possesses hyperosmotic action. Glycerin may be administered rectally and can cause rectal discomfort. Sorbitol can cause intestinal irritation and may affect blood glucose levels in diabetic patients. Osmotic agents may cause flatulence, abdominal cramping, and bloating. Polyethylene glycol (PEG) 3350 (MiraLAX) is used to treat occasional constipation and expected to produce a bowel movement within 1 to 3 days. In patients with kidney disease, this over-the-counter product should be used only on the advice and supervision of a physician.

PEG 3350 with electrolytes, a prescription product (eg, GoLYTELY, Colyte), is used for acute complete bowel evacuation prior to GI examination. The patient is required to drink large volumes of liquid, which can cause nausea and distention. For this reason, its use has been largely supplanted by newer colonoscopy preparations that require ingestion of much less fluid volume.

▶ *Lubricants*

Lubricant laxatives coat the stool, allowing it to be expelled more easily. The oily film covering the stool also keeps the stool from losing its water to intestinal reabsorption processes. Oral mineral oil (liquid petrolatum) is a nonprescription heavy oil that should be used with caution, if at all, because it can be aspirated into the lungs and cause lipoid pneumonia. This is of particular concern in the young and elderly. It may also inhibit absorption of fat-soluble vitamins.

▶ *Stimulant Laxatives*

Diphenylmethane derivatives (eg, bisacodyl) and anthraquinones (eg, senna) have a selective action on the nerve plexus of intestinal smooth muscle leading to enhanced motility. Enteric-coated bisacodyl tablets should be swallowed whole to avoid gastric irritation and vomiting. Ingestion should be avoided within 1 to 2 hours of antacids, H_2-receptor antagonists, proton pump inhibitors, and milk. Bisacodyl oral tablets, rectal suppository, and enema products are available. The onset of effect is more rapid with rectal administration. The effects can be harsh (cramping), depending on the dose taken.

Sodium picosulfate (eg, Dulcolax Pico) is a stimulant laxative used for short-term relief of constipation. When used in combination preparations with magnesium oxide and anhydrous citric acid, which form magnesium citrate (eg, Clenpiq), it is indicated for colonic cleansing prior to colonoscopy in adults and children aged 9 years and older. There are no data regarding safety of sodium picosulfate in pregnant women.[12]

Castor oil is used less frequently; it is pregnancy category X and associated with uterine contractions and rupture. Use of castor oil in breastfeeding is considered “possibly unsafe.”

▶ *Emollients*

Also known as surfactants and stool softeners, emollients (eg, salts of docusate) act by increasing the surface-wetting action on the stool leading to a softening effect. They reduce friction and make the stool easier to pass. The onset of action of stool softeners is longer than with most stimulants and may take up to 72 hours. These agents tend to be less effective in treating constipation of long duration.

▶ *Saline Agents*

Salts of sodium, magnesium, and phosphate pull water into the lumen of the intestines resulting in increased enteral pressure. Magnesium and phosphate may accumulate in patients with renal dysfunction. Principal concerns with sodium phosphate derivatives include dehydration, hypernatremia, hyperphosphatemia, acidosis, hypocalcemia, and worsening renal function. Older persons and patients with heart failure and renal dysfunction should be advised to avoid saline agents. Nonprescription oral sodium phosphate solutions are no longer available because of the risk of acute phosphate nephropathy, a form of acute kidney injury.

Newer saline combination products containing sodium sulfate, potassium sulfate, and magnesium sulfate (eg, Suprep) are much safer and are widely used as precolonoscopy preparations.

▶ *Intestinal Secretagogues*

Lubiprostone (Amitiza) This oral agent is derived from prostaglandin E_1 and acts locally on intestinal chloride channels to increase intestinal fluid secretion, resulting in increased intestinal motility and passage of stool.[11] It is approved for treatment of CIC in adults, OIC in adult patients with chronic noncancer pain, including patients with chronic pain related to prior cancer or its treatment who do not require frequent (eg, weekly) opioid dosage escalation, and in irritable bowel syndrome with constipation (IBS-C) in women at least 18 years old (Table 22–3). Effectiveness for treating OIC in patients taking methadone has not been established. In patients taking diphenylheptane opioid derivatives (eg, methadone), a dose-dependent decrease in lubiprostone effectiveness can occur. Lubiprostone is contraindicated in patients with known or suspected mechanical GI obstruction. Common adverse effects include nausea, diarrhea, syncope, hypotension, dyspnea, bowel obstruction, headache, abdominal distension and pain, and flatulence. The effectiveness of lubiprostone has not been established in children aged 6 years and older. The capsule should be swallowed whole and not be chewed or broken apart.[13,14]

Linaclotide (Linzess) The parent compound and its active metabolite activate guanylate cyclase-C (GC-C) act locally by increasing intracellular and extracellular concentrations of cyclic guanosine monophosphate (GMP). Cyclic GMP stimulates secretion of chloride and bicarbonate into the intestinal lumen, resulting in increased interstitial fluid and intestinal transit.[15] Linaclotide is indicated for treatment of IBS-C and CIC in adults only.

The linaclotide dose for CIC is 145 mcg is administered once daily on an empty stomach at least 30 minutes before the first

Table 22–3

Medications for Treatment of Opioid-Induced Constipation

Agent	Adults and Children Ages 12 and Over
Lubiprostone	24 mcg PO twice daily with food and water
Methylnaltrexone bromide	Given subcutaneously every other day based on body weight: 12 mg if 62–114 kg; 8 mg if 38–61 kg; other doses based on weight if outside these parameters
Naloxegol	25 mg PO once daily in the morning on an empty stomach or if not tolerated 12.5 mg PO daily
Naldemedine	0.2 mg PO once daily with or without food

[a] Safety and efficacy have not been established in children younger than age 12.

meal of the day; 72 mcg once daily can be used based on patient presentation and tolerability (Table 22–3). The capsule should be swallowed whole and not be broken or chewed.

Adverse effects of linaclotide include diarrhea, headache, fatigue, dehydration, abdominal pain, flatulence, and abdominal distention. Loose stools and greater stool frequency may occur after administration with a high-fat breakfast. Patients should be monitored for fluid and electrolyte loss. Linaclotide is classified as pregnancy category C.

Plecanatide (Trulance) This medication functions as a guanylate cyclase-C (GC-C) agonist. It is indicated for treatment of CIC and IBS-C in adults. The efficacy and safety of plecanatide have not been established in children less than 18 years of age, and it should be avoided in persons aged 6 to 18 years. It is contraindicated in children under the age of 6 years because increased fluid secretion may lead to serious dehydration. It is also contraindicated in patients with known or suspected mechanical GI obstruction.[16]

The recommended adult dose of plecanatide is 3 mg orally once daily. The tablet can be given with or without food and should be swallowed whole. For adults with swallowing difficulties, the tablets can be crushed and administered orally either in applesauce or with water or given with water via a nasogastric or gastric feeding tube.

The major adverse effect associated with plecanatide is diarrhea, which may lead to discontinuation in some patients. Less common adverse effects include sinusitis, upper respiratory tract infection, abdominal distention, flatulence, abdominal tenderness, and increased hepatic enzymes. Although there are insufficient data on potential harm in pregnancy, plecanatide and its active metabolite are absorbed negligibly, and maternal use is not expected to result in fetal drug exposure. No human lactation studies have yet been conducted.[16]

▶ *Peripherally Acting μ-Opioid Receptor Antagonists (PAMORAs)*

PAMORAs are prescribed for treatment of OIC. There are currently three antagonists of opioid binding at the μ-opioid receptor that have negligible ability to cross the blood–brain barrier: naldemedine, methylnaltrexone bromide, and naloxegol (Table 22–3). They function as peripherally acting μ-opioid receptor antagonists (PAMORAs) in tissues such as the GI tract, thereby decreasing the constipating effects of opioids without diminishing the opioid analgesic effects in the CNS. They are indicated for treatment of OIC in adults with chronic pain that is not caused by active cancer (including chronic pain related to prior cancer or its treatment) who do not require frequent (eg, weekly) opioid dosage escalation.[11] The opioid analgesic regimen does not need to be altered before starting a PAMORA. Patients should be near toilet facilities after a PAMORA is administered. Patients receiving opioids for less than 4 weeks may be less responsive to these agents. All maintenance laxative therapy should be discontinued before starting a PAMORA; laxatives may be resumed if there is suboptimal response to the PAMORA after 3 days. Concomitant PAMORA use with other opioid antagonists can result in additive adverse effects and should be avoided. PAMORA treatment should be stopped if opioid therapy is discontinued.

The most common PAMORA adverse effects are abdominal pain, nausea, diarrhea, flatulence, and vomiting. GI perforation has been reported in patients with other conditions that reduce the structural integrity of the GI tract wall (eg, peptic ulcer disease, Crohn disease); the PAMORA should be discontinued if severe, persistent, or worsening abdominal pain occurs. Symptoms of opioid withdrawal may occur (sweating, chills, diarrhea, abdominal pain, anxiety, yawning) in patients physically dependent on opioids.[11]

Naldemedine (Symproic) is a derivative of naltrexone that contains an added side chain that increases molecular weight and reduces its ability to cross the blood–brain barrier. It has binding affinities for μ-, δ-, κ-opioid receptors.[17] The recommended dose is 0.2 mg orally once daily with or without food.

Concomitant use of strong CYP3A inducers such as rifampin should be avoided because decreased naldemedine concentrations can occur. On the other hand, increased naldemedine concentrations can occur when moderate (eg, fluconazole) or strong (eg, itraconazole) CYP3A4 inhibitors are used concomitantly; patients should be monitored for adverse reactions. Naldemedine is also a substrate of the P-glycoprotein (P-gp) efflux transporter; patients taking P-gp inhibitors (eg, amiodarone, captopril, cyclosporine, and verapamil) should be monitored for adverse effects due to increased naldemedine concentrations.[17]

Naloxegol (Movantik) is a pegylated derivative of naloxone. The recommended dose is 25 mg orally once daily on an empty stomach at least 1 hour prior to the first meal of the day or 2 hours after the meal. The dose may be reduced to 12.5 mg daily if the larger dose is not tolerated. The starting dose should also be reduced to 12.5 mg daily in patients with moderate-to-severe renal impairment. If a patient cannot swallow the tablet whole, it may be crushed to a powder, mixed with 4 oz (120 mL) of water, and administered immediately; the glass should then be refilled with 4-oz water, stirred, and the contents drunk. Patients should avoid consumption of grapefruit and grapefruit juice because these foods may increase plasma naloxegol concentrations.

Naloxegol is contraindicated in patients receiving strong CYP3A4 inhibitors (eg, clarithromycin, ketoconazole) and should be avoided if possible in patients taking moderate CYP3A4 inhibitors (eg, diltiazem, erythromycin, and verapamil) due to increased naloxegol concentration that may increase the risk of adverse reactions.[18]

Methylnaltrexone Bromide (Relistor) is a quaternary amine derivative of naltrexone. The recommended oral dose is 450 mg (3 × 150-mg tablets) once daily with water on an empty stomach at least 30 minutes before the first meal of the day; there is a subcutaneous (SC) product that can also be used for treating OIC in adults with chronic noncancer pain; the dose is 12 mg SC once daily. The SC injection is also indicated for treatment of OIC in adults with advanced illness or pain caused by active cancer who require opioid dosage escalation for palliative care. The SC injection is usually given every other day as needed; the dose is weight-based for this indication (refer to product labeling). The oral or SC methylnaltrexone dose must be reduced in patients with moderate to severe renal or hepatic dysfunction.[19]

Treatment Recommendations

The conventional effective, safe, and inexpensive modalities (fluid intake; dietary and supplemental fiber; stool softeners; and saline, stimulant, or osmotic laxatives) should be attempted before agents such as secretagogues are prescribed. The μ-receptor antagonists are indicated only for treatment of OIC.[11]

Patients who are not constipated but need to avoid straining (eg, patients with hemorrhoids, hernia, or myocardial infarction) may benefit from stool softeners or mild laxatives such as PEG 3350.

Pregnant women should be advised to eat regular meals that are balanced among fruits, vegetables, and whole grains and maintain adequate water intake to avoid constipation. Bulk producers and stool softeners are probably safe during pregnancy because they are poorly absorbed. Lactulose and magnesium products are pregnancy category B. Magnesium-based antacids have minimal absorption and are considered low risk in pregnant women. Long-term use of magnesium citrate should be avoided (pregnancy category B).

Patient Encounter 1

A 30-year-old woman with a history of iron-deficiency anemia and constipation was admitted to the hospital after a fall. The patient is status-post exploratory laparoscopic surgery. Presently, she is being treated for acute pain and is being discharged to home. Medication profile includes ferrous sulfate 325 mg orally three times a day, ibuprofen 400 mg orally every 6 hours as needed for pain equal to 4/10 or 5/10, oxycodone/acetaminophen 5 mg/325 mg 1 tablet orally every 6 hours as needed for pain equal to 6/10 or 7/10, and 2 tablets orally every 6 hours as needed for pain equal to 8 to 10/10.

What general approach to this patient should be employed?

What are the possible contributing causes of her constipation?

What nonpharmacologic and pharmacologic therapies would be appropriate for her constipation?

Laxatives may provide relief for constipation occurring during the postpartum period when the mother is not breastfeeding.

Children younger than 6 years old should be evaluated by a health-care provider before being given a laxative because they may not be able to describe their symptoms well. Evaluation of the patients' ability to recognize and self-report constipation symptoms should be considered. Treating secondary causes may resolve constipation without the use of laxatives. As in adults, children benefit from a balanced diet and adequate water intake.

Because many older persons experience constipation, laxative use is sometimes viewed as a normal part of daily life. However, oral ingestion of mineral oil can present a hazard to bedridden individuals because inhalation of oil droplets can lead to pneumonia. Lactulose may be a better choice in this situation. Regular use of any laxative that affects fluid and electrolytes may result in significant adverse effects.

Patients with the following conditions should use laxatives only under the supervision of a health-care provider: (a) colostomy; (b) diabetes mellitus (some laxatives contain sugars such as dextrose, galactose, and/or sucrose); (c) heart disease (some products contain sodium); (d) kidney disease; and (e) swallowing difficulty (bulk-formers may produce esophageal obstruction). Saline laxatives containing magnesium, potassium, or phosphates should be used cautiously in persons with reduced kidney function. Monitor appropriate serum electrolyte concentrations in patients with unstable renal function evidenced by changing serum creatinine or creatinine clearance.

OUTCOME EVALUATION

- Ask the patient about symptom improvement to determine effectiveness of laxative therapy. Patients should have an increase in stool frequency to three or more well-formed stools per week. Patients should report reduced defecation time or the absence of excessive straining.
- When acute overuse or chronic misuse of saline or stimulant laxatives is suspected, electrolyte disturbances should be evaluated (eg, hypokalemia, hypernatremia, hyperphosphatemia, and hypocalcemia).
- Some laxatives (eg, bulk producers) contain significant amounts of sodium or sugar and may be unsuitable for salt-restricted or diabetic patients. Monitoring of fluid retention (edema) and blood pressure changes is indicated in patients on sodium-restricted diets. Glucose monitoring may be required in diabetic patients with chronic use. The use of low-sodium or sugar-free products may be indicated.
- All laxatives are contraindicated in patients with undiagnosed abdominal pain, nausea, or vomiting. Patients should consult their health-care providers if changes in bowel habits persist for more than 14 days or if laxative use for 7 or more days results in no effect.

Patient Care Process for Constipation

Collect Information:

- Document the patient's age, bowel movement frequency, medical conditions, and medication use.
- Ask about symptoms to determine if patient-directed therapy is appropriate or if physician evaluation is required. Determine type, frequency, and duration of symptoms; the presence or absence of abdominal pain; and exclude the presence of alarm symptoms.
- Review available information to determine potential causes and type of constipation. List factors that seem to make it better or worse. Assess dietary habits, fluid intake, and level of physical activity. The use of bowel and medication diary may help identify patterns. The use of the Bristol Stool Form Scale may be considered (see https://en.wikipedia.org/wiki/Bristol_stool_scale).

Assess the Information:

- Obtain a thorough history of prescription medication, nonprescription product, and dietary supplement use. Determine what treatments have been helpful in the past, whether the patient is taking any medications that may contribute to constipation, usual diet, and fluid intake. Assess for the presence of adverse drug reactions, drug allergies, and drug interactions.
- Assess the presence of pain to help differentiate functional constipation condition from possible IBS-C.

Develop a Care Plan:

- Recommend administration of soluble dietary fiber such as psyllium, then an osmotic agent such as PEG, and then a magnesium-based or stimulant/stool softener-based product.
- Provide patient education about constipation, dietary modifications, and drug therapy. Consider asking, "Do you take the time to have a bowel movement?"

Implement the Care Plan:

- Educate the patient about causes of constipation and recommend ways to avoid it.
- Counsel the patient on appropriate laxative use, when to expect onset of relief, need for adequate fluid intake, and to seek medical attention if there is no improvement with laxative use in 3 or more days or if symptoms worsen.
- Advise the patient to seek medical attention if alarm symptoms occur.

Follow-up: Monitor and Evaluate:

- Develop a plan to assess the effectiveness of laxative use. Include dosing, monitoring parameters (eg, improvement in symptoms/complaints), and recommended duration of therapy.

DIARRHEA

The definition of diarrhea is based on two characteristics of stool: frequency and consistency.[2,20] Diarrhea is defined as the increased frequency of passing abnormally liquid or unformed stools. Functional diarrhea is the presence of loose or watery stools, without predominant abdominal pain or bothersome bloating, occurring in more than 25% of stools. The symptoms must be present for the last 3 months with symptom onset at least 6 months before the diagnosis is made. Patients meeting the criteria for IBS-D should be excluded.[2,21,22] Diarrhea is defined as acute if it lasts less than 2 weeks, persistent if it lasts from 2 to 4 weeks, and chronic if it lasts longer than 4 weeks. The World Health Organization (WHO) describes three levels of severity: (a) mild (diarrhea three or more times a day with occasional abdominal discomfort); (b) moderate (diarrhea three or more times a day with painful abdominal cramps and thirst); and (c) severe (diarrhea three or more times a day with severe abdominal cramps, thirst, nausea, and tiredness).[21] Diarrhea can also be classified as watery.[22] Contributors to diarrhea include IBD, colitis, and infection.[23] Patients presenting with diarrhea should be evaluated for these conditions as well as functional diarrhea and IBS-D. The evidence to support the use of laboratory tests with functional diarrhea is uncertain, and presently no tests exist that support the confirmative diagnosis of IBS-D.[24,25]

EPIDEMIOLOGY AND ETIOLOGY

The WHO reported that in 2016 diarrhea was the ninth leading cause of death globally (> 1.3 million deaths). Worldwide, diarrhea is a significant area of concern for children aged 5 years and under in resource-limited regions.[26] The incidence and prevalence of diarrhea are difficult to quantify. Prevalence rates of functional diarrhea reported from different countries range from 1.5% to 17%. Although it has not been well studied, incidence rates of diarrhea may be lower in regions where higher level sanitation systems are available and utilized.[26]

Acute Diarrhea

Acute diarrhea generally involves the sudden onset of three or more loose or liquid stools above baseline in a 24-hour period. More than 90% of cases of acute diarrhea are caused by infectious agents. Acute diarrheal infection is also referred to as gastroenteritis. Most infectious diarrheas are acquired by fecal–oral transmission or via ingestion of food or water contaminated with human or animal fecal pathogens.[27] Many of these cases are accompanied by abdominal pain and cramps, bloating, flatulence, passage of bloody stools, tenesmus, fecal urgency, fever, and vomiting. Some acute GI infections may cause vomiting as a predominant symptom with little to no diarrhea. The remaining 10% of acute diarrhea cases are caused by medications, toxic ingestions, ischemia, food intake, and other conditions. Acute diarrhea is a leading cause of outpatient visits and hospitalizations and has a direct negative impact on quality of life.

Viruses cause a large proportion of acute diarrhea cases. Common culprits include Rotavirus, Norwalk, and adenovirus. Bacterial causes include *Escherichia coli*, *Salmonella* species, *Shigella* species, *Vibrio cholerae*, and *Clostridioides difficile* (especially if antibiotics had been administered). The term *dysentery* describes some of these bacterial infections when associated with serious occurrences of bloody diarrhea.[27]

Acute or persistent diarrheal conditions can also result from parasites and protozoa such as *Entamoeba histolytica*, *Microsporidium*, *Giardia lamblia*, and *Cryptosporidium parvum*. Most of these infectious agents can cause **traveler's diarrhea**, a common condition that can afflict travelers worldwide. It usually occurs during or just after travel following the ingestion of food or water that is contaminated with feces. It has an abrupt onset but usually subsides within 2 to 3 days (see Chapter 80, Gastrointestinal Infections, for more detailed information on traveler's diarrhea).

Brainerd diarrhea may be associated with subtle distal small intestine or proximal colonic inflammatory changes and is believed to be caused by an infectious agent. It is described as an abrupt-onset diarrhea that persists for 4 weeks and may last 1 to 3 years. It is named after Brainerd, Minnesota, the community where the first outbreak occurred in 1983.

Noninfectious causes of acute diarrhea include drugs and toxins, laxative abuse, food intolerance, IBS, IBD, ischemic bowel disease, lactase deficiency, vitamin B_{12} deficiency anemia, diabetes mellitus, malabsorption, fecal impaction, diverticulosis, and celiac sprue.[23]

Lactose intolerance is a gastrointestinal disorder that is due to the inability to digest lactose into glucose and galactose. Symptoms include loose stools, **borborygmus**, flatulence, abdominal pain and bloating, and nausea. Low levels of the enzyme needed to digest lactose is a common form of disaccharidase deficiency. Lactose intolerance is responsible for many cases of acute diarrhea, especially in persons of African descent, Asians, South Americans, and Native Americans. Possible food-related causes include fat substitutes, dairy products, and products containing nonabsorbable carbohydrates.

The diarrhea of IBS is sudden, perhaps watery but likely loose, usually accompanied by urgency, bloating, and abdominal pain often in the morning or immediately following a meal. IBD is typically associated with the sudden onset of bloody diarrhea accompanied by urgency, crampy abdominal pain, and fever. Patients who experience bowel ischemia may develop bloody diarrhea, particularly if they progress to shock.[24,25]

In the United States, high-risk groups for acquiring acute diarrhea include travelers, consumers of certain foods, immunodeficient persons, daycare attendees and their family members, and institutionalized persons.

Chronic Diarrhea

Chronic diarrhea is much less likely to be infectious and usually results from functional or inflammatory bowel disorders, endocrine disorders, malabsorption syndromes, and drugs (including laxative abuse). Daily watery stools may not occur with chronic diarrhea. Diarrhea may be either intermittent or continual.[22,24]

PATHOPHYSIOLOGY

In patients who present with watery diarrhea, abnormal physiological control of intestinal fluid and electrolyte transport mechanisms or derangement in barrier properties may occur. The inability to sufficiently absorb solutes or the impact active secretion of solutes into the gut lumen or both may occur. In addition, the integrity of the intestinal epithelial barrier function contributes to control of the ability to dehydrate the stool. These actions influence the amount of fluid found within the intestinal lumen. Intestinal cellular mechanisms of fluid transport are dependent upon sodium secretion and chloride absorption. The absence of the transporter proteins due to genetic coding, the presence of inflammatory cytokines, and the presence of single nucleotide polymorphisms may influence the volume of fluid collected within the small and large intestines, thus resulting in the development of watery diarrhea.[20,24,25] Sodium secretion is also affected

Table 22–4

Selected Drugs and Substances That May Cause Acute Diarrhea

Drugs			
Antibiotics	Hydralazine	Metformin	Sorbitol
Colchicine	Laxatives	Misoprostol	Theophylline
Digitalis	Mannitol	Quinidine	Thyroid products
Dietary Supplements			
St. John's wort	Echinacea	Ginseng	Aloe vera
Poisons			
Arsenic	Cadmium	Mercury	Monosodium glutamate

by the expression of intestinal epithelial sodium channels.[20] Factors that increase active chloride secretion include bile acid malabsorption, the presence of mutations in the guanylate cyclase 2C gene that encodes for chloride secretagogues such as guanylin and uroguanylin, and other mechanisms.

Disruption of barrier permeability function of the junctions that link adjacent intestinal epithelial cells through pores can occur. During inflammatory processes, improper increased contraction may contribute to inappropriate epithelial leakage. It is proposed that reduced barrier permeability in the presence of disruption of ion movement and fluid collection in the intestinal lumen can cause leakage of adsorbed solutes into the lumen and interfere with absorptive transport.[20]

Diarrhea may be attributed to a single or to multiple overlapping mechanisms. For example, malabsorption syndromes and traveler's diarrhea are associated with both secretory and osmotic mechanisms.[20]

Medications are a common cause of diarrhea (Table 22–4). Drug-induced diarrhea can occur by several mechanisms. First, water can be drawn into the intestinal lumen osmotically (eg, saline laxatives). Second, the intestinal bacterial ecosystem can be upset leading to the emergence of invasive pathologic organisms triggering secretory and inflammatory processes (eg, antibiotic use). Third, some drugs increase intestinal motility. Other drugs produce diarrhea through undetermined mechanisms (eg, procainamide, colchicine). Discontinuation of the offending drug may be the only measure needed to ameliorate diarrhea.

CLINICAL PRESENTATION AND DIAGNOSIS

Patients with diarrhea should be questioned about the onset of symptoms, recent travel, diet, source of water, and medication use; see accompanying box for the clinical presentation of diarrhea. Other important considerations include duration and severity of the diarrhea and the presence of abdominal pain or vomiting; blood in the stool; stool consistency, appearance, and frequency; and weight loss. Although most cases of diarrhea are self-limited, infants, children, elderly persons, and immunocompromised patients are at risk for increased morbidity.

The diagnostic criterion for functional diarrhea is the presence of loose or watery stools without predominant abdominal pain or bothersome bloating, occurring in more than 25% of stools. The criterion needs to be fulfilled for the prior 3 months with the symptom onset at least 6 months before diagnosis. Patients meeting criteria for diarrhea-predominant IBS should be excluded.[24,25]

Findings on physical examination can assist in determining hydration status and disease severity. The presence of blood in the stool suggests an invasive organism, an inflammatory process, or perhaps a neoplasm. Large-volume stools suggest a small-intestinal disorder, whereas small-volume stools suggest a colon or rectal disorder. Further investigation should be performed in patients who present with diarrhea in the presence of alarm symptoms such as unintentional weight loss, diarrhea awakening the patient, recent antibiotic use, hematochezia (in the absence of documented bleeding hemorrhoids or anal fissures), very frequent bowel movement (> 6–10 daily), high volume diarrhea (> 250 mL of feces daily), evidence of malnutrition, family history of new or abnormal growth of colorectal tissue, celiac disease, or IBD. Patients with prolonged or severe symptoms may require colonoscopic evaluation to identify the underlying cause.[24,25]

Clinical Presentation of Diarrhea

Signs and Symptoms of Acute Diarrhea

- Acute diarrhea presents abruptly as loose, watery, or semiformed stools.
- Abdominal cramps and tenderness, rectal urgency, nausea, bloating, and fever may be present.
- Patients infected with invasive organisms may have bloody stools and severe abdominal pain.

Laboratory Tests in Acute Diarrhea

- Stool cultures can help identify infectious causes. Methods using real-time polymerase chain reaction shorten the reporting time.
- Stool may be analyzed for mucus, fat, osmolality, fecal leukocytes, and pH. Mucus fragments suggest colonic involvement; fat in the stool suggests malabsorption. Fecal leukocytes are present in inflammatory diarrheas including bacterial infections. Stool pH (normally > 6) is decreased by bacterial fermentation processes.
- Assessment of stool volume and electrolytes in large-volume watery stools may identify osmotic or secretory diarrhea.
- CBC and blood chemistries to determine extent of vitamin and electrolyte deficiencies may be helpful when symptoms persist. Findings of anemia, leukocytosis, or neutropenia offer further clues to the underlying cause.

Signs and Symptoms of Chronic Diarrhea

- Presenting symptoms may be severe or mild. Weight loss can be demonstrated, and weakness may be present.
- Dehydration may manifest as decreased urination, dark-colored urine, dry mucous membranes, increased thirst, and tachycardia.

Laboratory Tests in Chronic Diarrhea

- Tests described for acute diarrhea are also useful to diagnose chronic diarrhea; the differential diagnosis is more complicated. Results can help categorize the diarrhea as watery, inflammatory, or fatty, narrowing the focus on a primary disorder.
- Colonoscopy allows visualization and biopsy of the colon and is preferred when there is blood in the stool or if the patient has acquired immune-deficiency syndrome.

TREATMENT

Acute diarrhea is generally self-limited, lasting 3 to 4 days even without treatment. Most healthy adults with diarrhea do not develop significant dehydration or other complications and can self-medicate symptomatically if necessary. KEY CONCEPT Dehydration can occur when diarrhea is severe and oral intake is limited, particularly in older persons and infants. Evidence of dehydration includes increased thirst, dry mouth, dry skin, reduced skin elasticity, infrequent urination, reduced urine volume, orthostatic hypotension with rapid pulse, lightheadedness, tachypnea, fatigue, muscle cramps, muscle weakness, and sunken eyes. Clinical laboratory abnormalities may include increased blood urea nitrogen/serum creatinine ratio, hemoglobin and hematocrit, serum sodium concentration, and serum osmolality. Assessment of medication use history (eg, diuretics) is also important for dehydration assessment.

Children are more susceptible to dehydration (particularly when vomiting occurs) and may require medical attention early in the course, especially if younger than 3 years. Physician intervention is also necessary for older patients who are sensitive to fluid loss and electrolyte changes due to concurrent chronic illness.

Patients should seek medical attention in the following circumstances: (a) moderate to severe abdominal tenderness, distention, or cramping; (b) bloody stools; (c) evidence of dehydration; (d) high fever (38.3°C or 101°F or higher); (e) evidence of weight loss greater than 5% of total body weight; and (f) diarrhea that lasts longer than 48 hours.[27]

Desired Outcomes

The goals of treatment for diarrhea are to relieve symptoms, maintain hydration, treat the underlying cause(s), and maintain nutrition. KEY CONCEPT The primary treatment of acute diarrhea includes fluid and electrolyte replacement, dietary modifications, and drug therapy.

Nonpharmacologic Therapy

▶ *Fluid and Electrolytes*

Fluid replacement is not a treatment to relieve diarrhea but rather an attempt to restore fluid balance. In many parts of the world where diarrheal states are frequent and severe, fluid replacement is accomplished using oral rehydration solution (ORS), which are a measured mixture of water, salts, and glucose. The solution recognized by the WHO consists of 75 mEq/L (mmol/L) sodium, 75 mmol/L glucose, 65 mEq/L (mmol/L) chloride, 20 mEq/L (mmol/L) potassium, and 10 mEq/L (3.3 mmol/L) citrate, having a total osmolarity of 245 mOsm/L (mmol/L). A simple solution can be prepared from 1 L water mixed with eight teaspoonfuls of sugar and one teaspoonful of table salt.[28] Some commercial products include Pedialyte, Rehydralyte, and CeraLyte.

Consistent intake of water (perhaps by slowly sipping), along with eating as tolerated, should restore lost fluids and salt for typical diarrhea sufferers. Patients may also replace lost fluid by drinking flat soft drinks such as ginger ale, tea, fruit juice, broth, or soup. Although sports drinks may be used to treat dehydration, caution should be exercised so they are not viewed as a casual panacea. Severe diarrhea may require the use of parenteral solutions, and parenteral products should be used if patients are vomiting or unconscious.[27]

▶ *Dietary Modifications*

During an acute diarrheal episode, patients typically eat less as they focus on the diarrhea. Both children and adults should attempt to maintain nutrition because food helps replete lost nutrients and fluid volume. However, food-related fluid may not be sufficient to compensate for diarrheal losses. Some foods may be inappropriate if they irritate the GI tract or if they are implicated as the cause of the diarrhea. Patients with chronic diarrhea may find that increasing bulk in the diet may help (eg, rice, bananas, whole wheat, and bran).

Pharmacologic Therapy

The goal of drug therapy is to control symptoms, enabling the patient to continue with as normal a routine as possible while avoiding complications (Table 22–5). Most infectious diarrheas are self-limited or curable with anti-infective agents.[27]

▶ *Adsorbents and Bulk Agents*

Attapulgite adsorbs excess fluid in the stool with few adverse effects; it is available in Canada but not the United States. Calcium polycarbophil is a hydrophilic polyacrylic resin (widely available in the United States) that also works as an adsorbent, binding about 60 times its weight in water and leading to formation of a gel that enhances stool formation. Neither attapulgite nor

Table 22–5

Pharmacotherapy for Diarrhea

Drug	Usual Oral Dose	Type of Diarrhea
Calcium polycarbophil (OTC)	Adults: 1000 mg four times daily PO or after each loose stool, not to exceed 12 tablets per day Children 6–12 years: 500 mg PO three times daily Children 3–6 years: 500 mg twice daily	Chronic
Loperamide (OTC, RX)	Adults: 4 mg initially, then 2 mg PO after each subsequent loose stool. Maximum: 8 mg in 24 hours (OTC), 16 mg in 24 hours (RX) Children maximum daily doses: Age 2–5: 3 mg Age 6–8: 4 mg Age 8–12: 6 mg	Acute and chronic
Diphenoxylate/atropine (RX)	Adults: Two tablets (5 mg) initially, then one tablet PO every 3–4 hours, not to exceed 20 mg in 24 hours Children 2–12 years: Oral solution (avoid tablets) 0.3–0.4 mg/kg/day in divided doses. Do not administer to children younger than 2 years	Acute and chronic
Bismuth subsalicylate (OTC) (Kaopectate, PeptoBismol)	Adults and children 12 years and over: 524 mg/30 mL PO every 30–60 minutes as needed; Do not exceed 8 doses (240 mL or 16 tablets) per day Children: Consumers should speak with a physician before giving to children under 12 years of age	Traveler's and nonspecific acute diarrhea

OTC, over the counter; PO, by mouth; RX, prescription only.

polycarbophil is systemically absorbed. Calcium polycarbophil is effective in reducing fluid in the stool. However, caution must be exercised because it can also adsorb nutrients and other medications, thereby reducing their benefits. Its administration should be separated from other oral medications by 2 to 3 hours. Psyllium and methylcellulose products may also be used to reduce fluid in the stool and relieve chronic diarrhea.

▶ *Antiperistaltic (Antimotility) Agents*

Antiperistaltic drugs prolong intestinal transit time, thereby reducing the number of stools and the amount of fluid lost in the stool. The two drugs in this category are loperamide HCl (available over-the-counter as Imodium A–D and generically) and diphenoxylate HCl with atropine sulfate (available by prescription as Lomotil and generically). The atropine is included only as an abuse deterrent; when taken in large doses, the unpleasant anticholinergic effects of atropine negate the euphoric effect of diphenoxylate. Both loperamide and diphenoxylate are effective in relieving symptoms of acute noninfectious diarrhea and are safe for most patients experiencing chronic diarrhea. These products should be discontinued in patients whose diarrhea worsens despite therapy.

Loperamide is considered safe when used in recommended doses. When excessive doses are ingested, severe problems such as cardiac arrhythmias and death can occur.[29] Loperamide misuse and abuse has been reported.[30] Coadministration of potent CYP450 3A4 inhibitors (eg, azole antifungals, clarithromycin, conivaptan, delavirdine, erythromycin, nefazodone, protease inhibitors, and telithromycin) and 2C8 inhibitors (eg, gemfibrozil, clopidogrel) with loperamide may increase plasma loperamide concentrations and adverse effects. Patients who have ingested large doses of loperamide alone or with medications that can enhance loperamide effect may experience dizziness, lightheadedness, fainting, palpitations, irregular heart rhythm, shortness of breath, or syncope and should be advised to discontinue loperamide and seek medical attention.[29,30]

▶ *Antisecretory Agents*

Bismuth subsalicylate (BSS) is thought to have antisecretory and antimicrobial effects and used to treat acute diarrhea. Although it passes largely unchanged through the GI tract, the salicylate portion is absorbed in the stomach and small intestine. For this reason, BSS should not be given to people who are allergic to salicylates, including aspirin. Patients taking BSS should be informed that their stool will turn black. Caution should be exercised with regard to the total dose given to patients taking salicylates for other reasons to avoid salicylism. Signs and symptoms of salicylism include nausea, vomiting, tinnitus, hypotension, hyperventilation, wheezing, hyperactivity, agitation, hallucinations, fever, confusion, bleeding seizures, rhabdomyolysis, renal failure, and respiratory failure.

Octreotide is an antisecretory agent used for severe secretory diarrhea associated with cancer chemotherapy, human immunodeficiency virus, diabetes, gastric resection, and GI tumors. It is administered as a subcutaneous or IV bolus injection in an initial dose of 50 mcg three times daily to assess the patient's tolerance to GI adverse effects. Possible adverse effects include nausea,

Patient Encounter 2

A 42-year-old male account executive visited an urgent care center complaining of a history of heartburn usually after eating, which usually worsens at night, trouble swallowing, and a sensation of a lump in his throat. He stated that about 28 days ago he started over-the-counter self-treatment with omeprazole 20 mg, and about 7 days ago he began experiencing repeated bouts of diarrhea. He admitted that at times he takes twice as much medication as recommended.

Assess the likelihood that his diarrhea is due to Clostridioides difficile–associated diarrhea.

Identify findings that suggest the presence of dehydration.

Discuss potential treatment measures for this patient.

Patient Care Process for Diarrhea

Collect Information:

- Determine symptoms, severity, frequency, and exacerbating factors.
- Review hydration status.
- Determine if patient-directed therapy is appropriate or a referral is needed.
- Inquire about recent foreign travel.
- Obtain history of prescription, nonprescription, and dietary supplement use.

Assess the Information:

- Review current therapy as potential cause(s) of diarrhea.
- Determine if any diarrhea treatments have been attempted, including home remedies.
- Assess need for medical evaluation if patient is pregnant, breastfeeding, younger than 3 years or older than 70 years, or has multiple medical conditions.

Develop a Care Plan:

- If home care is recommended, provide clear instructions about how to proceed if symptoms do not improve or new symptoms emerge.
- Discuss the importance of maintaining nutrition by diet modification.
- Educate the patient about: (a) acute and chronic diarrhea causes, (b) possible complications, (c) treatment goals, (d) the medication used to manage diarrhea, and (e) if appropriate, the circumstances when antibiotics are necessary.

Implement the Care Plan:

- Educate the patient about diarrhea and its likely causes.
- Advise the patient to seek medical attention if diarrhea does not resolve.

Follow-up: Monitor and Evaluate:

- Although most diarrheal episodes resolve with minimal intervention, individuals with a protracted course should be followed until symptoms have abated or are under control. Pay special attention to the very young, the aged, and those who are medically compromised.
- Refer the patient for medical attention if needed.

bloating, pain at the injection site, and gallstones (with prolonged therapy).

▶ *Probiotics, Prebiotics, and Synbiotics*

Probiotics are dietary supplements containing bacteria (*Saccharomyces boulardii*, *Lactobacillus* species, *Bifidobacterium bifidum*, and others) that may promote health by enhancing the normal microflora of the GI tract while resisting colonization by potential pathogens.[31] Probiotics can be taken in tablets, gummies, capsules, powders, and liquids. Prebiotics are nondigestible food ingredients that are fermentable in the colon and stimulate potentially health-promoting bacteria such as bifidobacteria and lactobacilli. Synbiotics are formed when prebiotics and postbiotics are joined.[31]

Yogurt may provide relief from diarrhea due to lactose intolerance. The *Lactobacillus acidophilus* in yogurt, cottage cheese, and acidophilus milk may improve digestion of lactose and may prevent or relieve diarrhea related to lactose deficiency and milk intake. Although lactase is not a probiotic, lactase tablets may also be used to prevent diarrhea in susceptible patients.

Fecal microbiota transplantation (FMT) for treatment of diarrhea is under investigation. In 2020, the FDA issued a safety alert regarding the use of fecal microbiota for transplantation and the potential risk of serious adverse reactions, which were likely due to transmission of the pathogenic organisms thereby increasing the potential risk of serious life-threatening infections.[32] The FDA was made aware of six infections caused by enteropathogenic *E. coli* (EPEC) and Shigatoxin-producing *E. coli* (STEC) in patients being treated for *C. difficile* infection unresponsive to standard therapies.[32] Although risk of transmission is unknown and presently there is limited information about the availability and sensitivity of direct stool tests, the FDA also issued a safety alert regarding additional safety precautions pertaining to SARS-CoV2 and COVID-19 related to the transplantation of fecal microbiota.[33]

OUTCOME EVALUATION

- Monitor the patient with diarrhea from the point of first contact until symptoms resolve, keeping in mind that most episodes are self-limiting.
- Question the patient to determine whether symptom resolution occurs within 48 to 72 hours in acute diarrhea.
- Monitor for the maintenance of hydration, particularly when symptoms continue for more than 48 hours. Ask about increased thirst, decreased urination, dark-colored urine, dry mucous membranes, and rapid heartbeat, which suggest dehydration especially when nausea and vomiting are present.
- Monitor for symptom control in patients with chronic diarrhea.
- When antibiotics are used, monitor for completion of the course of therapy.

IRRITABLE BOWEL SYNDROME

KEY CONCEPT IBS is a functional bowel disorder (FBD) in which recurrent abdominal pain is associated with defecation or a change in bowel habits. In the absence of alarm symptoms such as rectal bleeding, family history of colon cancer, or unintentional weight loss, disordered bowel habits such as constipation, diarrhea, or a mix of constipation and diarrhea and symptoms of abdominal bloating/distention are usually present. IBS is classified into one of four types: (a) constipation predominant (IBS-C), (b) diarrhea predominant (IBS-D), (c) mixed with both constipation and diarrhea (IBS-M), or (d) unsubtyped (IBS-U; hard or lumpy stools less than 25% of the time and loose or watery stools less than 25% of the time). IBS is associated with frequent fluctuation in symptoms, loss of productivity, and decreased quality of life.[2,24,25]

EPIDEMIOLOGY AND ETIOLOGY

The diagnosis of IBS is considered a diagnosis of exclusion.[24,34] While pooled global population-based data estimated the prevalence of IBS to be between 7% and 21%, the prevalence of IBS in places like North America is estimated to be about 12%.[24,35]

A meta-analysis found that more than 10% of patients who were diagnosed with infectious enteritis later developed IBS. Although there were some differences in the studies analyzed, the risk was four times higher than in patients who did not have a diagnosis of infective enteritis. The authors also found that women who developed severe enteritis are at increased risk for developing IBS. Other patients at risk for developing enteritis included those experiencing psychological distress and users of antibiotics during enteritis.[36]

PATHOPHYSIOLOGY

Enteric nerves control intestinal smooth muscle action and are connected to the brain by the autonomic nervous system. IBS is thought to result from dysregulation of this "brain–gut axis." The enteric nervous system is composed of two ganglionated plexuses that control gut innervation: the submucous plexus (Meissner plexus) and the myenteric plexus (Auerbach plexus). The enteric nervous system and the CNS are interconnected and interdependent. Several neurochemicals mediate their function, including serotonin (5-hydroxytryptamine or 5-HT), acetylcholine, substance P, and nitric oxide.[37]

Serotonin is particularly important because the GI tract contains the largest amounts in the body. Two 5-HT receptor subtypes, 5-HT_3 and 5-HT_4, are involved in gut motility, visceral sensitivity, and gut secretion. The 5-HT_3 receptors slow colonic transit and increase fluid absorption, whereas 5-HT_4 receptor stimulation accelerates colonic transit.

Although no single pathologic defect accounts for the pattern of exacerbation and remission in IBS, CNS abnormalities, dysmotility, visceral hypersensitivity, and other factors have been implicated.[37]

The passage of fluids into and out of the colon is regulated by epithelial cells. In IBS, the colonic lining (epithelium) appears to function properly. However, increased movement of the contents in the colon can overwhelm its absorptive capacity. Disturbed intestinal motility appears to be a central feature of IBS and leads to altered stool consistency. Studies suggest that the colon of IBS sufferers is abnormally sensitive to normal stimuli. Enhanced visceral sensitivity manifests as pain, especially related to gut distention.[37]

Some IBS patients demonstrate sensitivity to common foods such as wheat, beef, pork, soy, and eggs. Evidence suggests that an immune component may be involved in IBS patients who experience bloating and dysmotility-like dyspepsia and that gender specificity exists.

CLINICAL PRESENTATION AND DIAGNOSIS

Refer to the accompanying box for the clinical presentation of IBS. **KEY CONCEPT** The diagnosis of IBS is made by symptom-based criteria, the absence of alarm symptoms, and the exclusion of organic disease. Patient diagnosis is categorized by the predominant disorder (IBS-C, -D, -M, or -U).

IBS is diagnosed by obtaining a thorough history to distinguish the characteristic symptoms of IBS from other conditions having similar symptoms, physical examination including anorectal examination, limited diagnostic tests, and careful follow-up. Patients should be questioned about the frequency, consistency, color, and size of stools. Because of the functional nature of IBS, a patient may present with symptoms of upper GI problems such as gastroesophageal reflux disease or with excessive flatulence. Patients should also be questioned about diet to establish any symptom relationship to meals or specifically after consumption of certain foods.

Barium enema, sigmoidoscopy, or colonoscopy may be indicated in the presence of red flag symptoms (fever, weight loss, bleeding, anemia, and persistent severe pain), which often point to a potentially serious non-IBS problem. A barium enema may identify polyps, diverticulosis, tumors, or other abnormalities that might be responsible for the symptoms. Furthermore, barium enema may detect exaggerated haustral contractions, which can impede stool movement and contribute to constipation. Flexible sigmoidoscopy can identify obstructions in the rectum and lower colon, whereas colonoscopy can evaluate the entire colon for organic disease.

The Rome IV diagnostic criteria for IBS include symptoms of recurrent abdominal pain occurring on average at least 1 day per week in the last 3 months, associated with two or more of the following: (a) related to defecation, (b) associated with a change in frequency of stool, or (c) associated with a change in form (appearance of stool). These findings should exist for the last 3 months with symptom onset at least 6 months prior to diagnosis.[1]

TREATMENT

Desired Outcomes

KEY CONCEPT The principal goal of IBS treatment is to reduce or control symptoms. The treatment strategy is based on: (a) the prevailing symptoms and their severity, (b) the degree of functional

Clinical Presentation of IBS

Symptoms

- Patients report a history of abdominal pain or discomfort that is relieved with defecation. Symptom onset is associated with change in frequency or appearance of stool. Some persons experience hard, dry stools; others have loose or watery stools. Stools may be small and pellet-like or narrow and pencil-like in appearance.
- KEY CONCEPT Symptoms can typically be categorized as either IBS-D or IBS-C. Patients with IBS-D usually report more than three loose or watery stools daily. Those with IBS-C usually have fewer than three bowel movements per week; stools are typically hard and lumpy and accompanied by straining. However, stool frequency may be normal in many cases.
- IBS-C can often be distinguished from functional constipation by the presence of abdominal pain and discomfort. Although pain and discomfort may be present in some patients with functional constipation, it is an expected feature of IBS.
- Some patients report alternating episodes of diarrhea and constipation (IBS-M).
- Patients with IBS-U report hard or lumpy stools less than 25% of the time and loose or watery stools less than 25% of the time.
- Other common symptoms include: (a) feelings of incomplete evacuation, (b) abdominal fullness, (c) bloating, (d) flatulence, (e) passage of clear or white mucus with stool, and (f) occasional fecal incontinence.
- Periods of normal stools and bowel function are punctuated by episodes of sudden symptoms.
- Symptoms are often exacerbated by stress.
- Left lower quadrant abdominal pain is often brought on or made worse by eating. Passage of stool or flatus may provide some relief.
- Patients with IBS may experience comorbidities outside the GI tract such as fibromyalgia, sleep disturbances, headaches, dyspareunia, and temporomandibular joint syndrome.

Signs

- The physical examination is often normal in IBS.
- The patient may appear to be anxious.
- Palpation of the abdomen may reveal left lower quadrant tenderness, which may indicate a tender sigmoid colon.
- Abdominal distention may be present in some cases.
- The following "red flag" or alarm features are *not* associated with IBS and may indicate inflammatory bowel disease, cancer, or other disorders: fever, weight loss, bleeding, anemia, and persistent severe pain.

Laboratory Tests

- In most cases, laboratory testing reveals no abnormalities, but certain tests can help identify other causes for the patient's symptoms:
- CBC may identify anemia, which may suggest blood loss and an organic source for GI symptoms.
- Serum electrolytes and chemistries may indicate metabolic causes of symptoms.
- Thyroid-stimulating hormone (TSH) should be ordered when thyroid dysfunction is suspected. Hypothyroidism may be responsible for constipation and related symptoms.
- Stool testing for ova and parasites may identify *Clostridioides difficile* and amoebae as possible causes of diarrhea rather than IBS.
- Fecal leukocytes can be found in inflammatory diarrhea, especially when due to invasive microorganisms.
- A positive stool guaiac test indicating blood in the GI tract does not support a diagnosis of IBS.
- An elevated erythrocyte sedimentation rate is consistent with a systemic inflammatory process such as inflammatory bowel disease rather than IBS.
- Testing for lactase deficiency can confirm the presence of lactose intolerance, which may explain the symptoms.

Patient Encounter 3

A 25-year-old man presents to the clinic complaining of headaches, sleep disturbances, cramping abdominal pain, bloating, excessive flatulence, and small amounts of hard, dry stools. When asked to show where his abdomen hurts, he pointed to both his lower left and lower right abdomen. He indicated that the pain seemed to lessen after a bowel movement. Further, he stated that the symptoms have become worse over the last month with dry stools that make it difficult to defecate. He stated that he sometimes will go a few days without a single bowel movement. About 4 months ago, he was diagnosed with fibromyalgia and was started on pregabalin. He stated that the pregabalin has helped.

Identify symptoms characteristic of IBS in this patient.

Discuss how this patient fits within the typical epidemiologic profile of patients with IBS.

impairment, and (c) the presence of psychological components. A standard treatment regimen is not possible because of the heterogeneous nature of the IBS patient population. Patients suffering from IBS can benefit from clinician support and reassurance.

Nonpharmacologic Therapy

▶ *Diet and Other General Modifications*

Dietary modification is a standard therapeutic modality. Food hypersensitivities and adverse effects have been associated with IBS, especially IBS-D. Elimination diets are the most commonly used strategy, usually focusing on milk and dairy products, fructose and sorbitol, wheat, and beef. Flatulence may be controlled by reducing gas-causing foods (beans, celery, onions, prunes, bananas, carrots, and raisins). Response to elimination diets varies widely, but they may be useful in individual patients. Care should be taken to avoid nutritional deficits while attempting to eliminate offending foods.

The low FODMAP diet is said to control IBS symptoms in some patients. FODMAPs are carbohydrates (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) that are poorly absorbed and quickly fermented by bacterial action in the gut. The gas by-product of the bacterial action is thought to contribute to IBS symptoms.[38]

The American Gastroenterological Association (AGA) Clinical Practice Guidelines on the role of probiotics in managing GI disorders made no recommendation about the use of probiotics in symptomatic children and adults with IBS because of the variability in clinical trial methodology; the guidelines further state that probiotics should be used only in the context of a clinical trial.[31]

Pharmacologic Therapy

The recommendations that follow are based on the 2014 AGA Institute Guideline on the Pharmacological Management of Irritable Bowel Syndrome.[39,40] New guidelines were expected to be published in 2021, so readers should refer to the newer guidelines when available.

▶ *Agents for Pain and Bloating*

Botanicals Peppermint oil is widely advocated; it acts as an antispasmodic agent due to its ability to relax GI smooth muscle. However, it also relaxes the lower esophageal sphincter, which could allow the reflux of gastric contents into the esophagus. The usual dose is one to two enteric-coated capsules containing 0.2 mL of peppermint oil two to three times daily. *Matricaria recutita*, known as German chamomile, is also purported to have antispasmodic properties. It is taken most often as a tea up to four times a day. Benzodiazepine, alcohol, and warfarin users should be cautioned against taking this product because it can cause drowsiness, and it contains coumarin derivatives. Primrose oil is used by some patients, but evidence of effectiveness is lacking.

Patient Encounter 3, Part 2

Upon further questioning, the patient recalled experiencing similar symptoms about 2 years ago when he thought he would have to leave school because of dwindling finances. He did not seek medical attention then because he did not have health insurance. He is a full-time student who is self-financing his higher education. His diet consists mostly of fast food.

PMH: Insomnia, headaches, fibromyalgia

FH: None

SH: Has a glass of wine occasionally with dinner

Meds: Duloxetine 30 mg orally once daily as needed for fibromyalgia; melatonin 3 mg one tablet 1 to 2 hours before bedtime as needed for insomnia; acetaminophen/aspirin/caffeine tablets two tablets every 6 hours as needed for headache; loperamide 2 mg as needed for diarrhea; bisacodyl 10 mg as needed for constipation.

Allergies: No known drug allergies

PE:

General: thin appearing; somewhat anxious and nervous when speaking

VS: BP 128/70 mm Hg; pulse 86 beats/min; RR 18 breaths/min; T 97.4°F (36.3°C); Ht. 5′4″ (163 cm); Wt. 140 lbs. (63 kg)

Integ: Skin appears dry and scaly

HEENT: PERRLA, EOMI

Ext: Normal, no swelling

Chest: Clear to A and P bilaterally

CV: RRR

Abd: (+) BS, tender LLQ and LRQ

Rectal: No abnormalities, negative stool guaiac test

Which of this patient's findings are indicative of IBS?

Propose a comprehensive treatment approach to IBS in this patient. Where appropriate, consider the presence and influence of comorbidities.

▶ *Agents for Constipation Predominance (IBS-C)*

Bulk Producers These agents may improve stool passage in IBS-C but are unlikely to have a favorable effect on pain or global IBS symptoms. Psyllium may increase flatulence, which can worsen discomfort in some patients. Methylcellulose products are less likely than psyllium to increase gas production. Although fiber-based supplement use is common in IBS-C, methylcellulose may be dose adjusted in diarrhea to increase stool consistency.

Osmotic Laxatives More studies are needed to determine the evidence of benefit on quality of life, number of stools, symptom improvement, and the ability to continue therapy in patients with IBS-C with use of polyethylene glycol 3350 (PEG) or PEG 3350 with electrolytes. The 2014 AGA practice guideline suggests the use of laxatives over no treatment for patients with IBS-C.[39]

Linaclotide (Linzess) This drug is a guanylate cyclase-C (GC-C) agonist indicated for treatment of IBS-C in adults. In IBS-C, the recommended linaclotide dose is 290 mcg orally once daily. Linaclotide relieves the abdominal pain, bloating, and constipation associated with IBS-C while exhibiting a low tendency for systemic side effects. However, diarrhea may lead to discontinuation in some patients. Clinical trials have demonstrated symptom relief and improved quality of life in treated patients. Studies of linaclotide had high overall quality of evidence across all critical outcomes such as abdominal pain response, spontaneous complete bowel movement response, improvement in quality of life, and improvement in stool consistency and urgency. The 2014 AGA practice guideline recommends the use of linaclotide over no treatment in patients with IBS-C.[39,40]

Lubiprostone (Amitiza) This agent is also FDA approved for treatment of IBS-C, but only in women age 18 years and older. Lubiprostone is generally well tolerated in such patients. It is typically given in smaller doses than those used in CIC. However, as with treatment for constipation, nausea may limit its use. Diarrhea leading to treatment discontinuation may occur. Recent evidence indicated a moderate degree of symptom relief and improvement in quality of life with lubiprostone use. No clinical studies currently exist that compare the beneficial effects or harm associated with the use of linaclotide versus lubiprostone. In patients with IBS-C the 2014 AGA practice guideline suggests use of lubiprostone over no drug treatment.[39,40]

Plecanatide (Trulance) This guanylate cyclase-C agonist is indicated for treatment IBS-C.[41] Plecanatide and its active metabolite act locally on the luminal surface of the intestinal epithelium to increase the availability of intra- and extracellular cyclic GMP. In animal models, increased availability of cyclic GMP has been associated with decreased activity of pain-sensing nerves of visceral pain and stimulation of secretion of chloride and bicarbonate via activation of the cystic fibrosis transmembrane conductance regulator (CFTR) ion channel into the intestinal lumen, resulting in increased intestinal fluid and accelerated transit. Due to risk of serious dehydration, plecanatide is contraindicated in patients less than 6 years of age, and its use should be avoided in patients aged 6 to 18 years of age. The safety and efficacy of plecanatide in patients less than 18 years of age has not been established. The recommended adult dosage for treating IBS-C is one 3-mg tablet orally once daily. The tablet should be swallowed whole and can be taken with or without food. Diarrhea leading to discontinuation is the most common adverse reaction associated with plecanatide. Most cases of diarrhea occurred within the first 4 weeks of therapy, but severe diarrhea has been reported within the first day of treatment. Less commonly reported adverse effects included nausea, nasopharyngitis, upper respiratory tract infection, urinary tract infection, and dizziness. Increased liver alanine aminotransferase (ALT) levels have been reported.[41]

Tegaserod maleate (Zelnorm) is indicated for the treatment of adult women younger than 65 years of age who are diagnosed with IBS-C.[42] It acts by enhancing intestinal secretion and motility through its partial 5-hydroxytryptamine (5-HT$_4$) receptor partial agonist activity. The recommended dosage is 6 mg taken twice daily orally at least 30 minutes before meals. Tegaserod should be discontinued if patients do not achieve adequate symptom control after 4 to 6 weeks of treatment. Tegaserod is contraindicated in patients with a history of serious cardiac conditions, ischemic colitis, or other forms of intestinal ischemia, severe renal impairment (eGFR< 15 mL/min/1.73 m^2), or end-stage renal disease. It is also contraindicated in moderate or severe hepatic impairment (Child-Pugh B or C), a history of bowel obstruction, symptomatic gallbladder disease, suspected sphincter of Oddi dysfunction, or abdominal adhesions and hypersensitivity to tegaserod. The benefit of tegaserod use lasts about 90 days. Before tegaserod is prescribed, the potential risks of tegaserod treatment must be balanced with expectations in improvements in symptoms of IBS-C. Discontinue treatment in patients who experience a myocardial infarction, stroke, transient ischemic attack, or angina. Evaluate the risks and benefits of continued treatment in patients who develop clinical or other evidence of cardiovascular ischemic heart disease and/or experience changes in health status that could increase cardiovascular risk during treatment. Patients with ischemic colitis should be monitored for rectal bleeding, bloody diarrhea, and new or worsening abdominal pain; discontinue tegaserod if symptoms develop. Volume depletion associated with diarrhea can occur. Instruct patients to discontinue tegaserod and contact their health-care provider if severe diarrhea, hypotension, or syncope occur. Monitor patients for clinical worsening of depression and emergence of suicidal thoughts and behaviors, especially during the initial few months of treatment. Instruct patients to immediately discontinue tegaserod and contact their health-care provider if their depression is persistently worse or they are experiencing emergent suicidal thoughts or behaviors. Adverse reactions include headache, abdominal pain, alopecia, nausea, diarrhea, flatulence, dyspepsia, and dizziness. Available data from case reports indicated that use in pregnant women has not identified a drug-associated risk of major birth defects, miscarriage, or adverse maternal or fetal outcomes.[42]

▶ *Agents for Diarrhea Predominance (IBS-D)*

Loperamide This antidiarrheal inhibits peristalsis and fluid secretion, thereby improving stool consistency and reducing the number of stools. Consequently, it is most useful in patients who have diarrhea as a prominent symptom. However, it does not lessen abdominal pain and can occasionally aggravate pain. Recent evidence indicates that the level of symptom relief and improvement in quality of life with loperamide is very low. As described in the Diarrhea section, excessive dosing can result in serious cardiovascular adverse effects; patients should be instructed not to exceed the maximum recommended dose of 8 mg (OTC) or 16 mg (prescription) daily.[30] In patients with IBS-D, the 2014 AGA practice guideline suggests that loperamide should be used over no drug treatment.[39]

Antispasmodics Dicyclomine and hyoscyamine have been among the most frequently used medications for treating abdominal pain in patients with IBS (Table 22–6). They have shown improvement in global symptoms and abdominal pain associated with IBS. Nevertheless, the overall quality of evidence across all critical outcomes for antispasmodics is low. The 2014 AGA practice guideline suggests the use of antispasmodics over no drug in patients with IBS.[39]

Side effects include dry mouth, dizziness, blurred vision, constipation, urinary retention, and (rarely) psychosis. Although their effectiveness remains unconfirmed, these drugs may deserve a trial in patients with intermittent postprandial pain.

Antidepressants Tricyclic antidepressants (TCAs) (eg, amitriptyline, desipramine, trimipramine, and doxepin) may help patients with IBS who predominantly experience abdominal

Table 22–6

Pharmacologic Treatments for IBS

Generic Name	Dose
Antispasmodics	
Dicyclomine	10–20 mg PO every 4–6 hours as needed
Hyoscyamine	0.125–0.25 PO mg or sublingually every 4 hours as needed
Propantheline bromide	15 mg PO three times a day (before meals) and 30 mg at bedtime
Clidinium bromide plus chlordiazepoxide HCl	5–10 mg PO three to four times a day
Hyoscyamine, scopolamine, atropine, phenobarbital	One to two tablets PO three to four times daily
Tricyclic Antidepressants	**In IBS with Diarrhea:**
Amitriptyline	50–150 mg PO daily
Doxepin	10–150 mg PO daily
Selective Serotonin-Reuptake Inhibitors	**In IBS with Constipation:**
Paroxetine (others can be used)	10–40 mg PO daily
Bulk-Forming Laxatives	
Psyllium	2.5–4 g PO daily
Methylcellulose	4–6 g PO daily
Antimotility Agents	
Loperamide	4 mg PO; then 2 mg PO after each loose stool; daily maximum: 8 mg (OTC) or 16 mg (RX)
5-HT$_3$ Receptor Antagonist	
Alosetron[a]	0.5 mg PO two times a day for 4 weeks; then assess appropriate dose
5-HT$_4$ Receptor Agonist	
Tegaserod maleate[a]	6 mg PO twice daily
Guanylate Cyclase-C (GC-C) Agonist	
Linaclotide	290 mcg PO once daily
Plecanatide	3 mg PO once daily
Nonabsorbable antibiotic	
Rifaximin	550 mg PO three times daily for 14 days; patients who experience symptom recurrence can be retreated up to two times with the same dosage regimen
Mu-Opioid Receptor Agonist	
Eluxadoline	100 mg PO twice daily with food; 75 mg PO twice daily is recommended for select patients (eg, hepatic impairment)
Chloride Channel Activator	
Lubiprostone	8 mcg PO twice daily with food and water

[a] Withdrawn from general use; available only on a restricted basis.

pain. They modulate pain principally through effects on neurotransmitter reuptake, especially norepinephrine and serotonin. Their effectiveness in functional GI disorders seems independent of mood-altering effects normally associated with these agents. Continued TCA therapy may be limited by adverse effects. The overall effect of TCAs on quality of life, symptom relief, and presence of adverse events leading to treatment discontinuation is reported as low. In patients with IBS, the 2014 AGA practice guideline suggests the use of tricyclic antidepressants over no drug treatment.[39]

The selective serotonin-reuptake inhibitors (SSRIs) paroxetine, fluoxetine, and citalopram are potentially useful due to the significant effect of serotonin in the gut. SSRIs principally act on 5-HT$_1$ or 5-HT$_2$ receptors, but they can also have some effect on gut-predominant 5-HT$_3$ and 5-HT$_4$ receptors, perhaps reducing visceral hypersensitivity. Serotonin–norepinephrine reuptake inhibitors (SNRIs) do not offer improvement of abdominal pain and no improvement in global relief of symptoms within a 6- to 12-week treatment period. Recent evidence indicates that the use of SSRIs in IBS patients in relationship to the overall quality of evidence across all critical outcomes was rated as low. The 2014 AGA practice guideline suggests against using SSRIs for patients with IBS.[39]

Rifaximin (Xifaxan) Semisynthetic antibacterial agent is structurally similar with rifampin. It has very low systemic absorption and is FDA approved for treatment of IBS-D in adults.[43] Research suggests bacterial overgrowth plays a role in producing bloating experienced by some IBS patients. Rifaximin is not to be used in patients with diarrhea accompanied by fever or blood in the stool or diarrhea due to pathogens other than *E. coli*. It should be used with caution in patients with severe (Child-Pugh Class C) hepatic impairment. Rifaximin has proven to be better than placebo in relieving bloating, and its lack of absorption reduces the likelihood of adverse effects. The overall quality of evidence across outcomes such as pain relief, stool consistency, and the return of complete spontaneous bowel movements is moderate.[39]

For treatment of IBS-D, rifaximin 550-mg tablets are administered orally three times daily for 14 days.[43] The same regimen can be repeated up to two times in patients who experience recurrence. Potential adverse reactions include nausea, increased ALT and creatine kinase (CK) enzymes, *C. difficile*–associated colitis, myalgia, and hypersensitivity reactions including exfoliative dermatitis, rash, swelling of the face and tongue, and difficulty swallowing. Hypersensitivity reactions can occur within 15 minutes of rifaximin ingestion. Rifaximin use for treatment of IBS-D has not been studied in pregnant women or children under the age of 18. Caution should be used in patients with liver dysfunction. The 2014 AGA practice guideline suggests the use of rifaximin in patients with IBS-D over no drug therapy.[39]

Alosetron (Lotronex) Stimulation of 5-HT_3 receptors triggers hypersensitivity and hyperactivity of the large intestine. Alosetron, a selective 5-HT_3 antagonist, blocks these receptors and is indicated only for women with severe IBS-D who have: (a) chronic IBS symptoms (6 months or longer); (b) no anatomic or biochemical abnormalities of the GI tract; and (c) not responded adequately to conventional therapy. The recommended starting dose is 0.5 mg twice daily, increasing to 1 mg twice a day after 4 weeks if the starting dosage is well tolerated but does not adequately control IBS symptoms. The most common adverse effects are constipation, abdominal discomfort and pain, nausea, and GI discomfort and pain. Alosetron labeling contains a black box warning related to serious GI adverse reactions, including ischemic colitis and serious complications of constipation that have resulted in hospitalization and, rarely, blood transfusion, surgery, and death. The 2014 AGA practice guideline suggests that in patients diagnosed with IBS-D alosetron use may improve global symptoms over no drug treatment.[39]

Eluxadoline (Viberzi) This μ-opioid receptor agonist reduces bowel contractions and is FDA approved for treatment of adults with IBS-D.[44] The recommended dose is 100 mg orally twice daily taken with food. The dose can be reduced to 75 mg twice daily with food in patients who cannot tolerate the 100-mg dose and in patients with mild or moderate hepatic impairment.[45] The most common adverse effects are constipation, nausea, and abdominal pain. It is contraindicated in persons who drink more than three alcoholic beverage per day because these patients are at increased risk for acute pancreatitis.[45] Eluxadoline should not be used in patients without a gallbladder because these patients are at increased risk of developing pancreatitis and/or sphincter of Oddi spasm. Eluxadoline is a Schedule IV controlled substance.

OUTCOME EVALUATION

- Monitor for adequate symptom relief. Patients whose pain does not respond to drug therapy may have a psychological comorbid condition requiring psychiatric intervention.
- Monitor for relief of pain if initially present. Monitor IBS-C or IBS-D patients for stool frequency, appearance, and size relative to normal characteristics. As stools normalize, associated symptoms such as bloating and abdominal distention should resolve.
- For IBS-C and IBS-M patients taking bulk producers, monitor for relief of constipation. Hard stools should soften within 72 hours.
- Monitor antidepressant and antispasmodic therapy for relief of abdominal pain and potential adverse effects.
- Assess 5-HT_4 receptor agonists for relief of crampy abdominal pain and bloating.
- Monitor linaclotide for treatment-limiting diarrhea in IBS-C.
- Evaluate 5-HT_3 receptor antagonists (alosetron) for relief of abdominal pain and fecal incontinence. Monitor for constipation.
- Expect antimotility agents to reduce stool frequency and control diarrhea within 18 to 36 hours unless severe.
- Monitor CBC, serum electrolytes and chemistries, stool guaiac, and erythrocyte sedimentation rate yearly for changes that might signal an overlapping organic problem.
- Refer for medical evaluation any patient presenting with red flag signs (eg, fever, weight loss, bleeding, anemia, and persistent severe pain).

Patient Care Process for IBS

Collect Information:

- Determine the type, severity, and frequency of symptoms and possible exacerbating factors.
- Obtain a thorough current history of prescription, nonprescription, and dietary supplement use.

Assess the Information:

- Determine if any IBS treatments have been attempted and their effectiveness.
- Establish whether self-care is appropriate or a medical referral is needed.

Develop a Care Plan:

- Determine whether the patient has received prior education about IBS, lifestyle modifications, drug therapy for IBS, and symptom prevention measures. If necessary:
- Explain medication use relative to symptom intensity
- Describe potential adverse effects
- List drugs that may interact with the therapy

Implement the Care Plan:

- Provide patient education about IBS and the treatment selected.

Follow-up: Monitor and Evaluate:

- Encourage patients to report every professional interaction since their last encounter to remain current with all treatment recommendations.
- Be vigilant for the occurrence of red flag symptoms.

Abbreviations Introduced in This Chapter

BSS	Bismuth subsalicylate
CBT	Cognitive behavioral therapy
CIC	Chronic idiopathic constipation
FBD	Functional bowel disorder
FGID	Functional gastrointestinal disorder
FMT	Fecal microbiota transplantation
GMP	Guanosine monophosphate
IBS	Irritable bowel syndrome
IBS-C	Irritable bowel syndrome with constipation
IBS-D	Irritable bowel syndrome with diarrhea
IBS-M	Irritable bowel syndrome with constipation and diarrhea (mixed)
NTC	Normal-transit constipation
OIC	Opioid-induced constipation
ORS	Oral rehydration solution
STC	Slow-transit constipation
PAMORA	Peripherally acting μ-opioid receptor antagonist
TCA	Tricyclic antidepressant
TD	Traveler's diarrhea

23 Portal Hypertension and Cirrhosis

Laurajo Ryan

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of cirrhosis and portal hypertension.
2. Identify signs and symptoms of cirrhosis.
3. Identify laboratory abnormalities that result from liver disease and describe the associated pathophysiology.
4. Describe the consequences associated with cirrhosis and decreased hepatic function.
5. Identify treatment goals for a patient with complications of cirrhosis.
6. Recommend a specific treatment regimen for a patient with cirrhosis that includes lifestyle changes, nonpharmacologic measures, and pharmacologic therapy.

INTRODUCTION

Cirrhosis involves replacement of normal hepatic architecture with fibrous scar tissue. Scarring is accompanied by the loss of viable hepatocytes (the functional cells of the liver) and alterations in hepatic blood flow. Cirrhosis is characterized by progressive damage and deterioration of liver function, but even with extensive scarring, some patients remain asymptomatic. **KEY CONCEPT** Advanced cirrhosis is irreversible and leads to portal hypertension, which in turn is responsible for the complications that define decompensated cirrhosis. Complications of cirrhosis include ascites, spontaneous bacterial peritonitis (SBP), hepatic encephalopathy (HE), hepatorenal syndrome (HRS), and variceal bleeding.[1] These complications carry high mortality rates and indicate disease progression. The only cure for cirrhosis is liver transplantation.

EPIDEMIOLOGY AND ETIOLOGY

Overall, cirrhosis is the 11th leading cause of death in the United States. Rates vary by age, gender, race, and ethnicity, but cirrhosis places an enormous burden on society from hospitalizations, lost wages, decreased productivity, and emotional strain on patients and their families.

Cirrhosis results from long-term insult to the liver, but damage usually doesn't become clinically evident until the fourth decade of life. Infection with one or more strains of viral hepatitis causes acute, potentially reversible hepatic inflammation, whereas chronic infection with hepatitis B (HBV) or C (HCV) often leads to cirrhosis. Globally, viral hepatitis and alcoholic and nonalcoholic liver disease are the most common causes of cirrhosis. Alcohol and HCV are the most common causes of cirrhosis in the United States, whereas HBV accounts for the majority of cases worldwide.[2] Newer HCV therapies provide sustained virologic response (SVR) and are expected to dramatically decrease new cases of HCV cirrhosis. Even patients who have already developed HCV cirrhosis benefit from antiviral therapy, and recent guidelines recommend treatment for nearly all patients (see Chapter 25, Viral Hepatitis, for more details).[3]

Nonalcoholic fatty liver disease (NAFLD) begins with asymptomatic fatty liver but can progress to cirrhosis; it is the leading cause of chronic liver disease worldwide. NAFLD is a diagnosis of exclusion; viral, genetic, and environmental causes must be ruled out. NAFLD is so closely associated with diabetes mellitus, dyslipidemia, obesity, insulin resistance, and other conditions associated with increased hepatic fat that an international consensus recently recommended a change in nomenclature to metabolic dysfunction–associated fatty liver disease (MAFLD).[4]

Alcoholic cirrhosis usually develops after decades of heavy drinking. It develops more quickly in women than men, even after taking body weight into account. Estimates vary, but alcoholic cirrhosis can develop after as few as two to three daily drinks in women and three to four drinks in men, although five to eight daily drinks is more typical.[5] Differences in metabolism may account for the gender disparity; women metabolize less alcohol in the gastrointestinal (GI) tract, allowing delivery of more ethanol (which is directly hepatotoxic) to the liver.[6] Genetic factors also play a role in disease progression; some patients develop cirrhosis with much less cumulative alcohol intake than is typical (either fewer drinks per day or faster disease onset), while others with much larger intake may never develop cirrhosis.

Alcoholic Liver Disease

Alcoholic liver disease stimulates changes in metabolism that result in the deposition of fat in the liver, hypertriglyceridemia, and acidemia. The disease progresses through several distinct phases—fatty liver followed by alcoholic hepatitis (inflammation) and finally cirrhosis. Early stages (fatty liver, hepatitis) are often reversible with cessation of alcohol intake, and although the scarring of cirrhosis is permanent, stopping drinking can decrease complications and slow progression to end-stage liver disease.[7]

Ethanol metabolism to acetaldehyde begins in the gastric mucosa even prior to absorption. Because it is highly lipid soluble, the remaining alcohol is rapidly absorbed from the GI tract and transported to the liver. **KEY CONCEPT** Alcohol dehydrogenase oxidizes ethanol to acetaldehyde, which causes inflammation and fibrosis.[7] Acetaldehyde exerts direct toxic effects on the liver by damaging hepatocytes, inducing fibrosis, and directly coupling to proteins, interfering with their intended function. When ethanol saturates the alcohol dehydrogenase enzyme system, an inducible form of the cytochrome P450 (CYP450) enzyme system (CYP2E1) takes over the detoxification process. Metabolism via CYP2E1, like alcohol dehydrogenase, produces acetaldehyde as its end product and further adds to inflammation by producing reactive oxygen species (ROS).[8]

Less Common Causes of Cirrhosis

Genetics and metabolic risk factors mediate other less common causes of cirrhosis. These diseases vary widely in prevalence, disease progression, and treatment options.

Primary biliary cholangitis (PBC) is characterized by progressive inflammatory destruction of the bile ducts. Immune-mediated inflammation of the intrahepatic bile ducts causes remodeling and scarring, resulting in the retention of bile in the liver and hepatocellular damage, which can lead to cirrhosis. PBC is uncommon, and patients are frequently diagnosed incidentally during routine healthcare visits.

Hereditary hemochromatosis is an autosomal recessive disease that causes increased intestinal iron absorption and subsequent deposition in hepatic, cardiac, and pancreatic tissue. Hepatic iron overload can cause fibrosis, hepatic scarring, cirrhosis, and hepatocellular carcinoma. Repeated blood transfusions can also cause hemochromatosis, but transfusions alone rarely lead to cirrhosis.

In Wilson disease (an autosomal recessive disease), the protein responsible for facilitating copper excretion in the bile is faulty, and copper accumulates in hepatic tissue. High copper levels are toxic to hepatocytes, and fibrosis leading to cirrhosis can develop in untreated patients. Patients with Wilson disease usually present with symptoms of liver and/or neurologic disease while still in their teens.

A third genetic disease that can cause cirrhosis is α_1-antitrypsin deficiency (AATD). Abnormalities in the α_1-antitrypsin protein cause it to accumulate in the liver. AATD can cause cirrhosis in children and adults; adults usually have concomitant pulmonary disease.

PATHOPHYSIOLOGY

Cirrhosis and Portal Hypertension

Progressive destruction of hepatocytes combined with an increase in fibroblasts and connective tissue culminates in cirrhosis. Fibrotic scar tissue nodules modify the basic architecture of the liver, disrupting hepatic blood flow and overall liver function.

Reduced hepatic blood flow significantly alters normal metabolic processes and interferes with protein synthesis as well as alterations in carbohydrate and lipid metabolism. Hepatic drug metabolism is also disrupted. These changes can result in higher systemic drug concentrations and toxicity by extending half-life of drugs normally eliminated by the liver (especially drugs with high first-pass metabolism). Decreased hepatic metabolism can also reduce or delay prodrug activation causing therapeutic failure. A healthy liver processes metabolic waste products for excretion; in cirrhosis, bilirubin (from the enzymatic breakdown of heme) can accumulate causing jaundice (yellowing of the skin), scleral icterus (yellowing of the sclera), and tea-colored urine (urinary bilirubin excreted as urobilinogen).

Changes in steroid hormone production, conversion, and handling are prominent features of cirrhosis. In men, the relative increase in estrogens manifests as decreased libido, gynecomastia (development of breast tissue), testicular atrophy, and feminization. Another effect of changes in sex hormone metabolism is the development of palmar erythema and spider angioma (nevi). Spider angioma are vascular lesions found mainly on the trunk that have a central arteriole (body) surrounded by radiating "legs." When blanched, the lesions fill from the center body outward toward the legs. Spider angioma are not specific to cirrhosis, but the number and size do correlate with disease severity, and their presence relates to the risk of variceal hemorrhage.[9]

Portal hypertension describes increased blood pressure in the portal vein and is a consequence of increased resistance to hepatic blood flow.[9] Portal hypertension can develop from prehepatic, intrahepatic (sinusoidal), or posthepatic damage that obstructs blood flow to the liver.

Hepatic sinusoids are porous vessels within the liver that surround radiating rows of hepatocytes (Figure 23–1). Sinusoids transport systemic blood to the hepatocytes where ingested substances (eg, nutrients, drugs, toxins) and waste products are processed for immediate use, storage, or detoxification.

The superior mesenteric and the splenic veins join to form the portal vein that is the primary blood vessel leading to the liver. The portal vein carries deoxygenated venous blood from the splanchnic bed (intestines, stomach, pancreas, and spleen) at a rate of 1 to 1.5 L/min (Figure 23–2). Portal flow accounts for approximately 75% of blood delivered to the liver; the hepatic artery provides the remaining 25% in the form of oxygenated blood from the abdominal aorta.

Intrahepatic resistance to portal blood flow increases pressure on the entire splanchnic bed; an enlarged liver (hepatomegaly) and enlarged spleen (splenomegaly) are common findings in cirrhotic patients.

Portal hypertension causes systemic and splanchnic arterial vasodilation by triggering production of nitric oxide and other vasodilators in an attempt to balance the pressure gradient. The fall in systemic arterial pressure activates the sympathetic nervous system, increases antidiuretic hormone (ADH, vasopressin) release, and activates the renin–angiotensin–aldosterone system (RAAS). This attempt to restore arterial pressure results in avid sodium and water retention.[10]

As a result of the increased pressure, the umbilical vein (which is usually eradicated in infancy) may become patent and cause prominent dilated veins that are visible on the surface of the abdomen. This phenomenon is called *caput medusae* because it resembles the head of the mythical Gorgon Medusa.

Ascites

Ascites is the accumulation of fluid in the peritoneal space. It is the most common condition associated with decompensated cirrhosis and indicates a poor prognosis.[7]

The pathophysiology of ascites, portal hypertension, and volume overload are interrelated (Figure 23–3). Cirrhotic changes and subsequent decreases in synthetic function lead to decreased albumin production (hypoalbuminemia). Because albumin is the primary intravascular protein responsible for maintaining vascular oncotic pressure, low serum albumin levels, elevated hydrostatic pressure, persistent splanchnic vasodilation, and increased capillary permeability allow fluid to leak from the vascular space

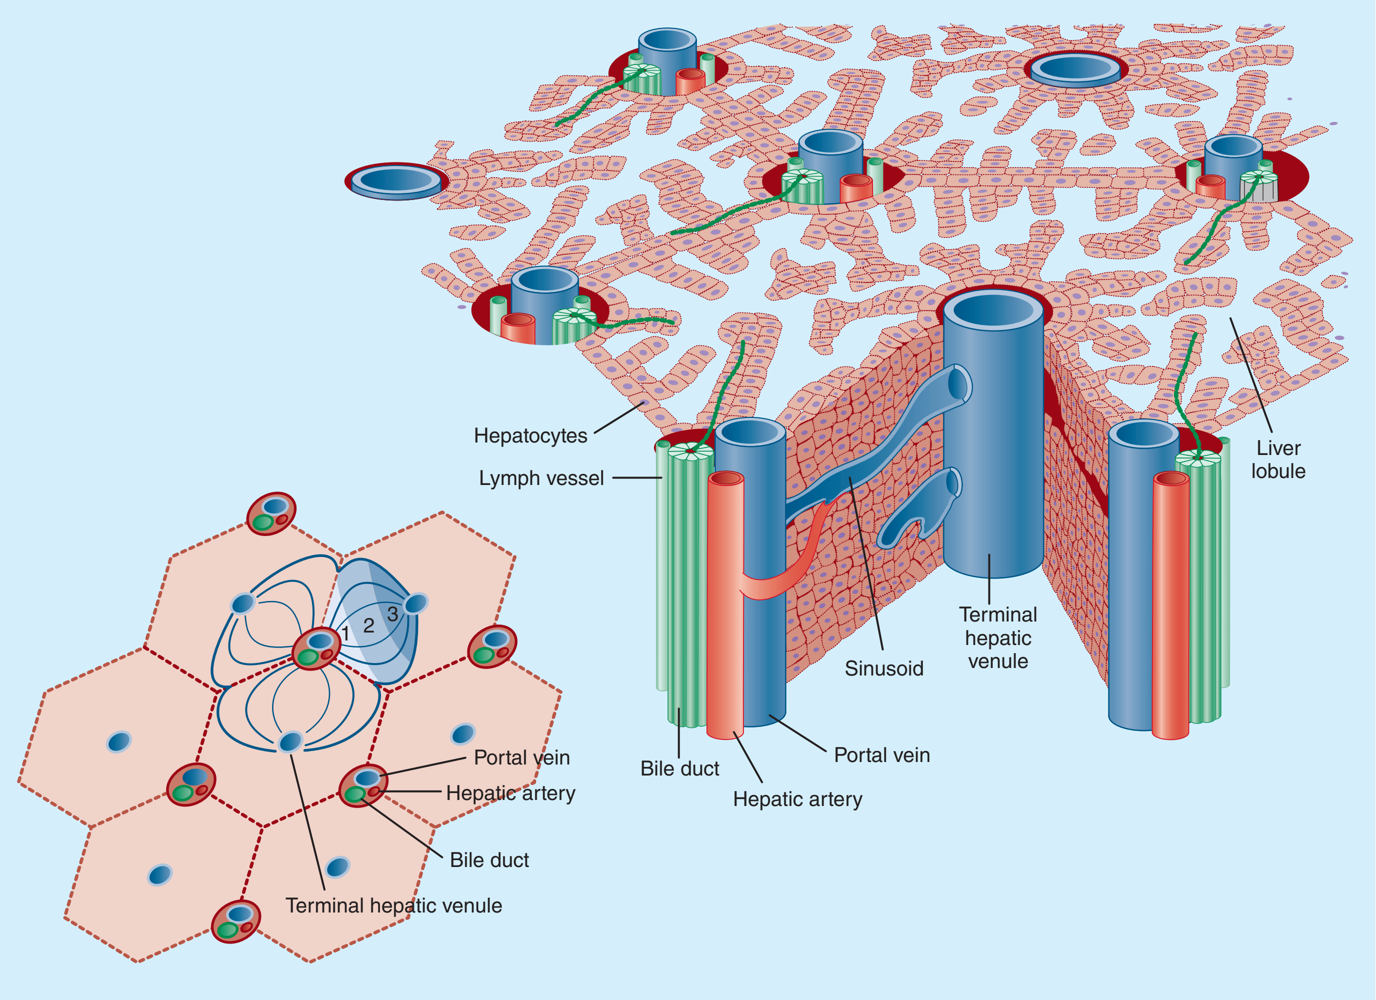

FIGURE 23–1. Relationship of sinusoids to hepatocytes and the venous system. (From Sease JM, Clements JN. Portal hypertension and cirrhosis. In: DiPiro JT, Yee GC, Posey LM, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill, 2020. www.accesspharmacy.com, with permission.)

into body tissues. The result is ascites, peripheral edema, and fluid in the pulmonary system. Obstruction of hepatic sinusoids and hepatic lymph nodes also allows fluid to seep into the peritoneal cavity, further contributing to ascitic fluid formation.

Fluid redistribution results in decreased effective intravascular volume, which decreases renal perfusion. Decreased renal perfusion increases RAAS activity, increasing plasma renin levels, aldosterone production, and sodium retention. The subsequent increase in the intravascular volume furthers the imbalance of intravascular oncotic pressure, allowing even more fluid to escape to the extravascular spaces, increasing ascitic fluid volume and peripheral edema. Unchecked, these combined effects enable the cycle of portal pressure and ascites to continue, creating a self-perpetuating loop of ascites formation.

Patients with ascites avidly retain both sodium and water through multiple mechanisms. Elevated aldosterone concentrations (from a combination of increased production and decreased hepatic clearance), increases in ADH, and sympathetic nervous system activation all impair free water excretion, and patients often become hyponatremic. This is not the result of too little sodium; it is a dilutional effect. Hyponatremia also serves as a marker of disease severity. Untreated, this combination of factors can lead to a decrease in renal function and HRS.[4,10]

Hepatorenal Syndrome

HRS is a decline in renal function in the setting of cirrhosis that is not reversible with volume repletion. The deterioration is not caused by intrinsic renal disease but by ineffective arterial pressure resulting from the cumulative effects of portal hypertension.

Type 1 HRS is characterized by rapid deterioration of renal function (acute kidney injury [AKI]). Untreated, it is rapidly fatal with a 50% mortality rate at 14 days. Renal artery vasoconstriction (stimulated by the sympathetic nervous system and RAAS) and decreased mean arterial pressure (mediated by nitric oxide) decrease renal perfusion and precipitate renal failure. Production of renin stimulates a cascade that causes fluid retention and peripheral vasoconstriction to increase arterial pressure. Prostaglandin E_2 and prostacyclin production increase to stimulate renal vasodilation and maintain renal blood flow. HRS develops when these mechanisms are overwhelmed, and renal perfusion drops acutely. SBP is a common trigger for HRS, as are nonsteroidal anti-inflammatory drugs (NSAIDs), which precipitate HRS by inhibiting prostaglandin production. Type 2 HRS has similar pathophysiology to type 1 HRS but is characterized by a less acute decline in renal function.

The traditional laboratory parameters used to monitor renal function (serum creatinine, blood urea nitrogen [BUN]) tend to be deceptively low in cirrhotic patients because of reduced muscle mass and decreased hepatic urea production, respectively. Because of this, small changes in laboratory values can represent a significant decline in renal function, so even minor changes should be monitored closely.

Varices

The splanchnic system drains venous blood from the GI tract to the liver. Because portal hypertension increases resistance to drainage from the originating organ, collateral vessels (varices) develop in the esophagus, stomach, and rectum to compensate for the increase in pressure and blood volume. Varices divert blood meant for hepatic circulation back to the systemic circulation. This diversion decreases clearance of drugs and potential toxins through the loss of first-pass (presystemic) metabolism. Varices are weak superficial vessels; any additional increase in pressure can cause them to rupture and bleed.[9]

Spontaneous Bacterial Peritonitis (SBP)

SBP is an acute bacterial infection of peritoneal (ascitic) fluid in the absence of intra-abdominal infection or intestinal perforation; up to 30% of patients with ascites develop SBP.[11] The peritoneal cavity is usually a sterile space. One proposed mechanism of bacterial contamination is the translocation of intestinal bacteria to mesenteric lymph nodes, which then seed the ascitic fluid.[12] Bacterial translocation correlates with the delay in intestinal transit time and increased intestinal wall permeability observed in cirrhotic patients. Another possible mechanism of SBP is the hematogenous spread of bacteria into the peritoneal space.[12] Low-protein ascites (< 1 g/dL [10 g/L]) is associated with increased rates of SBP; low protein is presumably correlated to low antibacterial activity.

Enteric Gram-negative aerobes (*Escherichia coli*, *Klebsiella pneumoniae*) are the most common bacteria isolated from patients with SBP. *Streptococcus pneumoniae* is the most common Gram-positive pathogen.[7]

Hepatic Encephalopathy

Numerous factors, many of them poorly understood, are involved in the development of HE. In severe hepatic disease, systemic circulation bypasses the liver; substances that are normally metabolized by the liver accumulate in the systemic circulation. These by-products, especially nitrogenous waste, are neurotoxic.[13]

Ammonia (NH$_3$) is just one of the toxins implicated in HE. It is a metabolic by-product of protein catabolism and is also generated by gut bacteria. In a normally functioning liver, hepatocytes degrade ammonia to form urea, which is renally excreted; in cirrhosis, conversion to urea is reduced, and ammonia accumulates and contributes to encephalopathy. Patients with HE commonly have elevated serum ammonia concentrations, but ammonia levels do not correlate with the degree of CNS impairment.[13]

High levels of "false neurotransmitters" (aromatic amino acids, γ-aminobutyric acid, endogenous benzodiazepines) have also been implicated in HE. These substances bind to both the γ-aminobutyric acid and benzodiazepine receptors and act as agonists at the active receptor sites.[13]

HE is a clinical diagnosis; decreased cognition, confusion, and changes in behavior combined with physical signs such as asterixis (characteristic flapping of hands upon extension of arms with wrist flexion) indicate HE. A precipitating event associated with increased production and/or decreased elimination of nitrogenous waste products or toxins can often be identified in patients with previously stable cirrhosis who develop acute encephalopathy. Infections, variceal hemorrhage, renal insufficiency, electrolyte abnormalities, and increased dietary protein have all been associated with acute HE. Acute HE is often readily reversible, but changes of a more chronic, insidious nature are more difficult to treat; patients rarely recover fully from chronic HE.

Clinical Presentation of Cirrhosis and Complications of Portal Hypertension

General

- Many signs and symptoms are specific to the complication the patient is experiencing at presentation.

Symptoms

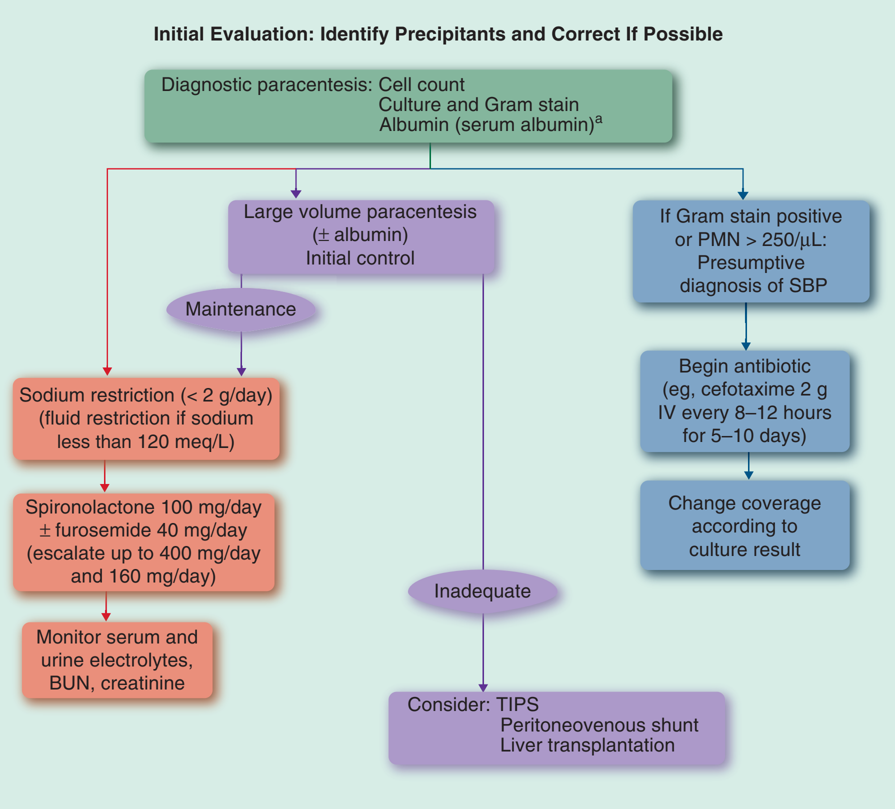
- Patients with cirrhosis may be asymptomatic until acute complications develop.
- Nonspecific symptoms include anorexia, fatigue, weakness, changes in libido, and disturbances in sleep patterns. Patients may also bruise easily or bleed from minor injuries.
- Patients with ascites describe feelings of abdominal fullness and pain, nausea, shortness of breath, and early satiety.
- Hemorrhage from esophageal or gastric varices often presents as nausea, vomiting, and **hematemesis** and may be associated with melena, pallor, fatigue, and weakness from blood loss. Bleeding from rectal varices may present as **hematochezia**.
- In patients with bleeding varices, digestion of swallowed blood can cause nausea and precipitate symptoms of HE.
- Neurologic changes from HE can be overwhelming or so subtle that they are not apparent except during a targeted clinical evaluation.
- Patients with HE may complain of disruption of sleep patterns; patients have delayed bedtime and wake times, which may progress to complete inversion of the normal diurnal cycle.
- SBP should be suspected in patients with symptoms of infection such as fever, chills, abdominal pain, and mental status changes.

Signs

- Nonspecific signs of liver disease include jaundice, scleral icterus, tea-colored urine, bruising, hepatomegaly, splenomegaly, spider angioma, caput medusae, palmar erythema, gynecomastia, and testicular atrophy.
- Ascites can be detected by increased abdominal girth accompanied by shifting dullness and a fluid wave.
- Signs of variceal bleeding depend on the degree of blood loss and abruptness of onset. Rapid and massive blood loss is more likely to result in hemodynamic instability than slow, steady bleeding.
- Signs of acute bleeding may include pallor, hypotension, tachycardia, mental status changes, and hematemesis.
- Markers of hepatic encephalopathy (HE) include decreased cognition, confusion, somnolence, changes in behavior or personality, and asterixis.
- Patients with SBP may present with fever, painful tympanic abdomen, and changes in mental status.
- Decreases in clotting factors and thrombocytopenia may manifest as abnormal bruising and bleeding.
- Dupuytren contracture is a contraction of the palmar fascia that usually affects the fourth and fifth digits. It is not specific to cirrhosis and can also be seen in repetitive use injuries.

Laboratory Abnormalities

- Hepatocellular damage manifests as elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The degree of elevation does not correlate with the remaining functional metabolic capacity of the liver. An AST level twofold higher than ALT suggests ongoing alcoholic liver damage.
- Elevated alkaline phosphatase is nonspecific and may correlate with liver or bone disease; it tends to be elevated in biliary tract disease; γ-glutamyl transferase (GGT) is specific to the bile ducts, and in conjunction with an elevated alkaline phosphatase, suggests hepatic disease. Extremely elevated GGT levels further imply obstructive biliary disease.
- Increased total, direct, and indirect bilirubin concentrations indicate defects in transport, conjugation, or excretion of bilirubin.
- Lactate dehydrogenase (LDH) is a nonspecific marker of hepatocyte damage; a disproportionate elevation of LDH points to ischemic injury.
- Thrombocytopenia may occur because of decreased platelet production and splenic sequestration of platelets.
- Anemia (decreased hemoglobin and hematocrit) occurs as a result of variceal bleeding, decreased erythrocyte production, alcohol use, and hypersplenism.
- Loss of hepatic synthetic function can manifest as elevated prothrombin time (PT) and international normalized ratio (INR).
- Decreased serum albumin and total protein occur in chronic liver damage due to the loss of synthetic capacity within the liver.
- Portal hypertension causes serum albumin-to-ascites gradient of 1.1 g/dL (11 g/L) or greater.
- Increased blood ammonia concentration is characteristic of HE, but levels do not correlate with the degree of impairment.
- Increased serum creatinine and blood urea nitrogen (BUN) signal a decline in renal function and may indicate hepatorenal syndrome.
- Hyponatremia is a result of sodium/water imbalance and does not imply a need for sodium supplementation.
- Signs and symptoms of infection (eg, mental status changes, fever, abdominal pain) should prompt a diagnostic paracentesis in a patient with ascites (**Figure 23–4**). In SBP, there is decreased total serum protein, elevated white blood cell count (with left shift), and the ascitic fluid usually contains at least 250 cells/mm^3 (0.250×10^9/L) neutrophils. Bacterial culture of ascitic fluid may be positive, but lack of growth or negative results on Gram stain does not exclude the diagnosis.



Initial Evaluation: Identify Precipitants and Correct If Possible
Diagnostic paracentesis: Cell count
Culture and Gram stain
Albumin (serum albumin)a
Large volume paracentesis
(± albumin)
Initial control
Maintenance

Consider: TIPS
Peritoneovenous shunt
Liver transplantation

FIGURE 23–4. Approach to the patient with ascites and spontaneous bacterial peritonitis (SBP). [a]If PMN is greater than 250/μL (0.250 × 10^9/L) but culture is negative (culture-negative neutrocytic ascites), begin empiric antibiotics and retap after 48 hours. If culture is positive but PMN less than 250/μL (0.250 × 10^9/L), treat as if PMN greater than 250/μL (0.250 × 10^9/L) (presumed SBP). If polymicrobial infection exists, exclude SBP. (BUN, blood urea nitrogen; PMN, polymorphonuclear leukocyte; SBP, spontaneous bacterial peritonitis; TIPS, transjugular intrahepatic portosystemic shunt.) (Adapted from Chung RT, Podolsky DK. Cirrhosis and its complications. In: Kasper DL, Braunwald E, Fauci AS, et al., eds. Harrison's Principles of Internal Medicine, 17th ed. New York, NY: McGraw-Hill, 2005:1858–1869, with permission.)

Bleeding Diathesis and Synthetic Failure

Coagulopathies signal end-stage liver disease. The liver manufactures both procoagulant and anticoagulant factors essential for blood clotting and maintenance of blood homeostasis. In advanced disease, the liver is unable to synthesize these proteins, resulting in extended clotting times (increased prothrombin time and INR) and bleeding irregularities.[14] These patients were previously thought to be "autoanticoagulated," but better appreciation of the spectrum of coagulation abnormalities has led to the understanding that these patients are not only at increased risk of bleeding but are also at increased risk of venous thromboembolism because of decreased production of protective factors in addition to having prolonged clotting times.[14]

Thrombocytopenia is also very common in advanced liver disease. Patients with cirrhosis have a twofold reason for decreased platelet levels; decreased platelet production through the loss of hepatic thrombopoietin and splenic sequestration that prematurely removes formed platelets from circulation.

CLINICAL PRESENTATION AND DIAGNOSIS

Refer to accompanying clinical presentation box for symptoms, signs, and laboratory abnormalities associated with cirrhosis.

Diagnosis of Cirrhosis

Cirrhosis may be diagnosed incidentally before the patient develops symptoms or acute complications, but many patients have decompensated disease and complications such as ascites, SBP, variceal bleeding, or HE at initial presentation. Patients may have some, all, or none of the laboratory abnormalities and/or signs and symptoms of cirrhosis.[11]

Liver biopsy can definitively diagnose cirrhosis, but because of the invasive nature and elevated bleeding risk, biopsy is usually deferred in lieu of a presumptive diagnosis using a noninvasive technique such as ultrasound or computed tomography. A nodular liver with increased echogenicity is consistent with cirrhosis. The Model for End-Stage Liver Disease (MELD) score predicts 3-month mortality; it is used to classify disease severity and prioritize patients awaiting deceased-donor liver transplantation. The calculator is available at the Organ Procurement and Transplantation Network website (https://optn.transplant.hrsa.gov/resources/allocation-calculators/meld-calculator/).

Patients with ascites or known varices are presumed to have portal hypertension, but direct measurement is typically deferred because it requires invasive testing and increases the risk of bleeding.

Diagnosis of Ascites

Analysis of ascitic fluid obtained during paracentesis provides diagnostic clues to the etiology of peritoneal fluid accumulation. Evaluation includes cell count with differential, albumin, total protein, Gram stain, and bacterial cultures. In patients without an established diagnosis of liver disease, the serum ascites–albumin gradient (SAAG) is used to determine the cause of ascites.[7] SAAG compares serum albumin concentration to ascitic fluid albumin concentration:

$$\text{Alb}_{\text{serum}} - \text{Alb}_{\text{ascites}} = \text{SAAG}$$

A value of 1.1 g/dL (11 g/L) or greater identifies portal hypertension as the cause of the ascites with 97% sensitivity.[7] Low albumin in the peritoneal space balances the oncotic pressure gradient with the hydrostatic pressure gradient from portal hypertension. The differential diagnosis for SAAG values less than 1.1 g/dL (11 g/L) includes peritoneal carcinoma, peritoneal infection (tuberculosis, fungal, cytomegalovirus), and nephrotic syndrome. Serum albumin should be measured at the time of paracentesis for an accurate comparison.[7]

TREATMENT OF PORTAL HYPERTENSION, CIRRHOSIS, AND COMPLICATIONS

Desired Outcomes

Recognizing and treating the underlying cause of cirrhosis is paramount. **KEY CONCEPT** Until recently, cirrhosis was considered irreversible, but treating the underlying cause in its early stages may reverse the damage. Eradication of HCV decreases mortality even with advanced disease. In patients without a reversible cause, cirrhosis treatment is directed at limiting disease progression and minimizing complications.[11] Immediate treatment goals are to stabilize acute complications such as variceal bleeding and prevent SBP and HRS. Once life-threatening conditions have stabilized, the focus shifts to preventing complications and further liver damage. The sections that follow concentrate on therapy to prevent and treat cirrhotic complications.

Patient Encounter Part 1

A 47-year-old man was brought to the emergency department by ambulance after his family called for a wellness check when they had not heard from him for a week. On arrival, he is only oriented to name and became obtunded shortly after vomiting a large quantity of blood.

Chief Complaint: Found down at home by EMS

HPI: Unknown

PMH: Unknown; patient is obtunded

Drug Allergies: Unknown

PSH: Unknown

SH: Unknown, other than he lives alone

FH: Unknown

Meds (Outpatient): Unknown

ROS: Patient is obtunded

PE:

VS: BP 82/46 mm Hg, HR 110 beats/min, T 100.8°F (38.2°C), RR 18 breaths/min, oxygen saturation 99% (0.99) on room air, Ht 74″ (188 cm), Wt 79 kg, BMI 22.4 kg/m^2

General: Obtunded, pale man who appears older than stated age

HEENT: PERRL, EOMI, (+) scleral icterus, mildly jaundiced skin

CV: Tachycardic, no murmurs, rubs, or gallops

Chest: CTA bilaterally, spider angioma on upper chest and back

Abd: Soft, nondistended abdomen with decreased bowel sounds, hepatosplenomegaly, and small ascites

Ext: 3+ pedal pulses, 1+ pitting edema

What signs and symptoms are consistent with cirrhosis?

Based on the current information, what is the most likely cause of his hematemesis?

What risk factors does he have for cirrhosis?

Nonpharmacologic Therapy

Avoiding additional hepatic damage and preventing complications are critical for successful cirrhosis management. Lifestyle modifications can limit disease complications and slow further liver damage. The only proven treatment for alcoholic liver disease is immediate cessation of alcohol use, and because alcohol is hepatotoxic, all cirrhotic patients should abstain from alcohol to prevent further liver damage regardless of the etiology of their cirrhosis.

Patients with ascites require dietary sodium restriction. Intake should be limited to less than 800 mg sodium (2 g sodium chloride) per day. More stringent restriction may cause faster mobilization of ascitic fluid, but adherence to such strict limits is very difficult. Ascites usually responds well to sodium restriction accompanied by diuretic therapy.[7]

Drug therapies must be monitored carefully for potential adverse effects; hepatically, metabolized drugs can accumulate in patients with liver disease. Unfortunately, little guidance is available on drug dosing in hepatic impairment because these patients have historically been excluded from drug trials. Routine acetaminophen use should not exceed 2 g/day. Dietary supplements, herbal remedies, and nutraceuticals have not been well studied in hepatic impairment and cannot be recommended.

In patients with acute variceal bleeding, nasogastric (NG) suction reduces the risk of aspirating stomach contents; aspiration pneumonia is a major cause of death in patients with variceal bleeding. Because blood in the GI tract is very nauseating, NG suction during variceal bleeding can also decrease nausea and vomiting by removing blood from the GI tract.

Endoscopic band ligation (EBL) involves application of a stricture around the varix to stop acutely bleeding varices. EBL is the preferred endoscopic treatment and effective in up to 90% of patients.[15] EBL is also the standard of care for secondary prophylaxis of repeat bleeding in patients with a history of either esophageal or gastric variceal bleeding. Band ligation is best used in conjunction with pharmacologic treatment.[9]

During episodes of acute HE, temporary protein restriction to decrease ammonia production can be a useful adjuvant to pharmacologic therapy, but long-term protein restriction in cirrhotic patients is not recommended. Cirrhotic patients are already in a nutritionally deficient state, and prolonged protein restriction will exacerbate the problem.[13]

Vaccination against hepatitis A and B is recommended in all patients with cirrhosis to prevent additional liver damage from an acute viral infection.[16] Pneumococcal and influenza vaccination may also be appropriate and can reduce hospitalizations.

Shunts are long-term solutions to decrease elevated portal pressure. Shunts divert blood flow through or around the diseased liver, depending on the location and type of shunt employed. Transjugular intrahepatic portosystemic shunts (TIPS) create a communication pathway between the intrahepatic portal vein and the hepatic vein. TIPS procedures may be preferred over surgically inserted shunts because they are placed through the vascular system rather than more invasive surgical procedures, but they still carry a risk of bleeding and infection. TIPS placement can improve HRS but is associated with an increased incidence of HE.[13] The increased risk of HE results from the decreased detoxification of nitrogenous waste products because the shunt allows blood to evade metabolic processing.

Hemodialysis is usually used only as a bridge for HRS patients awaiting liver transplantation. It can contribute to hemodynamic instability and does not correct the underlying liver disease.

Pharmacologic Therapy

Drug therapy directed at reducing portal hypertension can alleviate symptoms and prevent complications but cannot reverse cirrhosis.

Patients with chronic hepatitis C infection and compensated cirrhosis should be considered for drug treatment (see Chapter 25) with a goal of achieving sustained virologic response (SVR).

▶ *Portal Hypertension*

KEY CONCEPT Nonselective β-blockers (NSBB) such as propranolol and nadolol are first-line treatments for portal hypertension. They reduce bleeding and decrease mortality in patients with known varices.

Only nonselective β-blockers (those that block both β_1 and β_2 receptors) reduce bleeding complications in patients with known varices. Blockade of β_1 receptors reduces cardiac output and splanchnic blood flow, while β_2-adrenergic blockade prevents β_2-receptor–mediated splanchnic vasodilation while allowing unopposed α-adrenergic effects; this enhances vasoconstriction of the systemic and splanchnic vascular beds. The combination of β_1 and β_2 blockade makes the NSBB preferable to cardioselective (β_1 selective) agents in treating portal hypertension.[1,9] Although cardioselective β-blockers do lose β_1 selectivity at higher doses, most patients with cirrhosis cannot tolerate the high doses.

Because β-blockers decrease blood pressure and heart rate, they should be started at low doses to increase tolerability; cirrhotic patients often already have low blood pressure and heart rate. Propranolol is hepatically metabolized, so initial drug concentration, half-life, and pharmacologic effects are all increased in cirrhosis. A reasonable starting dose of propranolol is 10 to 20 mg once or twice daily.

Doses should be titrated as tolerated with the goal of decreasing heart rate by 25% or to approximately 55 to 60 beats/min.[9] Heart rate reduction is not an accurate predictor of portal pressure reduction but is associated with maximally tolerated effect.

Carvedilol is a unique NSBB that also blocks α_1 receptors. The α_1 blockade induces intrahepatic vasodilation for a more potent decrease in portal pressure compared to other NSBB, but it also mediates greater decreases in mean arterial pressure.

The role of NSBB was called into question after observational trials suggested increased mortality in patients with a history of refractory ascites or SBP.[9] Later publications identified a complex dose–response relationship for NSBB in these patients; high doses (propranolol doses above 160 mg/day) are associated with increased mortality risk, while lower doses are associated with improved survival.[17,18] NSBB use should be carefully monitored in cirrhotic patients with tenuous blood pressure or other evidence of circulatory dysfunction, and discontinued in patients with acute decompensation (eg, variceal bleed, SBP, HRS). Carvedilol should be avoided in patients with refractory ascites to avoid additional vasodilation.[9]

Nitrates (such as isosorbide mononitrate) have been shown in clinical trials to reduce portal pressure when used alone or in combination with β-blockers. However, they cause systemic vasodilation and increase mortality when used alone, and because patients treated with combination therapy have significantly more adverse events compared to β-blocker monotherapy, nitrates are seldom used in cirrhotic patients.[9]

▶ *Ascites*

KEY CONCEPT The goals of treating ascites are to minimize acute discomfort, reequilibrate ascitic fluid, and prevent SBP. Treatment should modify underlying disease pathology; without directed therapy, fluid rapidly reaccumulates.

Acute discomfort from ascites may be ameliorated by therapeutic paracentesis. Often removing just 1 to 2 L of ascitic fluid provides relief from pain and fullness. Volume resuscitation should be provided for large volume paracentesis; 6 to 8 g of IV albumin should be given for each liter of fluid removed. Albumin 25% should be used because it has one-fifth the volume of the 5% product. Large-volume paracentesis without albumin administration can precipitate HRS through decreased perfusion. Albumin has not been shown to be beneficial in hemodynamically stable patients if less than 5 L of fluid is removed.[7]

Diuretics Diuretics are usually required in addition to sodium restriction (see Nonpharmacologic Therapy). **KEY CONCEPT** Spironolactone (an aldosterone antagonist) with or without furosemide forms the basis of pharmacologic therapy for ascites. Cirrhosis is a high aldosterone state; spironolactone counteracts the effects of RAAS activation. Not only is aldosterone production increased in patients with cirrhosis, but decreased hepatic metabolism prolongs aldosterone half-life.

A loop diuretic is typically added to spironolactone for more potent diuresis and to balance serum potassium levels. A ratio of

Patient Encounter Part 2

The patient's older brother arrives and states that he is not aware of any medical conditions that the patient has other than a history of illicit drug use (heroin) in his early 20s, a history of viral hepatitis (he does not know what type) and alcohol use. He cannot quantify alcohol intake but states that his brother drinks "socially."

Laboratory results for the patient showed the following:

Sodium 128 mEq/L (mmol/L)
Potassium 3.4 mEq/L (mmol/L)
Chloride 99 mEq/L (mmol/L)
Bicarbonate 21 mEq/L (mmol/L)
BUN 8 mg/dL (2.9 mmol/L)
SCr 0.9 mg/dL (80 μmol/L)
Glucose 76 mg/dL (4.2 mmol/L)
Hemoglobin 6.2 g/dL (62 g/L; 3.85 mmol/L)
Hematocrit 19% (0.19)
WBC 9.8 × $10^3/\text{mm}^3$ (9.8 × 10^9/L)
Platelets 68 × $10^3/\text{mm}^3$ (68 × 10^9/L)
Albumin 1.8 g/dL (18 g/L)
Total bilirubin 5.3 mg/dL (90.6 μmol/L)
Alk phos 152 IU/L (2.5 μkat/L)
AST 132 IU/L (2.2 μkat/L)
ALT 58 IU/L (0.97 μkat/L)
INR 2.8
PT 37 seconds
GGT 84 IU/L (1.4 μkat/L)
LDH 201 IU/L (3.35 μkat/L)
Serum NH_3 122 mcg/dL (72 μmol/L)

Which laboratory values support a diagnosis of cirrhosis?

What test(s), if any, should be done to further investigate the source of hematemesis?

What test(s), if any, should be done to further investigate and evaluate the source of hepatic dysfunction?

40 mg furosemide (the most common loop diuretic) to 100 mg spironolactone usually maintains serum potassium within the normal range.

Doses should be titrated upward every 3 to 5 days. Because spironolactone is being used specifically for its antialdosterone effects, high doses (up to 400 mg/day) are used. If intolerable side effects such as painful gynecomastia occur with spironolactone, other potassium-sparing diuretics may be used, but clinical trials have not shown equivalent efficacy.[7]

Because ascites equilibrates with vascular fluid at a much slower rate than does peripheral edema, aggressive diuresis is associated with intravascular volume depletion as opposed to better efficacy in removing peritoneal fluid and may lead to hemodynamic instability. The maximum amount of ascitic fluid that can be removed through diuresis is approximately 0.5 L/day.[7] Aggressive diuresis should be avoided unless patients have concomitant peripheral edema. These patients may require increasing furosemide doses until they are euvolemic, and IV diuretics are often necessary. Diuretic therapy is typically lifelong.

▶ *Varices*

Variceal bleeding is common in cirrhotic patients. **KEY CONCEPT** During acute variceal hemorrhage, it is crucial to control bleeding, prevent rebleeding, and avoid complications such as SBP. Mortality at 6 weeks is 15% to 25%.[9] A treatment algorithm for acute variceal bleeding is depicted in Figure 23–5.

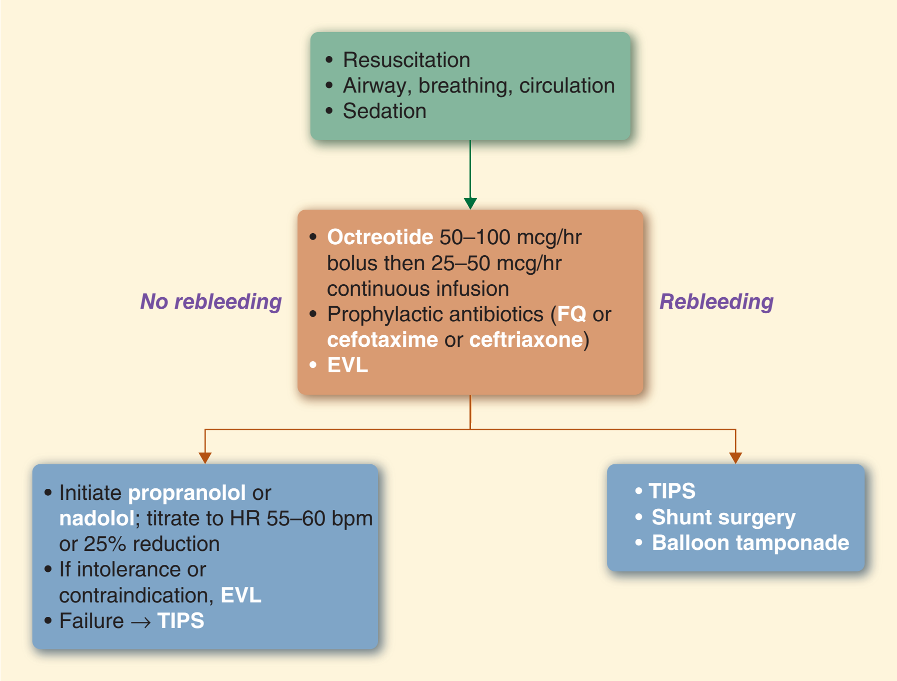
Octreotide (a synthetic somatostatin analog) causes selective vasoconstriction of the splanchnic bed, decreasing portal venous pressure with few serious side effects. A common octreotide dose is a 50-mcg IV loading dose followed by a 50 mcg/hour continuous IV infusion. Therapy should continue for at least 24 to 72 hours after bleeding has stopped, but the optimal treatment duration has not been defined. Some clinicians continue octreotide for a full 5 days because this is the time frame associated with the highest risk of rebleeding. Octreotide combined with endoscopic therapy results in decreased rebleeding rates and transfusion needs when compared with endoscopic treatment alone.[9] Short-term IV proton pump inhibitor (PPI) therapy during an acute variceal bleed can reduce the risk of rebleeding. These patients are at high risk of developing SBP, and prophylactic antibiotics provide both a morbidity and mortality benefit in this situation. Choice of a specific agent should be based on the local susceptibility data, but ceftriaxone (1 g IV every 24 hours) for 5 to 7 days has been proven effective.[9]

Terlipressin (a vasopressin analog) is commonly used in Europe to treat variceal bleeding.

▶ *Spontaneous Bacterial Peritonitis*

Prophylactic antibiotic therapy is recommended during acute variceal bleeding to prevent SBP; this is typically initiated with a third-generation cephalosporin. Prophylactic antibiotic therapy reduces inhospital infections and mortality in patients hospitalized for variceal bleeding.[9]

If SBP is suspected, empiric antibiotic therapy should be initiated with a broad-spectrum anti-infective agent after ascitic fluid collection, pending cultures and susceptibilities (Figure 23–4). In the setting of presumed infection, delaying treatment while awaiting laboratory confirmation is inappropriate and may result in death. The preferred initial antibiotic should be an IV third-generation cephalosporin (eg, cefotaxime 2 g every 8 hours, ceftriaxone 2 g every 24 hours).[7,9] These agents cover the most common organisms implicated in SBP, but local resistance patterns must be taken into account when choosing empiric antibiotic therapy. Once a bacterial pathogen is identified, coverage should be narrowed to an agent that is highly active against that particular organism. SBP is rarely polymicrobial.



• Resuscitation
• Airway, breathing, circulation
• Sedation
No rebleeding
• Octreotide 50–100 mcg/hr bolus then 25–50 mcg/hr continuous infusion
• Prophylactic antibiotics (FQ or cefotaxime or ceftriaxone)
• EVL
Rebleeding
• Initiate propranolol or nadolol; titrate to HR 55–60 bpm or 25% reduction
• If intolerance or contraindication, EVL
• Failure → TIPS
• TIPS
• Shunt surgery
• Balloon tamponade

FIGURE 23–5. Treatment of acute variceal bleeding. (EVL, endoscopic variceal ligation; FQ, fluoroquinolone; HR, heart rate; TIPS, transjugular intrahepatic portosystemic shunt.) (From Ryan L, Attridge RL, Moote R, Miller ML. Chapter 9. Portal Hypertension and Cirrhosis. In: Attridge RL, Miller ML, Moote R, Ryan L, eds. Internal Medicine: A Guide to Clinical Therapeutics, New York, NY: McGraw-Hill; 2013, with permission.)

SBP is the primary cause of HRS. The risk of progression to HRS can be reduced with albumin therapy, 1.5 g/kg immediately (within 6 hours of diagnosis), followed by 1 g/kg on day 3 of SBP therapy for high-risk patients with SCr greater than 1 mg/dL (88 μmol/L), BUN above 30 mg/dL (10.7 mmol/L), or bilirubin higher than 4 mg/dL (68.4 μmol/L).[19]

KEY CONCEPT Long-term SBP prophylaxis decreases mortality and is recommended in a select group of patients—those with a history of SBP, and those with low-protein ascites (ascitic fluid albumin less than 1.5 g/dL [15 g/L]) plus one of the following: SCr 1.2 mg/dL (106 μmol/L) or greater, BUN 25 mg/dL (8.9 mmol/L) or greater, serum sodium 130 mEq/L (mmol/L) or less, or Child–Pugh score of at least 9 (Child–Pugh classification estimates mortality from cirrhosis), with bilirubin of at least 3 mg/dL (51.3 μmol/L). Oral options are one trimethoprim–sulfamethoxazole double-strength daily or ciprofloxacin 500 mg daily.[7]

▶ *Hepatorenal Syndrome*

HRS is a life-threatening complication of cirrhosis. Targeted treatment increases central venous system volume. Peripheral vasoconstriction redistributes fluid from the periphery to the venous system; fluid is retained in the vascular space by administering albumin (to increase oncotic pressure). The ultimate goal is to increase renal perfusion.

A common regimen involves giving albumin 1 g/kg on the day of diagnosis (day 1), followed by 20 to 40 g on subsequent treatment days. This regimen is used in combination with midodrine (an α-agonist) and octreotide. The initial midodrine dose is 7.5 mg orally three times daily; octreotide is usually administered subcutaneously (as opposed to IV during variceal bleeding) 100 mcg three times daily. Both drugs can be titrated as tolerated to achieve increases in mean arterial pressure of at least 15 mm Hg.

Terlipressin, a vasopressin analog, has been used successfully in patients with HRS in Europe and was recently approved for use in the United States.

▶ *Encephalopathy*

Lactulose **KEY CONCEPT** Lactulose is the foundation of pharmacologic therapy to prevent and treat HE. It is a nondigestible synthetic disaccharide laxative that is hydrolyzed in the gut to an osmotically active compound that draws water into the colon and stimulates defecation. Lactulose lowers colonic pH, which favors the conversion of ammonia (NH_3) to ammonium (NH_4^+), which cannot cross back from the gut into the systemic circulation because it is ionic. Lactulose is usually initiated at 15 to 30 mL two to three times per day and titrated to a therapeutic goal of two to three soft bowel movements daily.[13]

Antibiotic Therapy Rifaximin is a nonabsorbable antibiotic that decreases urease-producing gut bacteria, decreasing ammonia production. It is used extensively in Europe as first-line therapy for HE. Although rifaximin is both effective and well tolerated, its expense may prohibit long-term use. In the United States, it is reserved for use as add-on therapy after lactulose failure. The rifaximin dose is 550 mg twice daily to prevent HE recurrences and 400 mg three times a day for treatment.

Metronidazole and neomycin have also been used to treat HE but are not generally recommended because of toxicity; prolonged metronidazole use is associated with peripheral neuropathy, and although neomycin is classified as a nonabsorbable aminoglycoside antibiotic, patients with cirrhosis do have detectable plasma concentrations. This is thought to be a result of decreased intestinal mucosa integrity, and it may lead to nephrotoxicity. Neomycin should not be used if other options exist.[13]

Patient Encounter Part 3

Ultrasound results were consistent with a diagnosis of cirrhosis, and the emergency endoscopy revealed seven bleeding varices that were banded.

The viral panel was negative for HBV and HIV, but the HCV antibody test was reactive. The results of the nucleic acid test (NAT) for HCV RNA are pending.

The team was unable to perform a diagnostic paracentesis because the volume of fluid was too small.

What therapy (if any) should be initiated for variceal bleeding?

Should the patient receive vitamin K?

Should the patient receive antibiotics?

If antibiotics are initiated, what is the most appropriate regimen?

Should the patient receive a nonselective β-blocker?

What are potential sources of his altered mental status?

How should his confusion be treated?

Flumazenil Evidence for false transmitters as the cause of encephalopathy has been demonstrated by functional improvement after administering flumazenil (a benzodiazepine antagonist). Unfortunately, long-term benefit has not been demonstrated, and because flumazenil can only be administered parenterally, it is not an appropriate choice for clinical use; flumazenil use is limited to the research setting.

▶ *Coagulation Abnormalities*

Vitamin K is essential for hepatic synthesis of coagulation factors. The elevated clotting time that results from decreased protein synthesis is indistinguishable from coagulopathy that is a result of malnutrition or poor intestinal absorption. When vitamin K_1 (phytonadione) is given subcutaneously (10 mg for 3 days), it can replete stores and establish if coagulation abnormalities are due to

Patient Encounter Part 4

The next day, the patient's mental status has improved, and he is awake but still somnolent. He states that he is aware that he had contracted hepatitis C in the past but never sought treatment for it because he quit using IV drugs many years ago. He was not aware that he had liver disease and states that he only drinks two to three times a month and only has three drinks maximum each time. He does not take any prescription drugs but does use OTC NSAIDs, acetaminophen, antihistamines as needed, and "herbal" products for occasional insomnia.

What pharmacologic and nonpharmacologic treatments are appropriate to reduce the risk of future variceal bleeding and other complications of cirrhosis?

Does he require long-term prophylaxis to prevent recurrent SBP?

malabsorption alone. It is unusual to completely reverse clotting abnormalities, but INR decreases in most patients, conferring a decreased risk of bleeding. Because cirrhotic patients may have decreased bile production resulting in decreased absorption of fat-soluble vitamins, phytonadione should be given subcutaneously instead of orally to ensure absorption.

OUTCOME EVALUATION

- Reevaluate the pharmacotherapy regimen at each visit to assess adherence, effectiveness, adverse events, and need for drug titration.
- Ask the patient about adherence to lifestyle changes such as cessation of ethanol intake and avoidance of over-the-counter medications (particularly NSAIDs and acetaminophen) and dietary supplements that may exacerbate complications of cirrhosis.
- Assess dietary sodium intake by patient food recall. Measure dietary sodium adherence using spot urine sodium-to-potassium ratio to assess appropriate sodium excretion.
- Ask the patient specific, directed questions regarding adherence and adverse effects of β-blockers; inquire about symptoms of orthostatic hypotension (eg, lightheadedness, dizziness, fainting).
- Evaluate effectiveness of diuretic therapy with regard to ascitic fluid accumulation and development of peripheral edema. Ask the patient directed questions regarding abdominal girth, fullness, tenderness, and pain. Weigh the patient at each visit and ask the patient to keep a weight diary. Assess for peripheral edema at each visit.
- Obtain complete blood count (CBC) and PT/INR to assess for anemia, thrombocytopenia, and coagulopathy. Ask about bruising, bleeding, hematemesis, hematochezia, and melena to assess for bleeding.
- Review biopsy reports and laboratory data. Hepatic transaminases and blood ammonia levels do not correlate well with disease progression, but increased coagulation times and decreased serum albumin are markers of loss of synthetic function, and hyponatremia is a marker of worsening disease.
- Evaluate for signs and symptoms of HE. Mental status changes may be subtle; questioning family members or caregivers about confusion or personality changes may reveal mild HE even if the patient is unaware of deficits. Ask about sleep patterns to assess for the loss of circadian rhythm. In patients taking lactulose therapy, titrate the dose to achieve two to four soft bowel movements daily as tolerated.

Patient Care Process

Collect Information:

- Perform a medication history at each visit and ask specifically about prescription, nonprescription, herbal products, and nutraceuticals as well as illicit substances. Be especially mindful of NSAID pain relievers and herbal remedies that can be hepatotoxic or affect renal function. Ask the patient how each medication is taken; this can provide insight into adherence.
- Ask about dietary compliance with sodium restriction; a 24-hour diet recall can help identify high-sodium intake.
- Complete a comprehensive review of systems and physical examination to identify subtle changes. Pay particular attention to fluid status and any GI complaints.

Assess the Information:

- Determine if the patient is taking any drugs that could adversely affect their liver disease or renal function.
- Identify drugs that can precipitate altered mental status or cause confusion.
- Identify medications that may have better alternatives or are not crucial to continue.
- Identify any changes in health status that could signal decompensation: (a) changes in fluid status (peripheral edema or new or worsening ascites); (b) changes in GI habits that could signal hematochezia, melena, or hematemesis; and (c) changes in mentation such as confusion, changes in sleep patterns, or increased forgetfulness that could signal hepatic encephalopathy.
- Examine laboratory results for signs of worsening hepatic synthetic function or decompensation.

Develop a Care Plan:

- Identify methods to achieve and maintain lifestyle changes, including avoiding alcohol and illicit drugs and achieving a low-sodium diet.
- Choose drug therapies that do not worsen hepatic or renal function, and avoid drugs that may impair cognition or balance. A good resource for those (although targeted at the geriatric population) is the BEERS criteria medication list; a printable pocket card is available on the Internet.

Implement the Care Plan:

- Educate the patient (and family as applicable) about lifestyle changes and pharmacotherapy regimens; make sure they understand the purpose of each.
- Select medications that are expected to be well tolerated as well as affordable, and choose the least burdensome dosing regimen.
- Educate the patient on potential adverse effects of drug therapy, how to identify and potentially mitigate those affects, and when to seek medical care.

Follow-up: Monitor and Evaluate:

- Follow up at regular intervals to assess both drug therapy and disease progression.
- Review adherence to lifestyle changes and medication regimens.
- Complete review of systems, physical and laboratory examinations as appropriate to assess changes in patient status.

Abbreviations Introduced in This Chapter

ADH	Antidiuretic hormone
ALT	Alanine aminotransferase
AST	Aspartate aminotransferase
BUN	Blood urea nitrogen
CBC	Complete blood count
CYP450	Cytochrome P-450 isoenzyme
GGT	γ-Glutamyl transferase
GI	Gastrointestinal
HE	Hepatic encephalopathy
HRS	Hepatorenal syndrome
INR	International normalized ratio
LDH	Lactate dehydrogenase
MELD	Model for End-Stage Liver Disease
NAFLD	Nonalcoholic fatty liver disease
NG	Nasogastric
NH_3	Ammonia
NH_4^+	Ammonium
NSAID	Nonsteroidal anti-inflammatory drug
PT	Prothrombin time
RAAS	Renin–angiotensin–aldosterone system
SAAG	Serum ascites–albumin gradient
SBP	Spontaneous bacterial peritonitis
TIPS	Transjugular intrahepatic portosystemic shunt

24 Pancreatitis

Lara M. Groetzinger

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of acute pancreatitis and chronic pancreatitis.
2. Differentiate acute pancreatitis from chronic pancreatitis.
3. Formulate care plans for managing acute and chronic pancreatitis.
4. Choose appropriate pancreatic enzyme supplementation for patients with chronic pancreatitis.

INTRODUCTION

The pancreas is a glandular organ in the abdominal cavity lying below the liver and behind the stomach. It is primarily an exocrine gland but also has endocrine functions. The endocrine cells are the islets of Langerhans, which secrete regulatory hormones such as insulin and glucagon directly into the bloodstream.[1] The exocrine cells of the pancreas are called acinar cells that produce and secrete digestive enzymes that mix with a bicarbonate-rich solution released from ductular cells to produce pancreatic juice. This alkaline solution is released through the ampulla of Vater into the duodenum to aid in digestion and buffer acidic fluid released from the stomach (Figure 24–1).[2]

Pancreatic enzymes are responsible for breaking down proteins (protease), lipids (lipase), and carbohydrates (amylase) in the small intestine. Normally, these enzymes are produced and stored as inactive proenzymes within zymogen granules to prevent autolysis and digestion of the pancreas. Amylase and lipase are released from the zymogen granules in the active form, whereas the proteolytic enzymes are activated in the duodenum by enterokinase. Enterokinase triggers the conversion of trypsinogen to the active protease trypsin, which then activates the other proenzymes to their active enzymes. The pancreas contains a trypsin inhibitor to prevent autolysis. Pancreatitis is inflammation of the pancreas causing exocrine and endocrine dysfunction and can be acute or chronic in nature.

ACUTE PANCREATITIS

EPIDEMIOLOGY AND ETIOLOGY

Acute pancreatitis (AP) is one of the most common inpatient gastrointestinal (GI) diagnoses in the United States and places a significant burden on healthcare costs and resources.[3] **KEY CONCEPT** In the Western Hemisphere, AP is caused mainly by ethanol use/abuse and gallstones (cholelithiasis), accounting for 80% to 90% of cases in the United States.[4,5] Less common causes include hypertriglyceridemia, endoscopic retrograde cholangiopancreatography (ERCP), trauma, and autodigestion due to the early activation of pancreatic enzymes. Numerous medications have been implicated as causes of AP (Table 24–1), but other etiologies should be ruled out before diagnosing drug-induced pancreatitis.[3,6,7]

PATHOPHYSIOLOGY

The pancreas sustains an initial insult from alcohol, gallstones, or another etiology. This acute injury leads to the aberrant activation of zymogens within the acinar cell,[8] which is followed by neutrophil, lymphocyte, and macrophage invasion of the pancreas and further activation of enzymes within the pancreas. Trypsin triggers activation of multiple proenzymes, including chymotrypsin, elastase, and phospholipase, which in turn damage the pancreas and surrounding tissues (Figure 24–2). This eventually leads to autodigestion and a profound systemic inflammatory response syndrome (SIRS).[8]

Gallstones can obstruct the ampulla of Vater causing pancreatic enzymes or bile to move in a retrograde fashion into the pancreas. This retrograde movement may be responsible for premature pancreatic enzyme activation and pancreatic autolysis.[2] Ethanol abuse may cause precipitation of pancreatic enzymes in pancreatic ducts, leading to chronic inflammation and fibrosis resulting in the loss of exocrine function. Ethanol may also be directly toxic to pancreatic cells by increasing the synthesis of enzymes that produce toxic metabolites leading to further damage.[9,10] Drug-induced pancreatitis can be due to an immunologic reaction, accumulation of toxic metabolites, a direct toxic effect, intravascular thrombosis, or altered viscosity of pancreatic juice.[11] High serum triglycerides (> 1000 mg/dL [11.3 mmol/L]) release toxic concentrations of free fatty acids, which accumulate and lead to additional damage to acinar cells.[12]

AP can progress to peripancreatic fluid collections in or around the pancreas; they are sterile collections, usually require no intervention, and resolve spontaneously.[13,14] Pancreatic pseudocysts are mature walled-off fluid collections often outside the pancreas that form 4 weeks or longer after the onset of AP. Many pseudocysts resolve spontaneously, but some require surgical or percutaneous drainage. Rupture of a pancreatic pseudocyst is a serious complication and can lead to peritonitis and GI bleeding.[13]

Pancreatic enzyme damage may lead to pancreatic necrosis, which is diffuse inflammation of the pancreas containing both necrotic tissue and fluid. **KEY CONCEPT** Pancreatic necrosis occurs within the first 2 weeks in 10% to 20% of patients with AP and can be sterile or infected. Infected pancreatic necrosis is a late complication of necrotizing pancreatitis[8]; it occurs in 16% to 47% of

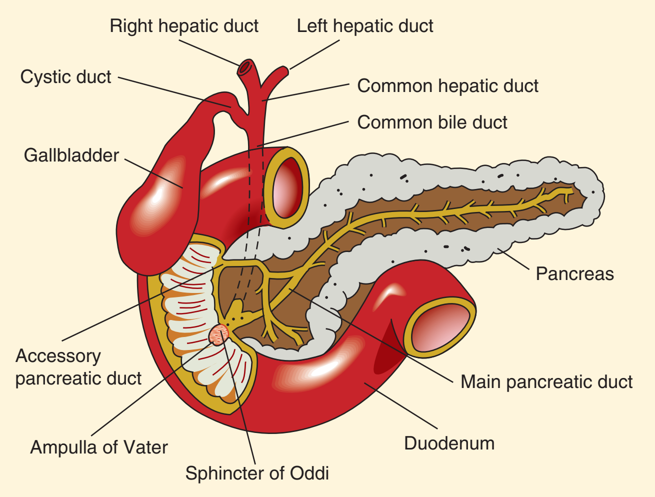

FIGURE 24–1. Anatomical structure of the pancreas and biliary tract. (From Bolesta S, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020; Figure 56–1, with permission. www.accesspharmacy.com.)

patients, usually due to bacteria normally present in the GI tract (*Escherichia coli, Enterobacteriaceae, Enterococcal species, viridans group streptococci*, and anaerobes). Disseminated infection and subsequent serious complications may result from pancreatic necrosis.[13,15] Pancreatic abscess is pancreatic necrosis that is walled off by granulation tissue and occurs weeks after AP.

CLINICAL PRESENTATION AND DIAGNOSIS

AP presentation can range from mild, self-limiting disease to severe, life-threatening illness, including multiorgan failure and shock.[8] Multiorgan failure is a poor prognostic indicator. Disease severity can be predicted using the Ranson criteria, Glasgow severity scoring system, Acute Physiology and Chronic Health Evaluation II (APACHE II), and sequential organ failure assessment. Patients with APACHE II scores above 8 should be monitored and treated in an intensive care unit. Awareness of risk factors for severe disease, including age greater than 55 years, comorbid conditions, laboratory findings, and the presence of SIRS, may be more beneficial than scoring systems.[16]

Table 24–1

Selected Medications Associated with Acute Pancreatitis

Cardiovascular: Enalapril, lisinopril, ramipril, losartan, **furosemide**, **hydrochlorothiazide**, amiodarone, statins, ethacrynic acid
Anti-infectives: Metronidazole, **sulfonamides**, **tetracycline**, tigecycline, **pentamidine**, isoniazid, lamivudine, **didanosine**, nelfinavir, interferon/ribavirin, **erythromycin, rifampin, nitrofurantoin**
Gastrointestinal: Omeprazole, mesalamine, **cimetidine**, ranitidine, sulfadiazine
Neurologic: Valproic acid, clozapine
Hormonal: Conjugated **estrogens**, tamoxifen, **oral contraceptives**
Oncologic: Ifosfamide, cytarabine, bortezomib, capecitabine, cisplatin
Analgesics: Sulindac, salicylates, **acetaminophen**

Clinical Presentation of Acute Pancreatitis

Signs and Symptoms

- Sudden upper abdominal pain is the most common symptom.
- Pain may radiate to the back, and ecchymosis may be present in the flank and periumbilical areas.
- Nausea and vomiting are common.
- Tachycardia, hypotension, fever, and abdominal distention may be present.

Laboratory Tests

- The serum amylase may be elevated to more than three times the upper limit of normal within the first 12 hours of the onset of AP. The degree of elevation does not correlate with disease severity, and levels may return to normal before the patient presents for care.
- Serum lipase rises within 4 to 8 hours of onset, peaks at 24 hours, and returns to normal within 8 to 14 days.
- Other laboratory abnormalities may include elevated white blood cell (WBC) count, hyperglycemia, hypocalcemia, hyperbilirubinemia, elevated serum lactate dehydrogenase (LDH), and hypertriglyceridemia.

DIAGNOSIS

Diagnosis of AP is based on patient history, signs and symptoms, and laboratory values. The history can identify risk factors, such as recent procedures, alcohol abuse, and medications. Abdominal pain is the hallmark presentation of AP.[8] It is epigastric and can radiate to the upper quadrants or back. Nausea and vomiting occur in 85% of patients.[7] Other findings with severe pancreatitis include fever, dyspnea, hypoxemia, and hypotension.[8] A serum lipase more than three times the normal limit supports the diagnosis. The serum lipase has greater sensitivity and specificity for AP than does the serum amylase due to its duration of elevation.[6,17] Elevated hepatic enzymes, alkaline phosphatase, and bilirubin may indicate gallstone pancreatitis,[8] and triglycerides should be checked to rule out hypertriglyceridemia as the cause.[6,16]

The diagnosis of AP requires at least two of the following: (a) upper abdominal pain, (b) serum lipase more than three times the upper limit of normal, or (c) evidence of AP on imaging such as computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound.[4,7] Abdominal ultrasound can identify gallstones and sludge in the common bile duct but has limited sensitivity. CT may be more useful in staging pancreatitis or identifying complications. ERCP should be used early when patients have concurrent acute infection of the biliary tract (cholangitis). MRI and magnetic resonance cholangiopancreatography (MRCP) are more costly options that can be used to evaluate severity and pancreatic abnormalities.[6,16]

TREATMENT

Desired Outcomes

The goals of treatment for AP include (a) resolution of nausea, vomiting, abdominal pain, and fever; (b) ability to tolerate oral intake; (c) normalization of serum amylase, lipase, and white blood cell count; and (d) resolution of abscess, pseudocyst, or fluid collection as measured by CT scan. **KEY CONCEPT** Therapy of AP is primarily supportive unless a specific etiology is identified (Figure 24–2). Supportive therapy involves fluid repletion, nutrition support, and analgesia.

Nonpharmacologic Therapy

Nonpharmacologic therapy consists of ERCP for removal of any biliary tract stones, other procedural interventions, and nutritional support.[7] Surgical or interventional procedures may be necessary if pancreatic necrosis or abscesses are present.

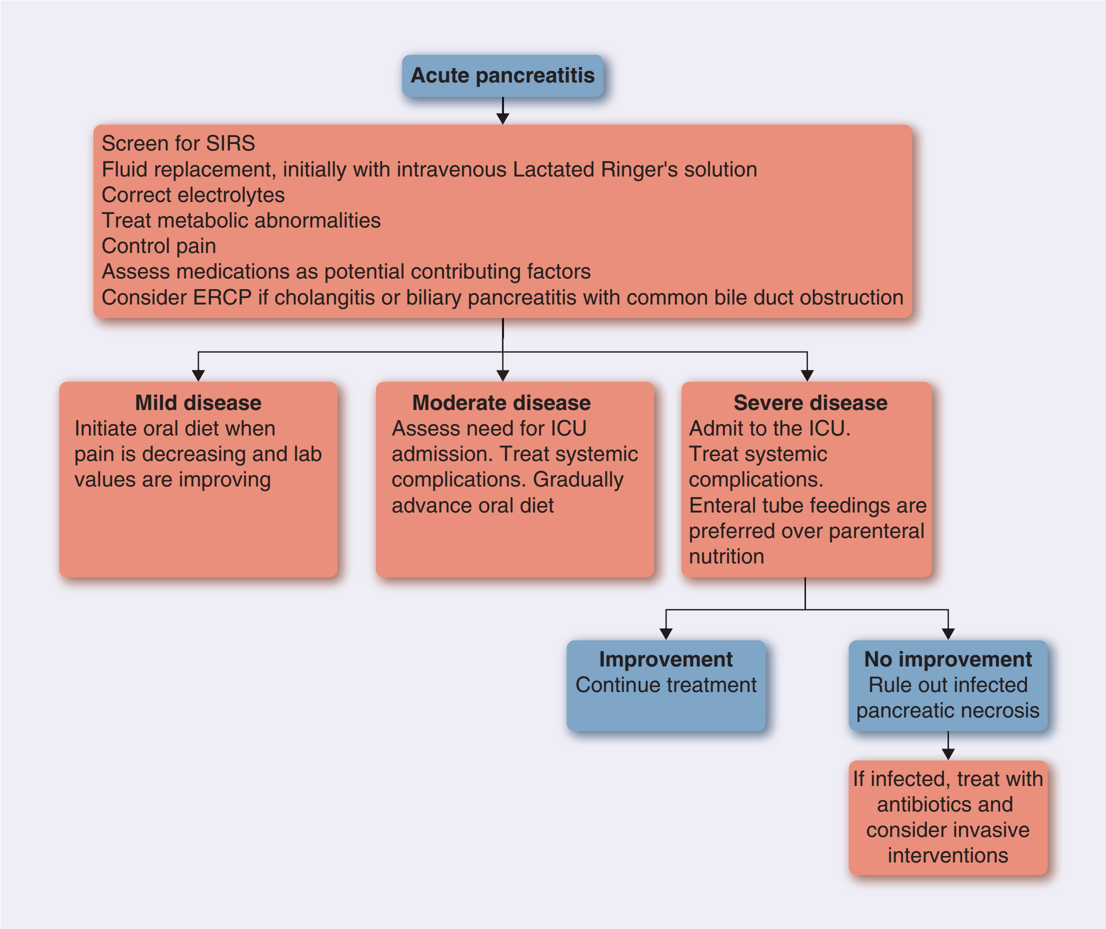
While it is common to discontinue oral feedings during AP, this does not prevent further damage because secretion of trypsin is already reduced.[15] In mild-to-moderate AP, a low-fat diet should be advanced based on resolution of nausea, vomiting, and pain. In severe AP enteral nutrition should be started as early as possible (ideally within 24 hours)[4] and may include nasogastric or nasojejunal feedings. Early use of enteral nutrition decreases surgical interventions and infectious complications.[18] Enteral feeding should ideally be delivered with an elemental or semielemental formula. Enteral nutrition has many advantages over total parenteral nutrition (TPN), including the ability to maintain gut integrity and therefore reduce bacterial gut translocation, decrease rate of ileus, fewer complications, and lower cost.[3] Additionally, randomized controlled trials have shown that TPN increases the risk of infected pancreatic necrosis, multiorgan failure, and need for surgical intervention.[4,19] For these reasons, enteral feeding is preferred. However, TPN may be necessary if enteral nutrition is not possible because of patient intolerance, failure to meet caloric goals, or other reasons.[7,15,20]

Pharmacologic Therapy

Pharmacologic therapy consists of fluid resuscitation, analgesics, and antibiotics.

▶ *Fluid resuscitation*

Early fluid therapy is one of the most important interventions but should be prescribed judiciously, especially when patients have concomitant cardiac, renal, or liver disease. Intravenous (IV) fluids are administered to maintain hydration and blood pressure. Crystalloids such as Lactated Ringer's solution or 0.9% sodium chloride (normal saline [NS]) are recommended. Lactated Ringer's solution may be preferred because it decreases systemic inflammation more than NS.[21] Additionally, NS may exacerbate acidosis, cause hyperchloremia, and potentially lead to renal failure when used as the resuscitative fluid in other disorders.[22,23] Aggressive fluid resuscitation at rates of 250 to 500 mL/hour has historically been recommended. However, there is limited evidence supporting this recommendation, and long-term aggressive fluid



Acute pancreatitis
Screen for SIRS
Fluid replacement, initially with intravenous Lactated Ringer's solution
Correct electrolytes
Treat metabolic abnormalities
Control pain
Assess medications as potential contributing factors
Consider ERCP if cholangitis or biliary pancreatitis with common bile duct obstruction
Mild disease
Initiate oral diet when pain is decreasing and lab values are improving
Moderate disease
Assess need for ICU admission. Treat systemic complications. Gradually advance oral diet
Severe disease
Admit to the ICU. Treat systemic complications. Enteral tube feedings are preferred over parenteral nutrition
Improvement
Continue treatment
No improvement
Rule out infected pancreatic necrosis
If infected, treat with antibiotics and consider invasive interventions

FIGURE 24–2. Algorithm for evaluation and treatment of acute pancreatitis. (ERCP, endoscopic retrograde cholangiopancreatography; ICU, intensive care unit; SIRS, systemic inflammatory response syndrome.) (From Bolesta S, Montgomery PA. Pancreatitis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020; Figure 56–3, with permission. www.accesspharmacy.com.)

Patient Encounter 1, Part 1

A 48-year-old man presents to the emergency department with a 3-day history of nausea, vomiting, and persistent abdominal pain. He states that nothing makes the abdominal pain better, and it is exacerbated by eating. He has not eaten in the last 2 days. Upon examination, his abdomen is found to be distended.

What information about the patient presentation is consistent with acute pancreatitis?

What tests may be helpful in diagnosing acute pancreatitis?

therapy can be associated with harms in AP.[24–27] Alternatively, some guidelines recommend a goal-directed approach titrating IV fluids to specific clinical and biochemical perfusion targets, including heart rate, blood pressure, urine output, blood urea nitrogen, and hematocrit.[4] One approach for hemodynamically unstable patients is to give an initial bolus of 1 to 2 L followed by a continuous rate of 250 mL/hour and then reassess and titrate fluid requirements carefully and frequently based on clinical targets described previously. Electrolytes such as potassium and magnesium may be added to the infusions if necessary. Hyperglycemia can be managed with insulin-containing IV infusions.[16]

▸ *Analgesics*

No single opioid analgesic is superior to other opioids in treating pain associated with pancreatitis.[28] Opioids should be titrated to the lowest effective dose since they may promote ileus and subsequent failure of enteral nutrition. Consideration should also be given to nonopioid analgesic therapy based on current perioperative pain management strategies.[18] (See Chapter 35, Pain Management.)

▸ *Antibiotics*

Antibiotics do not prevent the formation of pancreatic abscess or necrosis when given early in the course of AP[6,16] and are not recommended prophylactically.[4] Empiric antibiotics are not indicated if the patient has a mild disease or a known noninfectious cause. In necrotizing pancreatitis, antibiotics may be appropriate for patients who deteriorate or fail to improve after 7 to 10 days.[16] A CT-guided fine needle aspiration for Gram stain and culture can confirm infected AP and guide antibiotic therapy, but it is no longer routinely used in many centers.[20] Stable patients with infected necrosis should be treated with antibiotics; surgical, radiologic, and/or endoscopic drainage would ideally be delayed by 4 weeks to allow for the area of necrosis to become walled-off.[15,16,18] Consideration should be given to discontinuing antibiotics if no source of infection is confirmed.

Infections are usually polymicrobial, so broad-spectrum antibiotics with activity against enteric Gram-negative bacilli (*E. coli, Proteus, Klebsiella*) and Gram-positive organisms (*Staphylococcus aureus, Streptococcus species, Enterococcus*) in addition to anaerobic bacteria are appropriate (Table 24–2).[20] Fluoroquinolones (eg, ciprofloxacin, levofloxacin) are not recommended due to high rates of resistance by common enteric pathogens.[20] Patients may receive long courses of broad-spectrum antibiotics and may develop superinfections with resistant bacteria. Routine use of antifungal agents (eg, fluconazole) is not recommended but may be considered if peritonitis or GI perforation develops due to the presence of fungi such as *Candida albicans* in the GI tract.[2,16]

Patient Encounter 1, Part 2

PMH: Hypertension, obesity

Allergies: None

FH: Father—gallstones, hypertension, obesity; mother—noncontributory

SH: History of heavy drinking; tobacco 1 ppd; no recreational drugs

Meds: Ibuprofen, hydrochlorothiazide

Table 24–2

Selected IV Antimicrobial Regimens for Pancreatic Necrosis

Drug	Usual Dose[a]	Notes
Meropenem	1–2 g every 8 hours	Risk of superinfection
Piperacillin/tazobactam	3.375–4.5 g every 6–8 hours	Avoid if allergic to penicillin
Cefepime + metronidazole	2 g every 8–12 hours + 500 mg every 8 hours	Will not cover enterococci
Aztreonam + vancomycin + metronidazole	1–2 g every 8 hours + 15 mg/kg every 8–12 hours + 500 mg every 8 hours	Option for penicillin-allergic patients

[a]Doses must be adjusted for the degree of renal impairment.

Patient Care Process for Acute Pancreatitis

Collect Information:

- Assess fluid and nutritional status and abdominal pain severity using a pain scale.
- Review laboratory data: lipase and/or amylase; triglycerides.
- Review imaging results to determine potential causes (eg, obstruction) and extent of pancreatic damage.

Assess the Information:

- Review laboratory data, imaging, and medication history for potential risk factors for pancreatitis (Table 24–1).

Develop a Care Plan:

- Determine the level of monitoring required based on the patient's location (eg, ICU, medical floor).
- Determine how to assess ongoing pain.

Implement the Care Plan:

- Provide fluid resuscitation until the patient shows signs of adequate perfusion (monitor blood pressure and urine output).
- Provide analgesia using multimodal therapy.
- Initiate enteral nutrition early; consider parenteral nutrition if enteral nutrition is not tolerated within 1 week.

Follow-up: Monitor and Evaluate:

- Assess vital signs and pain frequently.
- Provide ongoing monitoring for potential infection.

▶ *Ineffective Therapies*

KEY CONCEPT Therapies with no proven benefit on morbidity and mortality include reducing pancreatic secretion by administering somatostatin analogues or atropine, reducing gastric acidity and pancreatic secretion with histamine$_2$-receptor antagonists, probiotics, and immunomodulation.[29]

OUTCOME EVALUATION

- Monitor hydration and nutrition status closely; replace electrolytes as necessary.
- Provide analgesia and monitor pain severity using validated scales.
- Monitor patients with moderate-to-severe AP in an intensive care setting with frequent monitoring of vital signs.
- Continually assess patients for signs of infection, including fever, leukocytosis, and other signs of sepsis.

CHRONIC PANCREATITIS

EPIDEMIOLOGY AND ETIOLOGY

The incidence of chronic pancreatitis (CP) ranges from 5 to 12 per 100,000 persons and is higher in men than in women.[30] KEY CONCEPT The most common cause of CP in adults in Western countries is ethanol abuse. Other causes include genetic predisposition, obstructive disease (secondary to ductal strictures or pseudocysts), autoimmune pancreatitis, abnormal cystic fibrosis (CF) transmembrane conductance regulator (CFTR) function as seen in CF patients, tropical pancreatitis, and idiopathic pancreatitis.[9,31] Cigarette smoking is an independent risk factor for CP.[32] Smoking, older age at diagnosis, and alcohol intake are major predictors of mortality.[8]

PATHOPHYSIOLOGY

CP is an inflammatory process that occurs over time, leading to impaired endocrine (islet cells) and exocrine (acinar cells) function secondary to diffuse scarring and fibrosis. Unlike AP, the pathologic changes of CP are irreversible.[3,8] The pathogenesis of CP is not completely understood and varies depending on etiology. One theory is that the formation of protein-rich plugs causes ductal obstruction and inflammation, ultimately causing parenchymal fibrosis and ischemic injury to the acinar cells.[33] CP is characterized by scarring and shrinkage of the pancreas from acinus fibrosis and atrophy.[8]

KEY CONCEPT Long-term sequelae of CP include dietary malabsorption, osteoporosis, impaired glucose tolerance, cholangitis, and potential addiction to opioid analgesics. As pancreatic exocrine function diminishes, patients have decreased ability to absorb lipids and protein with normal dietary intake, leading to weight loss and malnutrition. Fat- or protein-containing stools are common; carbohydrate absorption is usually unaffected.[31] Patients with CP are at risk and should be screened for deficiencies of vitamin B_{12} and fat-soluble vitamins (A, D, E, and K).[34,35]

CLINICAL PRESENTATION AND DIAGNOSIS

The symptoms, signs, and laboratory abnormalities associated with CP are similar to AP (see Clinical Presentation box). In the early stages, CP presents as recurrent episodes of AP. Later stages present with pain, sclerosis, calcification, glucose intolerance, and steatorrhea.[36] Chronic pancreatitis is a clinical diagnosis because there is no "gold standard" diagnostic test.[37] Guidelines recommend starting with a CT scan or ultrasound.[38] CP can be difficult to diagnose in the early phases because the pancreas may appear relatively normal with preserved function.[37] Diagnosis of early chronic pancreatitis has relied on a combination of endoscopic

Patient Encounter 1, Part 3

The patient was discharged and presents again to the hospital 2 weeks later with similar pain and feeding intolerance. On this admission, his WBC count is more elevated at $21.2 \times 10^3/\text{mm}^3$ ($21.2 \times 10^9/\text{L}$), and he has a temperature of 38.7°C (101.6°F). After 2 liters of Lactated Ringer's solution in the ED, he is still hypotensive with a MAP of 59 mm Hg, and his HR is 130 beats/min. His RR is 28 breaths/min and SCr is 2.0 mg/dL (177 μmol/L). A CT scan demonstrates pancreatic necrosis. His APACHE II score is calculated to be 13. Blood cultures that were drawn in the ED just returned with Gram-negative rods and Gram-positive cocci in pairs and chains.

Should this patient be admitted to the ICU or general floor unit?

Does this patient meet criteria for antibiotics? If so, what agents should be considered?

Besides antibiotics, what other pharmacologic treatments may need to be optimized?

Clinical Presentation of Chronic Pancreatitis

General

- Presentation of CP can be similar to that of AP.

Symptoms

- Abdominal pain is the most common symptom, and it typically starts in the epigastrium and may radiate to the back or scapula. Pain can be sharp or dull, is not relieved by antacids, and can be provoked by ethanol ingestion or a fatty meal. Pain can be episodic with pain-free intervals, or prolonged and requiring hospitalization.
- Pain may be associated with nausea and vomiting, causing patients to avoid food.
- Weight loss can result from chronic fat and protein malabsorption.

Signs

- **Steatorrhea** (due to fat malabsorption), malnutrition, and glucose intolerance are often present in advanced CP.
- Chronic obstruction of the common bile duct by the inflamed pancreas can cause icterus (jaundice), cholangitis, and biliary cirrhosis.

Laboratory Tests

- Serum amylase and lipase concentrations may be normal to slightly elevated in CP and are not particularly useful in the diagnosis.
- Glucose intolerance may occur because of chronic destruction of pancreatic endocrine function.
- The serum bilirubin or alkaline phosphatase may be elevated due to inflammation near the common bile duct.
- Anemia due to malabsorption of vitamin B_{12} or iron may be present.
- Patients can also have hypocalcemia, hypophosphatemia, osteomalacia, osteopenia, and osteoporosis from vitamin D deficiency and the binding of dietary calcium to unabsorbed fatty acids in the gut.
- Erythrocyte sedimentation rate (ESR), IgG4, rheumatoid factor, antinuclear antibody (ANA), and antismooth muscle antibody titer may be elevated in autoimmune pancreatitis.

ultrasound (EUS), MRCP, and/or pancreatic function testing (PFT).[39]

Several genetic mutations have been associated with CP (*PRSS1*, *SPINK1*, and *CFTR* genes) and may be useful in the diagnostic workup of CP.[6] In clinical practice, steatorrhea and associated weight loss are the most common and noticeable signs of exocrine pancreatic insufficiency.[8] Malabsorption and steatorrhea can be diagnosed using quantitative estimations of stool fat, including a 72-hour stool collection or the less cumbersome fecal elastase test.[40]

TREATMENT

Desired Outcomes

Treatment of CP is mainly symptomatic.[8] Goals of pharmacotherapy for CP include (a) relief of acute and chronic abdominal pain, (b) correction of dietary malabsorption with exogenous pancreatic enzymes, and (c) treatment of endocrine insufficiency and associated diabetes.

▶ *Nonpharmacologic Therapy*

KEY CONCEPT Avoidance of ethanol, cigarette smoking, and fatty meals can decrease the pain associated with CP. Alcohol and cigarette abstainers may have slower disease progression and better response to pain therapy than nonabstainers.[9,31,32] Avoiding further exposure to these toxins can also reduce the risk of secondary pancreatic cancer and other nonpancreatic complications.[37] Patients should consume a diet consisting of frequent small low-fat meals (< 20 g fat/day) or one with medium-chain triglycerides where absorption requires only minimal amounts of pancreatic enzymes.[9,41] Surgical procedures for CP include drainage procedures, partial pancreatic resection, and total pancreatectomy. Indications for surgery include poorly controlled pain, ductal obstruction, and symptomatic pseudocysts.[33] Most surgical procedures to reduce inflammation or remove strictures have not been studied in clinical trials and carry a high risk of morbidity and mortality.[9,31]

Pharmacologic Therapy

▶ *Analgesics*

KEY CONCEPT Pain management is an important component of therapy and similar to that of AP. Nonopioid analgesics (eg, acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs]) are preferred, but the severe and persistent nature of the pain often requires opioid therapy. Patients can require chronic doses of opioid analgesics, with resulting risk of addiction.[9,42] Patients should also be assessed for neuropathic pain and treated accordingly. Pregabalin (75 mg twice daily gradually titrated to 300 mg twice daily) has been shown to reduce pain in CP in a randomized, placebo-controlled trial.[43] Tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), and serotonin and norepinephrine reuptake inhibitors (SNRIs) may help patients with neuropathic pain and comorbid depression, but they have not been specifically studied for CP.[39,44] Refer to Chapter 35 (Pain Management) for guidance in selecting an analgesic dose.

▶ *Pancreatic Enzymes*

Pancreatic enzyme replacement therapy (PERT) is indicated in patients with maldigestion-related symptoms such as diarrhea, steatorrhea, weight loss, flatulence, abdominal distension, and nutritional deficiencies.[36] The goal is to deliver exogenous enzyme to the duodenum without causing further GI side effects, risking nonadherence due to the large number of dosage units required, or causing undue medication expense. **KEY CONCEPT** Supplementation with pancreatic enzymes may reduce pain and control fatty diarrhea associated with CP, restoring the absorption of fat to an acceptable level to cause weight gain.[3] Pancreatic enzymes contain lipase, protease, and amylase in varying proportions. The half-life of endogenous lipase is based on the presence of its substrates (ie, triglycerides), and therefore dietary fat restriction should be reconsidered when pancreatic enzyme replacement is used.[40,41]

PERT products approved by the US Food and Drug Administration are shown in Table 24–3.[45] These products are not interchangeable. Enteric-coated products are designed to release enzymes in the alkaline environment (pH > 5.5) of the duodenum, thus minimizing enzyme destruction in the stomach. However, in patients with delayed gastric emptying, the efficacy of the

[a] All products are porcine derived.

[b] Bicarbonate-buffered enteric-coated microspheres.

[c] Nonenteric-coated immediate-release tablets; must be administered with a proton pump inhibitor.

enteric-coated PERT may be decreased due to the early activation of the lipase enzymes. Addition of an H_2-blocker or proton pump inhibitor will decrease stomach acidity, thereby enhancing delivery of the PERT to the site of action. The only nonenteric-coated PERT available is Viokace, which is deactivated immediately in an acidic environment and therefore must be administered with a proton pump inhibitor.[40,41]

PERT should be taken immediately prior to or portioned throughout meals and snacks to aid in the absorption and digestion of food. **KEY CONCEPT** Dosing is initiated on body weight and adjusted based on clinical symptoms and stool fat content. The usual starting dose is 500 units/kg/meal of lipase with half of the mealtime dose administered with snacks. If a patient does not have an evenly calculated dose, it should be rounded to the closest dose provided by the PERT product allowing the fewest number of pills per day. Because doses often need to be rounded, one approach is to round down initially and gradually titrate the dose up based on the patient response. Several days should be allowed between dose adjustments. Doses of lipase more than 10,000 U/kg/day should be used with caution because they may be associated with colonic stricture and fibrosis.[40,41]

▶ *Glucose Control*

Patients with CP can develop glucose intolerance, but it usually does not progress to overt diabetes mellitus until late in the disease. Pancreatogenic diabetes is referred to as type 3c diabetes mellitus (T3cDM).[39] Fasting blood glucose should be monitored annually, and ensuing diabetes should be treated with insulin. Patients with CP are at increased risk of hypoglycemia due to dysfunction of the pancreatic alpha cells that are responsible for glucagon secretion.[9,31,46]

Patient Encounter 2

A 59-year-old man presents to the ED complaining of a chronic dull pain with a burning/tingling sensation in his abdomen for several months that is no longer relieved with over-the-counter analgesics. He also has had light-colored liquid stools for the last month. Most of his meals consist of fast food, but he has noticed weight loss in the last few months because of decreased appetite due to nausea and vomiting, and worsening abdominal pain with meals.

PMH: Unknown, previous records show three prior ED admissions for recurrent acute pancreatitis, but the patient typically leaves the hospital prematurely against medical advice.

SH: Consumes a six-pack of beer per day and has a 45-pack-year history of cigarette smoking

Meds: Pantoprazole as needed for GERD symptoms

ROS: (+) for RUQ abdominal pain that radiates to his back, decreased appetite, 20-lb (9 kg) weight loss, and diarrhea for the last two months. (–) for chest pain or shortness of breath

PE:

VS: BP 160/90 mm Hg, HR 80 beats/min, RR 15 breaths/min, T 37.1°C (98.8°F), Wt 100 kg (220 lb), Ht 5′10″ (178 cm)

Pain assessment: Ranges from 6 to 8 out of 10 (numerical rating scale); currently 9/10 pain. Describes as dull aching pain and tingling, needle-like pain

CV: Regular rate and rhythm, no murmurs

Abd: Distended, (+) rebound tenderness, (+) bowel sounds

Labs:

Amylase 50 IU/L (0.83 μkat/L)	BUN 19 mg/dL (6.8 mmol/L)
Lipase 70 IU/L (1.17 μkat/L)	SCr 0.9 mg/dL (80 μmol/L)
AST 42 IU/L (0.7 μkat/L)	Glucose 260 mg/dL (14.4 mmol/L)
ALT 29 IU/L (0.48 μkat/L)	Triglycerides 180 mg/dL (2.03 mmol/L)

CT scan abdomen: Diffuse pancreatic scarring and calcifications

What signs and symptoms are consistent with chronic pancreatitis?

How can you determine if this is acute or chronic pancreatitis?

What lifestyle modifications would you recommend for this patient?

What treatment regimens would you initiate, and how would you monitor their effects?

▶ *Other Therapies*

In patients with autoimmune pancreatitis, prednisolone 30 to 40 mg/day tapered over a 3-month period may provide rapid relief of symptoms.[47] Antioxidants such as methionine, ascorbic acid, and selenium may reduce the number of painful days per month in patients with CP, but studies have showed conflicting results.[9,48–50]

Patient Care Process for Chronic Pancreatitis

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements.
- Review the medical history and physical assessment findings to identify signs/symptoms of abdominal pain, steatorrhea, decreased appetite secondary to abdominal pain, and/or signs of glucose intolerance.
- Speak with the patient and review lifestyle and dietary habits, specifically any significant alcohol or smoking history.
- Ask the patient to rate the pain, if any, and relate factors that exacerbate and relieve the pain.

Assess Information:

- Determine whether the patient is receiving any medication(s) that may cause or exacerbate pancreatitis.
- Using validated pain scales, determine whether the pain is currently controlled.
- Review relevant laboratory tests (eg, amylase, lipase, basic metabolic panel, liver panel, complete blood count, lipid panel, fasting glucose, fat-soluble vitamin levels) and imaging (eg, ultrasound, CT, MRI, MRCP).
- If the patient is already receiving pharmacotherapy, assess efficacy, safety, and patient adherence.
- Identify any significant adverse drug effects or interactions.

Develop a Care Plan:

- If the patient has signs of malnutrition or nutritional deficiencies, determine if PERT or supplemental vitamins are indicated.
- If the patient has elevated fasting blood glucose or A1C, consider starting insulin therapy (see Chapter 44, Diabetes Mellitus).
- Develop an analgesic plan to control and prevent pain (see Chapter 35, Pain Management).

Implement the Care Plan:

- Provide resources for alcohol and smoking abstinence, if applicable.
- Address any patient concerns about pancreatitis and its management.
- Initiate PERT in patients with steatorrhea.
- Discuss importance of diet, medication adherence, and lifestyle modifications to reduce complications of AP and/or CP.

Follow-up: Monitor and Evaluate:

- Adjust PERT dosage based on nutritional status and pain with meals on a monthly basis until adequate control is achieved. Once stable doses of PERT and analgesia are established, monitor the patient once or twice yearly.
- Evaluate the patient's vitamin A, D, E, K, and B_{12} levels, fasting blood glucose, and A1C at least annually.
- Reassess analgesia and adjust medication and dosages as indicated.

OUTCOME EVALUATION

- Encourage lifestyle modifications such as abstinence from ethanol and cigarettes.
- Monitor pain control and adjust analgesics accordingly.
- Counsel patients to monitor for weight gain or loss and fatty stool output as markers of malabsorption.
- Educate patients that adherence to PERT is the key to improved outcomes.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Drs. Janine E. Then and Heather M. Teufel, coauthors of this chapter for the third, fourth, and fifth editions of this book.

Abbreviations Introduced in This Chapter

Viral Hepatitis

Juliana Chan

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Differentiate the five types of viral hepatitis by epidemiology, etiology, pathophysiology, clinical presentation, and natural history.
2. Identify modes of transmission and risk factors among the major types of viral hepatitis.
3. Evaluate hepatic serologies to understand how the type of hepatitis is diagnosed.
4. Create treatment goals for a patient infected with viral hepatitis.
5. Recommend appropriate pharmacotherapy for prevention of viral hepatitis.
6. Develop a care plan for treatment of chronic viral hepatitis.
7. Formulate a monitoring plan to assess adverse effects of pharmacotherapy for viral hepatitis.

INTRODUCTION

The most common types of viral hepatitis include hepatitis. Acute hepatitis may be associated with all five types of hepatitis and rarely exceeds 6 months in duration. Chronic hepatitis (disease lasting more than 6 months) is usually associated with hepatitis B, C, and D. **KEY CONCEPT** Chronic viral hepatitis may lead to the development of cirrhosis and may result in end-stage liver disease (ESLD) and hepatocellular carcinoma (HCC). Complications of ESLD include ascites, edema, hepatic encephalopathy, infections (eg, spontaneous bacterial peritonitis), hepatorenal syndrome, and esophageal varices. *Therefore, prevention and treatment of viral hepatitis may prevent ESLD and HCC.*

Viral hepatitis may occur at any age and is one of the most common causes of liver disease in the world. The true prevalence and incidence may be underreported because most patients are asymptomatic. The epidemiology, etiology, and pathogenesis vary depending on the type of hepatitis and are considered separately below.

EPIDEMIOLOGY AND ETIOLOGY

Hepatitis A (HAV)

HAV affects 1.4 million people yearly worldwide.[1] The prevalence is highest in economically challenged and underdeveloped countries, including Central and South America, Africa, the Middle East, Asia, and the Western Pacific.[2] The numbers of acute HAV infections and hospitalizations have decreased since the introduction of the HAV vaccine in 1995.[2] However, there has been a recent resurgence of hepatitis A infections in the United States since 2017 affecting primarily the homeless and people who inject drugs (PWID). As of August 2020, more than 33,000 cases have been reported, up from 12,474 in 2018.[3,4]

HAV is primarily detected in contaminated feces and infects people via the fecal–oral route.[1,2] Outbreaks typically occur in areas of poor sanitation or consumption of food or water infected with the HAV.[1,3] About 40% of the cases reported have no identifiable risk factors; individuals at greatest risk of acquiring HAV are listed in Table 25–1.[4]

There are no documented cases of chronic hepatitis A infections.[2,4] Approximately 100 annual fatalities in the United States are associated with fulminant hepatitis, which occurs in less than 1% of cases.[4]

Hepatitis B (HBV)

Approximately 2 billion people worldwide have evidence of past or present HBV infection, and more than 250 million people have chronic hepatitis B (CHB).[5,6] Globally, approximately 887,000 deaths were associated with HBV in 2015.[6] Despite having an effective vaccine against HBV since 1982, it is estimated that there were 21,600 acute HBV infections in 2018 in the United States.[7] Fewer than 1% of individuals in North America and Western Europe are chronically infected, compared with greater than 5% in developing areas in parts of Africa, South America, East Asia, and Pacific Islands.[5]

The primary modes of transmission of HBV are by blood and body fluids through perinatal, sexual, or percutaneous exposure (Table 25–1).[5,8] Infants born to mothers who are infected with actively replicating HBV have a 90% risk of becoming infected.[8]

Hepatitis C (HCV)

It is estimated that 71 million people worldwide and 2.4 million Americans have chronic HCV. However, the true prevalence in the United States may be as high as 4.1 million because certain populations (eg, incarcerated, homeless, immigrants, active military personal, and nursing home residents) have not been fully evaluated.[9,10] The prevalence is highest in PWID, who account for more than 70% of newly diagnosed acute HCV infections.[11] High-risk factors for acquiring HCV are listed in Table 25–1.

HCV is categorized by genotypes, which are geographically specific. There are seven genotypes (numbered 1–7) and 67 subtypes (eg, genotypes 1a, 1b, 2a, and 3b).[12] Genotypes 1a, 1b, 2,

Table 25–1

Risk Factors for Acquiring Viral Hepatitis

Hepatitis A

High Risk

International travelers to endemic areas (eg, Africa, Asia, and parts of South America)
Men having sex with other men
Persons who use illegal drugs (injection or noninjection)
Workers involved with nonhuman primates
Persons with close contacts of international adoptees
Persons experiencing homelessness
Persons living in group settings with developmental disabilities
Persons incarcerated in jail or prison
Persons infected with HIV

Low Risk

Patients with clotting factor disorders
Persons who work in food service establishments
Food sources contaminated with HAV (eg, raw foods including seafood, shellfish, green onion, and fruit)
Child care centers and schools
Health care providers with direct or indirect patient contact
Workers exposed to sewage
Public water systems (eg, swimming pools, public drinking water)

Hepatitis B and D

Infants born to infected mothers
International travelers to endemic areas
Men having sex with other men
Individuals with multiple heterosexual partners
Persons who use illegal drugs (injection or noninjection)
Recipients of contaminated blood, blood products, or organ transplantation
Household contacts with acute hepatitis B (eg, sharing razor or toothbrush)
Health care providers and public safety workers in contact with infected blood
Residents and staff of facilities for developmentally disabled persons
Patients undergoing dialysis
Persons with HCV and/or HIV
Persons with diabetes

Hepatitis C

High Risk

Current or former injection drug users

Low Risk

Recipients of blood products (clotting factor concentrates made before 1987, blood transfusions or solid organ transplants before July 1992)
Health care providers in contact with infected blood
Chronic hemodialysis (eg, contaminated blood or dialysis equipment)
Individuals having multiple sexual partners, especially men having sex with other men
HIV infection
Unregulated body piercing and tattooing
Household contacts with hepatitis C (eg, sharing razor or toothbrush)

and 3 are the most common in the United States.[12] Genotype does not indicate disease severity but had been used during the non-pangenotypic HCV therapy era to determine duration of therapy and the likelihood of a therapeutic response.[13]

Hepatitis D (HDV)

Hepatitis D is estimated to affect 20 million people worldwide; however, new prevalence data suggest that the rate may be underreported by two- to three-fold.[14] Areas with the highest prevalence include the Middle East, parts of Africa, Northern and Southeast Asia, Eastern Europe, the Mediterranean basin, and parts of South America.[14]

HDV infection is unique because it can only occur in people who are also infected with the HBV.[14] The most likely modes of transmitting HDV are similar to those of HBV (Table 25–1), with PWID being the most common risk factor.[14]

Hepatitis E (HEV)

An estimated 20 million individuals worldwide are infected annually with HEV, and the disease was associated with about 44,000 deaths in 2015.[15] The highest prevalence is found in East and South Asia.[15] HEV infection primarily occurs in underdeveloped countries with poor sanitation. The HEV is transmitted mainly by the fecal–oral route (eg, contaminated drinking water).[15]

PATHOPHYSIOLOGY

Hepatitis A

Hepatitis A is a nonenveloped single-stranded RNA virus classified as the *Hepatovirus* genus under the Picornaviridae family.[2] The primary host for the HAV is humans, with hepatic cells as the main site for viral replication. As part of the viral degradation process, the HAV is released into the biliary system causing elevated HAV concentrations in the feces. Hepatitis A infections are usually self-limiting and do not lead to chronic disease; rarely, it may result in fulminant hepatitis.[2,3]

Hepatitis B

The HBV belongs to the Hepadnaviridae family.[8] It is a partially double-stranded DNA virus with a phospholipid layer containing hepatitis B surface antigen (HBsAg) that surrounds the nucleocapsid. The nucleocapsid contains the core protein that produces hepatitis B core antigen (HBcAg), which is undetectable in the serum. Hepatocellular injury from HBV is thought to be due to a cytotoxic immune reaction that occurs when HBcAg is expressed on the surface of hepatic cells. Fortunately, antibodies against hepatitis B core antigen (anti-HBc) are measurable in the blood, where anti-HBc to immunoglobulin M (IgM) indicates active infection, and anti-HBc to IgG indicates either chronic infection or possible immunity against HBV.

Viral replication usually occurs when the hepatitis B envelope antigen (HBeAg) is present and circulating in the blood. Serum HBV DNA concentration measures viral infectivity and quantifies viral replication. Once the HBV infection resolves, antibodies against the hepatitis B envelope (anti-HBe) and antibodies against hepatitis B surface antigen (anti-HBs) develop, and HBV DNA levels become undetectable. However, if antibodies do not develop, the likelihood of developing CHB increases. This depends primarily on the host's immune system at the time of infection. In immunocompetent individuals, the disease resolves spontaneously and does not lead to further complications. In immunocompromised persons, the HBV is less likely to be eradicated, thus causing persistent infection leading to hepatic cell damage and inflammation.[5,8]

Approximately 90% of adults infected with the HBV develop anti-HBs, which results in lifelong immunity. Unfortunately, about 90% of infants born to mothers with active HBV infection will develop CHB.[5] About 50% of adults with acute HBV infections are asymptomatic, and those with symptoms may experience jaundice or fatigue.[8]

Patient Encounter Part 1

A 38-year-old woman who went to visit a friend in Los Angeles for a week and returned now presents to the primary care physician's office 2 days later for her yearly checkup. She states that her friend had acute hepatitis A and was not hospitalized. The patient states that she is feeling well with no complaints except for fatigue.

PMH: Diet-controlled hypertension, diet-controlled diabetes, HCV

PSH: Skin mole removed at age 25

FH: Father with HTN; mother with NASH and diabetes; married with a 22-year-old daughter

SH: Smoked tobacco 0.5 PPD in her 20s. Does not smoke now. One-time use of IV cocaine at age 18. Drinks red wine daily with meals for the last 3 years. Accountant at a law firm.

Meds: Multivitamin daily, calcium and vitamin D, docusate sodium, and influenza and pneumococcal vaccine given last year.

ROS: Constipation present. No blood in the stools. No nausea, vomiting, diarrhea, abdominal pain, or anorexia; never experienced an episode of jaundice, pale stools, or tea-colored urine.

PE:

VS: BP 130/85 mm Hg, P 82 beats/min, RR 20 breaths/min, T 37.0°C (98.6°F), Wt 76 kg (167 lb), Ht 5′10″ (178 cm)

Abd: Soft, nontender, normal liver span; no hepatosplenomegaly, no ascites

The remainder of the examination was within normal limits.

Labs (obtained 4 week ago):

Sodium 141 mEq/L (mmol/L)
Potassium 4.5 mEq/L (mmol/L)
Chloride 99 mEq/L (mmol/L)
CO_2 21 mEq/L (mmol/L)
BUN 20 mg/dL (7.1 mmol/L)
SCr 1.1 mg/dL (97 μmol/L)
ALT 90 IU/L (1.5 μkat/L)
AST 82 IU/L (1.37 μkat/L)
T. bilirubin 1.0 mg/dL (17.1 μmol/L)
Alk phos 164 IU/L (2.73 μkat/L)
Albumin 3.6 g/dL (36 g/L)
Glucose 122 mg/dL (6.8 mmol/L)
A1C 5.9% (0.059; 41 mmol/mol Hgb)
WBC $5.1 \times 10^3/\text{mm}^3$ (5.1×10^9/L)
Hgb 14.2 g/dL (142 g/L; 8.81 mmol/L)
Hct 42.1% (0.421)
Plt $199 \times 10^3/\text{mm}^3$ (199×10^9/L)
TSH 1.3 μIU/mL (mIU/L)
Anti-HAV IgM (–)
Anti-HAV IgG (+)
Anti-HCV (+), genotype 2b
HCV RNA 542,091 IU/mL (kIU/L)

FibroScan: Moderate fibrosis, F2 (7.8 kPa)

Limited abdominal sonogram of liver and spleen: Liver: Normal echogenicity. No intrahepatic biliary dilatation. No discrete hepatic mass. Simple hepatic cysts. Spleen: Normal size and echogenicity. Portal vein: normal color Doppler flow. Gallbladder: No gallstones, biliary sludge, wall thickening, or pericholecystic fluid. Negative sonographic Murphy's sign. Common duct: Measures up to 4 mm in diameter. Common bile duct: Obscured by overlying bowel gas. Other findings: No large ascites.

What information is suggestive of viral hepatitis?

What risk factors does she have for viral hepatitis?

What additional information do you need before creating a treatment plan for this patient?

Hepatitis C

Hepatitis is a blood-borne infection caused by a single-stranded RNA virus belonging to the Flaviviridae family and the *Hepacivirus* genus.[16] Antibodies against HCV (anti-HCV) in the blood indicate infection. Acute hepatitis C persists for less than 6 months, occurs in about 15% of the population, and resolves without further complications.[7] If the infection persists longer than 6 months and viral replication is confirmed by HCV RNA levels, the person has chronic hepatitis C (CHC), which occurs in about 55% to 85% of cases.[5,17] CHC may be due to an ineffective host immune system, with cytotoxic T lymphocytes unable to eradicate the HCV, thereby allowing persistent damage to hepatic cells. The most common risk factors for developing hepatic fibrosis include obesity, diabetes, heavy alcohol use, male sex, and coinfections with HIV or HBV.[13]

From 55% to 85% of CHC progress to mild, moderate, or severe hepatitis. Cirrhosis and its complications may take several decades to develop in 15% to 30% of patients infected with HCV. Once cirrhosis is confirmed, the risk of developing HCC is 2% to 4% per year.[5,17]

Hepatitis D

The HDV belongs to the genus *Delta virus* of the Deltaviridae family. The HDV is a defective single-stranded circular RNA virus that requires the presence of HBV for HDV viral replication, causing either coinfection (both hepatitis B and D infection occurring simultaneously) or superinfection (acquiring HDV after having long-standing HBV disease).[14] This occurs because the HDV antigen (HDVAg) is coated by the HBsAg.[14]

Hepatitis E

Hepatitis E is a nonenveloped single-stranded messenger RNA virus with at least eight different genotypes; several are found in humans and some in animals.[18] The HEV is transmitted via the fecal–oral route with the primary source being contaminated food and water.[15] Unfortunately, animals can acquire the HEV; thus, human consumption of these animals is considered a risk factor. HEV infections are usually self-limiting and rarely result in hepatic complications. Chronic infections occur rarely but may lead to cirrhosis; they are more common in immunocompromised individuals (eg, HIV infection, elderly) and organ transplant recipients.[15,18]

CLINICAL PRESENTATION AND DIAGNOSIS

See box for the clinical presentation of viral hepatitis.

Diagnosis of Viral Hepatitis

Diagnosing viral hepatitis may be difficult because most infected individuals are asymptomatic.[2,5,14,18] Because symptoms alone cannot identify the specific type of hepatitis, laboratory serologies must be obtained (Table 25–2). A liver biopsy may be obtained

Table 25–2

Interpretation of Viral Hepatitis Serology Panels

Type	Laboratory Test	Result	Interpretation of Panel
Hepatitis A	IgM anti-HAV	Negative	Susceptible to infection
	IgG anti-HAV	Negative	
	IgM anti-HAV	Positive	Acutely infected
	IgG anti-HAV	Positive	Immune due to either natural infection or HAV vaccine
Hepatitis B[a]	HBsAg	Negative	Susceptible to infection
	Anti-HBc	Negative	
	Anti-HBs	Negative	
	HBsAg	Negative	Immune due to natural infection
	Anti-HBc	Positive	
	Anti-HBs	Positive	
	HBsAg	Negative	Immune due to hepatitis B vaccination
	Anti-HBc	Negative	
	Anti-HBs	Positive	
	HBsAg	Positive	Acutely infected
	Anti-HBc	Positive	
	IgM anti-HBc	Positive	
	Anti-HBs	Negative	
	HBsAg	Positive	Chronically infected
	Anti-HBc	Positive	
	IgM anti-HBc	Negative	
	Anti-HBs	Negative	
	HBsAg	Negative	Four interpretations possible: (a) Resolved infection (most common); (b) false-positive anti-HBc, thus susceptible; (c) low-level chronic infection; (d) resolving acute infection
	Anti-HBc	Positive	
	Anti-HBs	Negative	
Hepatitis C	Anti-HCV	Negative	Susceptible to infection
	Anti-HCV	Positive	Acutely or chronically infected
Hepatitis D[b]	IgM anti-HDV	Positive	Acute HBV-HDV coinfection
	HDVAg	Positive	
	HBsAg	Positive	
	HBeAg	Positive	
	IgM anti-HBc	Positive	
Hepatitis E	IgM anti-HEV	Negative	Susceptible to infection
	IgG anti-HEV	Negative	
	IgM anti-HEV	Positive	Acutely infected
	IgG anti-HEV	Positive	Immune due to natural infection

[a] Centers for Disease Control and Prevention. Hepatology [Internet]. http://www.cdc.gov/hepatitis/HBV/PDFs/SerologicChartv8.pdf.

[b] Hepatitis D should be suspected in those who have HBsAg positivity. Hepatitis D may present as either coinfection where both HDV and HBV serologies appear simultaneously, whereas for superinfection, HBV has been present for some time and later HDV develops.

anti-HAV, hepatitis A antibody; anti-HBc, hepatitis B core antibody; anti-HBs, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; anti-HCV, hepatitis C antibody; anti-HDV, hepatitis D antibody; anti-HEV, hepatitis E antibody; HAV, hepatitis A virus; HBV, hepatitis B virus; HDV, hepatitis D virus; HDVAg, hepatitis D antigen; IgG, immunoglobulin G; IgM, immunoglobulin M.

Clinical Presentation of Viral Hepatitis

Symptoms

- Most patients infected with any type of viral hepatitis have no symptoms.
- Symptomatic patients may experience a flu-like syndrome, fevers, fatigue/malaise, anorexia, nausea, vomiting, diarrhea, dark urine, pale-appearing stools, pruritus, and abdominal pain.

Signs

- Jaundice may be evident in the whites of the eyes (scleral icterus) or skin.
- An enlarged liver (hepatomegaly) and spleen (splenomegaly) may be present.
- In fulminant hepatitis with hepatic encephalopathy, patients may have **asterixis** and coma.
- In rare instances, extrahepatic symptoms may develop (arthritis, postcervical lymphadenopathy, palmar erythema, cryoglobulinemia, and vasculitis).

Laboratory Tests

- See Table 25–2.

to determine the severity of the liver disease, but this is an invasive test that may be associated with complications such as severe pain, bleeding, and death.[19] Therefore, several patented blood tests (FibroTest, HepaScore) have been developed that use a panel of serum biomarkers (e.g., ALT, AST, and platelet count) along with the age and sex of the patient to determine the degree of hepatic fibrosis. A noninvasive imaging test that uses ultrasound vibration-controlled transient elastography (VCTE) is now recommended to assess the severity of liver disease.[19] These invasive and noninvasive tests are imperfect and are usually only able to identify mild and severe disease. Therefore, it is important to monitor laboratory values over time to assess the severity of liver fibrosis (eg, AST, ALT, serum albumin, platelet counts, and prothrombin time/INR).

▶ *Hepatitis A*

Hepatitis A is diagnosed by detecting immunoglobulin antibodies to the capsid proteins of the HAV. Detectable IgM anti-HAV in the serum indicates acute infection and usually appears about 3 weeks after exposure and becomes undetectable within 6 months. In contrast, IgG anti-HAV appears in the serum at approximately the same time that IgM anti-HAV develops but indicates protection and lifelong immunity against the HAV.[2]

▶ *Hepatitis B*

Hepatitis B is diagnosed when HBsAg is detectable in the serum, but it does not distinguish between acute and chronic HBV. The presence of IgM antibodies to HBcAg indicates active infection. IgG anti-HBc indicates either chronic infection or possible immunity against HBV.[8]

In most cases, detectable HBeAg indicates active viral replication. Measurement of HBV DNA determines viral infectivity and quantifies viral replication. Once HBV viral replication ceases, anti-HBe is detected in the serum. However, a minority of patients may develop anti-HBe and still have elevated HBV DNA levels because of a mutation in the HBV.[20] Therefore, CHB infections may be differentiated as either HBeAg-positive or HBeAg-negative.[20]

▶ *Hepatitis C*

Chronic hepatitis C (CHC) is diagnosed by testing for anti-HCV in the serum and confirmed by the presence of HCV RNA. HCV RNA levels quantify viral replication and are used to determine if treatment is effective. Undetectable HCV RNA levels indicate past infection or that the infection is resolved. The HCV genotype should be determined if a nonpangenotypic regimen will be prescribed.

▶ *Hepatitis D*

Hepatitis D infection requires the presence of HBV for HDV viral replication. Measuring HDV RNA levels confirms hepatitis D infection and is the most accurate diagnostic test. The presence of IgM anti-HD indicates active disease, and IgG anti-HD also becomes detectable if the infection does not resolve spontaneously. HDV antibodies do not confer immunity.[21]

▶ *Hepatitis E*

Diagnosis of acute hepatitis E is based on the presence of IgM anti-HEV. IgG anti-HEV emerges when the HEV infection resolves.[15,18] HEV RNA levels can be obtained from either blood or stool and are usually tested if chronic HEV infection is suspected.[18]

PREVENTION AND TREATMENT OF VIRAL HEPATITIS

Desired Outcomes

Treatment outcomes for viral hepatitis are to: (a) prevent the spread of infection, (b) prevent and treat symptoms, (c) suppress viral replication, (d) normalize hepatic aminotransferases, (e) improve liver histology, and (f) decrease morbidity and mortality by preventing cirrhosis, HCC, and ESLD.

For hepatitis B, additional treatment goals include seroconversion or loss of HBeAg, and ultimately seroconversion or loss of HBsAg.[20] The primary goal of treating chronic HCV is to achieve undetectable HCV RNA for at least 12 weeks after completing hepatitis C therapy, known as achieving a sustained virologic response (SVR).[13]

General Approach

Managing viral hepatitis involves both prevention and treatment. Prevention of hepatitis A and B (and indirectly for hepatitis D) can be achieved with immune globulin (IG) or vaccines. **KEY CONCEPT** Acute viral hepatitis is primarily managed with supportive care. Mild-to-moderate symptoms rarely require hospitalization, but hospital admission is recommended in individuals experiencing significant nausea, vomiting, diarrhea, and encephalopathy. Liver transplantation may be required rarely if fulminant hepatitis develops. Treatment is available for CHB, CHC, and chronic HDV.

Hepatitis A Prevention

KEY CONCEPT Good personal hygiene and proper disposal of sanitary waste are required to prevent HAV fecal–oral transmission.[2,3] This includes frequent handwashing with soap and water after using the bathroom and prior to eating meals. Drinking bottled water and avoiding fruits, vegetables, and raw shellfish harvested from sewage-contaminated water may minimize the risk of becoming infected with the HAV. Individuals at risk of acquiring HAV (Table 25–1) should receive serum IG and/or the hepatitis A vaccine.[2,3]

▶ *Immune Globulin (IG)*

IG (GamaSTAN) is the only FDA-approved agent containing antibodies from sterilized pooled human plasma that provides short-term passive immunization against HAV.[3] IG is available as an intramuscular (IGIM) formulation and should not be administered intravenously because it may cause renal dysfunction or failure, hemolysis, or transfusion-related acute lung injury.[3,22] Recommended doses are given in Table 25–3. Even though the risk of acquiring severe infections (including Creutzfeldt–Jakob disease) is low and no cases have been documented, patients should be informed that the risk exists because IG is obtained from human plasma.[22]

IGIM does not affect the immune response of inactivated or live-virus vaccines; however, administrating live vaccines concomitantly may decrease the immune response significantly.[22]

IGIM administration is indicated for individuals: (a) at high risk of acquiring the HAV infection (Table 25–1, hepatitis A section), (b) who elect not to receive the hepatitis A vaccine, or (c) who cannot receive the hepatitis A vaccine (eg, because of allergic reaction). Preexposure and postexposure prophylaxis dosing is based on patient's age, indication, and health status (Table 25–4). When IGIM and another vaccination (eg, hepatitis A vaccine) are to be given at the same time, it is recommended that the two

Table 25–3

Recommended Intramuscular Doses of Immune Globulin (GamaSTAN) for Hepatitis A

Indication	Duration of Exposure/Travel	Dose (mL/kg)[a,b]	Instruction for Administration[c]
Preexposure	≤ 1 month travel	0.1	Before departure to endemic area(s)
	≤ 2 months travel	0.2	Before departure to endemic area(s)
	> 2 months travel	0.2	Before departure and repeat every 2 months
Postexposure	Exposed < 2 weeks	0.1	Within 2 weeks of exposure

[a] Dose is based on weight for all ages, there is no maximum dose for protection for hepatitis A prophylaxis.

[b] Patients with prolonged immobilization, indwelling central vascular catheter, hypercoagulable disorders, using estrogen products, history of thrombosis or cardiovascular risk factors are at risk of thrombosis with IG. Do not administer doses higher than what is recommended.

[c] Live vaccines (eg, measles, mumps, and rubella) should not be administered for at least 2 weeks before and 6 weeks after administering immune globulin.

From Nelson NP, Weng MK, Hofmeister MG, et al. Prevention of Hepatitis A Virus Infection in the United States: Recommendations of the Advisory Committee on Immunization Practices, 2020. MMWR Recomm Rep. 2020 Jul 3;69(5):1-38. doi: 10.15585/mmwr.rr6905a1. PMID: 32614811.

immunizations be administered at different anatomical sites/limbs.[3]

▶ *Hepatitis A Vaccine*

Persons at risk of acquiring HAV should receive the hepatitis A vaccine to provide pre- and postexposure prophylaxis (Table 25–1). Children aged 12 to 23 months should receive the hepatitis A vaccine. Persons who did not receive the vaccine during the first 2 years of life should receive a catch-up HAV vaccination.[3] Two inactivated hepatitis A vaccines are available in the United States: HAVRIX and VAQTA. The recommended regimen is to administer two injections 6 months apart (at months 0 and 6).[3] These vaccines are considered interchangeable, and doses depend on age (Table 25–5).[3]

Efficacy is defined by measuring anti-HAV levels when they are greater than 10 mIU/mL (IU/L).[3] Within 4 weeks of administering the first vaccine dose, more than 95% of adults and 97% of children and adolescents develop protective antibody concentrations. All recipients receiving the second dose in clinical trials had 100% antibody coverage; therefore, postvaccination measurement of antibody response is not required.[2]

The hepatitis A vaccine may provide immunity for about 20 years in children more than 2 years of age and adults who completed the two-dose hepatitis A vaccination series.[3] The most common and often self-limiting adverse effects in adults include injection-site reactions (eg, tenderness, pain, and warmth), headaches, fatigue, and flu-like symptoms. Infants and children may have feeding disturbances. Local reactions may be minimized by using an age-appropriate needle length and injecting into the deltoid muscle. Data with hepatitis A vaccine given during pregnancy are limited; the risk of adverse events was not increased; however, infants may be smaller for their gestational age.[3]

Hepatitis B Prevention

KEY CONCEPT The risk of acquiring the HBV may be minimized by avoiding contaminated blood products and high-risk behavior (Table 25–1) and by receiving the hepatitis B vaccine.[23]

Screening pregnant women for HBV and providing universal hepatitis B vaccinations to all newborns is effective in preventing hepatitis B infections.[23] In some cases, postexposure prophylaxis with hepatitis B immune globulin (HBIG) may be recommended to prevent the development of acute infection and CHB.

Table 25–4

Preexposure and Postexposure Hepatitis A vaccine and Immune Globulin (GamaSTAN) dosing recommendations

Indication	Age of Patient	Risk Category/Health Status	HAV Vaccine	IGIM[a]
Postexposure[b,c]	< 12 months	Healthy	No	Yes
	12 months to 40 years old	Healthy	Yes	No
	> 40 years old	Healthy	Yes	Yes
	≥ 12 months	Immunocompromised, have chronic liver disease	Yes	Yes
	≥ 12 months	Contraindication to HAV vaccine	No	Yes
Preexposure	< 6 months	Healthy	No	Yes
	6–11 months	Healthy	Yes	No
	12 months to 40 years old	Healthy	Yes	No
	> 40 years old	Healthy	Yes	Yes
	> 6 months	Immunocompromised, have chronic liver disease	Yes	Yes
	> 6 months	Contraindicated to HAV vaccine or don't want vaccine	No	Yes

[a] See Table 25–3.

[b] Twinrix should not be used for postexposure prophylaxis since it contains half of the single -antigen hepatitis A vaccine adult dose.

[c] At least 1 dose of hepatitis A vaccine is recommended for persons exposed in a hepatitis A outbreak; completion of hepatitis A vaccine series is not required to achieve disease control but is recommended for long-term HAV protection.

Adapted from Nelson NP, Weng MK, Hofmeister MG, et al. Prevention of Hepatitis A Virus Infection in the United States: Recommendations of the Advisory Committee on Immunization Practices, 2020. MMWR Recomm Rep. 2020 Jul 3;69(5):1-38. doi: 10.15585/mmwr.rr6905a1. PMID: 32614811.

Table 25–5

Recommended Intramuscular Doses of Hepatitis A Vaccines

Product	Recipient Age (years)	Dose (Units)	Volume (mL)	No. of Doses	Schedule (months)
VAQTA	1–18	25	0.5	2	0, 6–18
	≥ 19	50	1	2	0, 6–18
HAVRIX	1–18	720 ELISA	0.5	2	0, 6–12
	≥ 19	1440 ELISA	1	2	0, 6–12

ELISA, enzyme-linked immunosorbent assay.

Table 25–7

Recommendations for Nonoccupational Postexposure Prophylaxis to the Hepatitis B Virus

	Treatment to Administer If Serology Test of Source Person Is:	
Exposed Person's Vaccination Status	HBsAg-Positive	Unknown HBsAg Status
Unvaccinated	HBIG and initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated	Administer HB vaccine booster dose	No treatment

HB, hepatitis B; HBsAg, hepatitis B surface antigen; HBIG, hepatitis B immune globulin.

▶ *Hepatitis B Immune Globulin (HBIG)*

Nabi-HB and HepaGam B are the only two FDA-approved HBIG products containing antibodies prepared from pooled human plasma that provide short-term passive immunization to prevent CHB infections in persons who had sexual, perinatal, or acute exposure to an HBsAg-positive person[24,25] (Tables 25–6 and 25–7).

The efficacy, side effect profile, and warnings of HBIG are similar to IG when used for immunization against HAV.[3,23–27]

▶ *Hepatitis B Vaccine*

The first hepatitis B vaccines in the United States were Recombivax HB and Engerix-B, which are given at months 0, 1, and 6 and approved to be administered intramuscularly at birth (Table 25–6). Heplisav-B is a newer HBV vaccine indicated for persons aged 18 or older and administered intramuscularly at months 0 and 1. Heplisav-B has a unique adjuvant that stimulates direct immune response to the HBsAg, which has higher seroprotective antibody protection (greater than 90%) compared to Engerix-B of 70% to 90%.[26] Therefore, the advantage of Heplisav-B is an improved dosing regimen and immunogenicity, which may be beneficial in certain populations (eg, diabetics, smokers, and patients older than 40 years).[27] **KEY CONCEPT** Persons at high risk of acquiring the HBV (Table 25–1) should be vaccinated.

The hepatitis B vaccine is also indicated for postexposure prophylaxis to prevent CHB. All individuals exposed to HBV should receive the hepatitis B vaccine with or without HBIG, preferably within 24 hours of exposure based on the source of exposure and the vaccination status of the exposed person. Recommendations are divided into nonoccupational (Table 25–7) and occupational, where the latter refers the reader to the CDC guidelines for the most up-to-date recommendations.[23] Postexposure prophylaxis for perinatal exposure depends on several factors, including maternal HBsAg status and the newborn's weight (Table 25–8).[23]

The hepatitis B vaccine is effective when antibody concentrations are greater than 10 mIU/mL (IU/L). Postvaccination

Table 25–6

Recommended Intramuscular Dosing Regimens for Single-Antigen Hepatitis B Vaccines

Product	Patient Categories	Dose (mcg)	Volume (mL)	No. of Doses	Schedule (months)
Recombivax HB	0–19 years of age	5	0.5	3	0, 1, 6
	11–15 years of age[a]	10	1	2	0, 4–6
	≥ 20 years of age	10	1	3	0, 1, 6
	Hemodialysis[b] < 20 years of age	5	0.5	3	0, 1, 6
	Hemodialysis ≥ 20 years of age	40	1	3	0, 1, 6
Engerix-B	0–19 years of age	10	0.5	3	0, 1, 6
	≥ 20 years of age	20	1	3	0, 1, 6
	Hemodialysis[b] < 20 years of age	10	0.5	3	0, 1, 6
	Hemodialysis ≥ 20 years of age	40[c]	2	4	0, 1, 2, 6
Heplisav-B	≥ 18 years of age	20 mcg HBsAg and 3000 mcg CpG 1018 adjuvant	0.5	2	0, 1

[a] Adolescents 11 through 15 years of age may receive either the 5-mcg three-dose pediatric formulation or a 10-mcg two-dose regimen using the adult formulation, administered as a two-dose schedule.

[b] Higher doses might be more immunogenic, but no specific recommendations have been made.

[c] Two 1.0-mL doses administered at one site.

Table 25–8

Recommendations for Hepatitis B Prophylaxis to Prevent Perinatal Transmission with Single-Antigen Hepatitis B Vaccine

		Mother's HBsAg Status		
Infant Birthweight	Hepatitis B[a]	Positive	Negative	Unknown
≥ 2000 g	Dose 1	Within 12 hours of birth with HBIG[b]	Within 24 hours of birth	Within 12 hours of birth. +/– HBIG[b,d]
	Dose 2	Month 1–2	Month 1–2	Month 1–2
	Dose 3	Month 6[c]	Month 6–18[c]	Month 6[c]
< 2000 g	Dose 1	Within 12 hours of birth with HBIG[b]	Hospital discharge or age 1 month	Within 12 hours of birth with HBIG[b]
	Dose 2	Month 1	Month 2	Month 1
	Dose 3	Month 2–3	Month 6–18[c]	Month 2–3
	Dose 4	Month 6[c]		At month 6[c]

[a] See Table 25–6 for appropriate hepatitis B vaccine dose.

[b] 0.5 mL intramuscularly in a different site from vaccine.

[c] The final dose should not be administered before age 24 weeks (164 days).

[d] Test mother's HBsAg as soon as possible after admission for delivery. If positive, give HBIG as soon as possible and prior to age 7 days; if negative, give no HBIG.

From Schillie S, Vellozzi C, Reingold A, et al. Prevention of Hepatitis B Virus Infection in the United States: Recommendations of the Advisory Committee on Immunization Practices. MMWR Recomm Rep. 2018 Jan 12;67(1):1-31. doi: 10.15585/mmwr.rr6701a1. PMID: 29939980; PMCID: PMC5837403.

antibody testing is not routinely recommended because most people completing the vaccination series obtain adequate antibody levels. However, it is recommended to determine if immunity has been achieved in infants born to HBsAg-positive mothers, health care and public safety workers with continued exposure to percutaneous and/or mucosal-infected body fluids, sex partners with CHB, and immunocompromised persons (eg, chronic dialysis, HIV, and organ transplant recipients).[23,28]

Effective immunity may last for more than 30 years in healthy individuals. However, patients with poor immune systems may have an anamnestic response that requires titers to be checked periodically with booster doses given.[23,28]

The most frequent adverse effects are local injection-site reactions, flu-like symptoms, nausea, dizziness, fever, and headaches.[23] Heplisav-B had more cardiovascular events than Engerix-B (0.27% vs 0.14%), but this difference is not statistically significant.[29] Recombivax HB and Engerix-B are not contraindicated during pregnancy and should be safe to the fetus because they are inactivated vaccines.[23] There are no data on Heplisav-B in pregnant women.[23]

▸ *Hepatitis A and B Combination Vaccine*

KEY CONCEPT Twinrix combines both inactivated HAV and HBV and is approved for individuals 18 years of age or older who are at risk for HAV and HBV infections.[3,23] A 1-mL dose of Twinrix may be administered at either months 0, 1, and 6 or in an accelerated schedule on days 0, 7, between 21 and 30, and with a fourth dose at month 12.[3,23] The accelerated schedule is intended for patients who start the vaccination series but are unable to complete the standard three-dose schedule in time to develop adequate immunity before embarking on travel that will put them at risk of exposure to hepatitis A and B.[27] The efficacy and side effect profile of Twinrix is similar to giving each vaccine separately.[3,28]

Chronic Hepatitis B Treatment

The American Association for the Study of Liver Diseases (AASLD) recommends treatment for HBeAg-positive patients with persistently elevated ALT (more than two times the upper limit of normal) or significant histological disease and elevated HBV DNA levels greater than 20,000 IU/mL (kIU/L) to delay progression to cirrhosis and prevent the development of ESLD.[20] Similar treatment criteria apply to patients infected with HBeAg-negative CHB except that therapy should be initiated when HBV DNA levels exceed 2000 IU/mL (kIU/L).[20]

The primary treatment endpoint is to suppress HBV replication to achieve undetectable serum levels. The ideal treatment should induce a biochemical response (normalize ALT levels), histological response (decrease liver inflammation documented by liver biopsy scores), and serological seroconversion (detectable antiHBe, antiHBs, and HBsAg loss).[20]

KEY CONCEPT The drug of choice for CHB depends on the patient's past medical history, ALT, HBV DNA level, HBeAg status, severity of liver disease, and history of previous HBV therapy. All HBV therapies are effective with no agent showing superiority to others in reducing the risk of developing HBV complications.[20]

Entecavir, tenofovir, and pegylated (peg) IFN-α_{2a} are recommended first-line therapies due to profound HBV DNA suppression; the latter agent should be considered in patients with compensated liver disease because of its finite treatment duration and lack of drug resistance.[20]

Adefovir and lamivudine are not recommended due to high rates of resistance.[20] Patients responding to therapy should continue them, but adding or switching to a more potent HBV agent should be considered if there is inadequate virologic response or drug resistance develops.

The side effect profiles for all oral HBV agents are mild; the most common complaints are nausea, headaches, dizziness, and fatigue. Patients should be monitored for lactic acidosis and severe hepatomegaly because some cases have been fatal. Hepatic function tests should be monitored if treatment is to be discontinued; severe acute hepatitis exacerbations have been reported. Dosage adjustments are required in patients with renal dysfunction. With all oral HBV agents, HIV resistance may develop if given as monotherapy; therefore, test for HIV prior to starting a single anti-HBV agent. Patients coinfected with HIV and HBV should receive concomitant highly active antiretroviral therapy (HAART) with an HBV agent. Each HBV agent is described in

Table 25–9

Antiviral Agents for Treatment of Chronic Hepatitis B

Generic Name	Brand Name	Recommended Dosing Regimen[a]	Notes
Pegylated interferon-α_{2a}	Pegasys	180 mcg SQ weekly for 48 weeks	Refer to Table 25–10 for adverse effects
Entecavir	Baraclude[b]	0.5 mg daily for treatment naïve 1 mg daily for resistance to lamivudine or telbivudine or decompensated liver disease	Give on empty stomach (at least 2 hours before or after a meal)
Tenofovir disoproxil fumarate	Viread	300 mg daily for patients weighing > 35 kg	Give on empty stomach
Tenofovir alafenamide	Vemlidy	25 mg daily	Take with food
Adefovir disoproxil	Hepsera[b]	10 mg daily	Take with or without food
Lamivudine	Epivir-HBV[b]	100 mg daily for adults 3 mg/kg, up to 100 mg for 2–17 years old	Take with or without food

[a] May need to treat longer per guidelines: Terrault NA, Lok ASF, McMahon BJ, et al. Update on prevention, diagnosis, and treatment of chronic hepatitis B: AASLD 2018 hepatitis B guidance. Clin Liver Dis (Hoboken*)*. 2018;12(1):33–34. Published 2018 Aug 22. doi:10.1002/cld.728.

[b] Generic available.

(SQ, subcutaneous)

the sections that in the following sections with recommended dosing regimens in Table 25–9.

▶ *Interferon and Pegylated Interferon*

PegIFN-α_{2a} (Pegasys) is the only IFN therapy approved for HBV that is effective in suppressing, and in some cases ceasing, viral replication without inducing resistance.[20] Approximately one-third of HBeAg-positive patients achieve HBeAg seroconversion after 48 weeks of pegIFN therapy.[20] HBeAg-negative hepatitis B may require more than 48 weeks of treatment to attain undetectable HBV DNA levels.[20] Factors associated with a greater chance of HBeAg seroconversion include low baseline HBV DNA concentrations and high pretreatment ALT levels.[20]

Although pegIFN lacks resistance and possible HBsAg loss or seroconversion (development of anti-HBs), its disadvantages include the need for subcutaneous injections and a pronounced adverse-effect profile that may require dosage reductions or treatment discontinuation (see Table 25–10). PegIFN is contraindicated in patients with autoimmune disorders, uncontrolled psychiatric diseases (eg, suicidal thoughts, major depression), uncontrolled seizures, and decompensated cirrhosis.[20]

▶ *Entecavir*

Entecavir (Baraclude) is a guanosine nucleoside analog approved for patients over 2 years of age with either HBeAg-positive or HBeAg-negative CHB.[20] Resistance rates are low (1%–2%) in lamivudine-naive patients treated with entecavir for up to 5 years.[30] For patients previously treated with lamivudine and switched to entecavir, the resistance rate is approximately 28% at 1 year and up to 51% at 5 years.[31] Therefore, the dose of entecavir is 0.5 mg for patients 16 years or older with compensated liver disease and naïve to lamivudine therapy and 1 mg for lamivudine or telbivudine resistance or decompensated liver disease.

▶ *Tenofovir Disoproxil Fumarate and Tenofovir Alafenamide*

Tenofovir disoproxil fumarate (TDF; Viread) is an acyclic adenine nucleotide reverse transcriptase inhibitor similar in structure to adefovir disoproxil that inhibits HIV and HBV replication. It is indicated for HBV patients older than 2 years of age, weighing at least 10 kg with either HBeAg-positive or HBeAg-negative CHB and/or HIV when prescribed with other HAART therapies.

TDF has high efficacy with almost no development of resistance and is generally well tolerated.[20,30] However, rare but significant adverse effects include nephrotoxicity and Fanconi syndrome, decreased bone mineral density, and osteomalacia.[20,30] TDF is a prodrug that is converted to tenofovir in the plasma and then phosphorylated to tenofovir diphosphate. High concentrations of the diphosphate compound in cells increase risk of kidney and bone toxicity. Creatinine clearance (CrCl), serum phosphate, liver function tests, and bone mineral density should be monitored prior

Table 25–10

Adverse Effects of Pegylated Interferon and Ribavirin

Pegylated interferon

Adverse Effect	Therapeutic Intervention
Flu-like symptoms (eg, fevers, chills, rigors, myalgias)	Premedicate with acetaminophen or nonsteroidal anti-inflammatory drugs. Administer at bedtime.
Psychiatric abnormalities (eg, irritability, depression, and rarely, suicidal, or homicidal ideations)	Seek mental health specialist, antidepressants, and anxiolytics. If symptoms are severe, discontinue treatment.
Neutropenia	Obtain a complete blood count with differential and monitor ANC. Consider reducing dose if less than 1.0×10^9/L (1.0×10^3/mm^3)
Thrombocytopenia	Obtain a complete blood count and monitor platelet count. Consider reducing dose if platelet count is significantly low.
Elevated ALTs	Obtain LFTs and monitor. Only use pegylated interferon in patients with compensated liver disease.
Ribavirin	
Dermatological (rash, itching, dry skin)	Recommend creams, lotions, and oral antihistamines
Hemolytic anemia	Monitor hemoglobin, shortness of breath, chest pain. Reduce dose if hemoglobin less than 10 g/dL (100 g/L; 6.21 mmol/L) or significant symptoms

to initiating treatment and during therapy. The TDF dose must be reduced with CrCl less than 50 mL/min (0.83 mL/s).

Tenofovir alafenamide (TAF; Vemlidy) was subsequently approved for compensated CHB. TAF offers antiviral activity similar to TDF but with a safer side effect profile. TAF delivers the prodrug tenofovir directly to hepatic cells intracellularly, resulting in lower concentrations in the kidneys and bone.[20] TAF may be administered at full doses until the CrCl is less than 15 mL/min (0.25 mL/s).

▶ *Adefovir Dipivoxil*

Adefovir dipivoxil (Hepsera) is a prodrug of adefovir, an adenosine nucleotide analog that inhibits DNA polymerase; it is indicated for CHB in patients older than 12 years of age. Resistance to adefovir is minimal for the first few years of treatment but increases to approximately 30% after 5 years of therapy.[30]

Similar to TDF, rare but significant adverse effects include nephrotoxicity when doses are greater than 30 mg/day and Fanconi syndrome. Renal function should be monitored during treatment in all patients, especially those with preexisting or risk factors for renal impairment.

▶ *Lamivudine*

Lamivudine (Epivir-HBV) is an oral synthetic cytosine nucleoside analog that is effective in suppressing HBV replication, normalizing ALT levels, and improving liver histology. Patients may have a similar or a superior response in achieving these endpoints when compared with pegIFN. Prolonged lamivudine therapy (up to 5 years) may be needed to sustain seroconversion but may lead to resistance rates as high as 70% at 5 years.[20,30] Due to the high rate of resistance, lamivudine is no longer recommended as first-line therapy for CHB.[20]

Hepatitis C Prevention

There are currently no vaccines to prevent HCV, but several are under development.[12] Avoiding high-risk behaviors such as sharing needles among PWID is the primary means of acquiring HCV. More than 75% of individuals infected with the HCV were born during the "baby boomer" generation.[32] Additionally, from 2009 to 2017, similar HCV rates were found in people between the ages of 20 and 39. Because this population contains women of childbearing age, the number of live neonates infected with HCV has increased.[17,32] Therefore, the CDC recommends that all adults over the age of 18 be tested for HCV at least once in their lifetime.[17] Also, women should be tested for HCV during each pregnancy. Individuals with elevated ALT levels and those with HCV risk factors listed in Table 25–1 should be tested for HCV at least once in their lifetime. PWID or share intravenous drug paraphernalia or patients receiving hemodialysis should be tested yearly.[17]

Chronic Hepatitis C Treatment

Treatment for HCV has been revolutionized over the past decade, with efficacy rates well above 90% compared to 50% to 80% before 2011.[33] The primary goal of HCV treatment is to achieve a sustained virologic response (SVR), defined as undetectable HCV RNA levels at 12 weeks or longer after treatment completion. Normalization of liver function tests and improvement of histology are additional treatment outcomes, but the primary goal is to prevent progression and development of cirrhosis, HCC, and ESLD.[13] Patients who achieve SVR do not cure the existing liver disease; those with advanced disease and cirrhosis continue to have liver disease progression; thus, cirrhotic surveillance must be performed (eg, ultrasound to evaluate for HCC). Initiating HCV treatment early before development of advanced liver disease may slow the progression of cirrhosis and the complications associated with ESLD. Therefore, the World Health Organization (WHO) and National Academies of Sciences, Engineering, and Medicine (NASEM) recommend treating *all* patients infected with the HCV, in hopes of eliminating viral hepatitis in the world by 2030.[10,34]

Patient Encounter Part 2: Creating a Care Plan

Based on the information presented, create a care plan for this patient's hepatitis. Your plan should include:

(a) a statement of the drug-related needs and/or problems;

(b) the goals of therapy;

(c) a patient-specific detailed therapeutic plan;

(d) a follow-up plan to determine whether the goals have been achieved; and

(e) a follow-up plan to identify potential adverse effects of therapy.

▶ *Interferon/Pegylated Interferon and Ribavirin*

IFN and pegIFN are no longer recommended for chronic HCV because SVR rates (about 50%) are suboptimal along with a number of untoward events (Table 25–10). The addition of ribavirin, a synthetic guanosine analog that inhibits viral polymerase, had increased SVR rates with pegIFN (50%–80%) and continues to be prescribed with direct-acting antivirals (DAA) for certain patient populations to enhance SVR rates.[13] Ribavirin causes a dose-related hemolytic anemia that may require dosage reductions or discontinuation.[13] Dermatological effects (eg, rash, pruritus, and dry skin) occur commonly with ribavirin. Because ribavirin can be teratogenic and embryocidal, all women of childbearing age and men who are able to father a child must use two forms of contraception during HCV therapy containing ribavirin and for 6 months after completion of treatment. Patients with renal insufficiency require dosage adjustments with ribavirin.

▶ *Direct-Acting Antiviral Agents*

The two first-generation DAAs (boceprevir and telaprevir) and several second-generation DAAs (eg, simeprevir) are no longer available because newer agents have superior response rates, fewer adverse effects, reduced pill burden, simplified dosing regimens, fewer drug interactions, and lower rates of viral resistance.[13]

Third-generation DAAs (Table 25–11) have SVR rates well above 90%, once daily dosing, fewer adverse effects, safety for all stages of renal dysfunction, shorter treatment durations with less complex regimens, and several agents that are pangenotypic (treat all HCV genotypes). **KEY CONCEPT** Selection of a DAA is based on previous HCV treatment history, severity of liver disease, current medical conditions and medications, and the presence or absence of resistance-associated substitutions (RAS).[13] Selected DAAs require RAS testing before starting HCV therapy (Table 25–11). If RAS are present, the options are to choose a drug from a different DAA, add ribavirin, and/or treat for longer than 12 weeks.

Prior to having FDA-approved HCV pangenotypic HCV treatments, obtaining HCV genotypes was standard of care because it determines the likelihood of response and the duration of treatment. At present, genotyping is no longer recommended in naïve and noncirrhotic patients since several DAAs treat all genotypes; assuming a pangenotypic HCV regimen is prescribed. However, if patients have failed previous HCV therapy, have cirrhosis, or a nonpangenotypic DAA is selected, then the genotype should be

Table 25–11

Direct-Acting Antiviral Agents for Treatment of Hepatitis C

Brand Name	Generic Name	Dosage (mg)	Regimen[e]	Drug Interactions	Resistance Testing Required
Sovaldi	Sofosbuvir[3]	400	1 daily with other DAA ± ribavirin[e]	P-gp[b]	
Harvoni[d]	Ledipasvir[2]/ sofosbuvir[3] FDC[c]	90/400	1 daily ± ribavirin[e]	P-gp[b] BCRP[h] Acid suppressing agents	NS5A RAS Genotype 1a, treatment experienced
Zepatier	Elbasvir[2]/grazoprevir[1] FDC[c]	50/100	1 daily ± ribavirin[e]	OATP1B1/3 CYP3A	NS5A RAS
Epclusa[d]	Sofosbuvir[3]/velpatasvir[2] FDC[c]	400/100	1 daily	P-gp[b] BCRP[h] OATP1B1/3 OATP2B1 CYP2B6 CYP2C8 CYP3A4 Acid suppressing agents	NS5A RAS, Genotype 3, naïve and cirrhotic
Vosevi	Sofosbuvir[3]/ velpatasvir[2]/ voxilaprevir[1] FDC[c]	400/100/100	1 daily	P-gp[b] BCRP[h] OATP1B1/3 OATP2B1 CYP1A2 CYP2B6 CYP2C8 CYP3A4 Acid suppressing agents	
Mavyret	Glecaprevir[1]/ pibrentasvir[2,c]	100/40	3 daily	P-gp BCRP[h] OATP1B1/3 CYP3A CYP1A2 UGT1A1[i]	

[a] Wholesale acquisition cost

[b] P-glycoprotein

[c] Fixed-dose combination tablet

[d] Generic available

[e] Refer to www.hcvguidelines.org for the most up-to-date HCV treatment regimen.

[f] All patients should be evaluated for HBV and be vaccinated if not yet immune. If HBV is positive, then treat before initiating HCV therapy with any DAA.

[g] If coadministered with ribavirin, then refer to the warnings and contraindications associated with ribavirin.

[h] Breast cancer resistance protein

[1] NS3/4A protease inhibitor

[2] NS5A polymerase inhibitor

[3] NS5B Nucleotide polymerase inhibitor

obtained prior to initiating therapy.[13] Prior to administering any DAA regimen, the presence of HBV should be excluded because cases of HBV reactivation have occurred, leading to fulminant hepatitis or death. Patients positive for HBV should be treated either prior to or concomitantly with the DAA. Patients not immune against HBV should receive the HBV vaccine.

Patients with decompensated Child-Pugh B and Child-Pugh C cirrhosis should not receive DAA regimens that include a protease inhibitor (eg, voxilaprevir, grazoprevir, and glecaprevir) because hepatic decompensation and/or failure, need for transplant, or death may occur.

All DAA have potential drug–drug interactions that may render treatments ineffective or toxic. The more notable interactions include proton pump inhibitors, statins, antimicrobials, antiepileptic agents, amiodarone, immunosuppressive agents, St John's wort, and HAART agents. Prior to prescribing a DAA regimen, it is imperative to obtain an updated medication list of over-the-counter and prescription medications and dietary supplements. Clinicians may use the University of Liverpool's Hepatitis Drug Interactions website, https://www.hep-druginteractions.org/checker, to assess for DDIs.

The approved DAAs for HCV are described below; however, refer to www.hcvguidelines.org for the most up-to-date treatment recommendations.[13]

Sofosbuvir (Sovaldi) is the first agent of the NS5B polymerase inhibitor class approved for treatment of HCV genotypes 1, 2, 3, and 4 in patients older than age 3; it also has efficacy in genotypes 5 and 6.[13] Sofosbuvir is commonly administered with other DAAs in a fixed-dose combination (FDC) to achieve SVR rates above 90%. Treatment durations range from 8 to 24 weeks with the most common being 12 weeks.[13]

Sofosbuvir and Ledipasvir (Harvoni) is the first FDA-approved all-oral FDC HCV regimen that does not require administration with pegIFN or ribavirin. Ledipasvir has a different mechanism of action than sofosbuvir; it inhibits the HCV NS5A protein, which is required for viral replication. This FDC is indicated for CHC genotype 1, 4, 5, and 6 infection in patients older than age 3. Sofosbuvir 400 mg/ledipasvir 90 mg is given daily for 12 or 24 weeks depending on prior HCV treatment history, cirrhosis status, genotype, and baseline viral load.[13] Noncirrhotic patients with genotype 1a, 1b, and 4 (not 4r) without HIV with a HCV RNA level less than 6 million IU/mL may be treated for 8 weeks.[13]

Elbasvir and Grazoprevir (Zepatier) is an FDC tablet approved for HCV genotype 1 or 4. Elbasvir is an NS5A inhibitor and grazoprevir is a NS3/4A protease inhibitor; these mechanisms inhibit different parts of the virus to halt viral replication. Patients with genotype 1a disease should be tested for the NS5A RAS; if NS5A polymorphism is absent, monotherapy for 12 weeks results in a SVR rate above 90%. If the polymorphism is present, ribavirin is added and treatment is extended to 16 weeks. Patients with genotype 1b and having mild fibrosis (defined as a transient elastography score ≤ 9.5 kPa) may be considered for 8 weeks of therapy.[13] This FDC is safe and well tolerated for patients with renal insufficiency including those on hemodialysis because the drugs are primarily eliminated via the feces.

Sofosbuvir and Velpatasvir (Epclusa) is the first FDC approved for all six HCV genotypes (known as a pangenotypic DAA) and is indicated for patients older than 6 years or weighing greater than 17 kg. Sofosbuvir (400 mg), an NS5B polymerase inhibitor, is combined with velpatasvir (100 mg), an NS5A inhibitor (also available in 200 mg/50 mg, respectively, for children weighing 17–30 kg) that achieves an SVR well above 90% for all patients without cirrhosis and those with compensated cirrhosis (except for genotype 3). Patients with compensated cirrhosis and genotype 3 should be tested for the NS5A RAS Y93H prior to initiating treatment. If the polymorphism is present, ribavirin is added (or select another DAA) and if absent, then monotherapy with Epclusa may be recommended.[13] Because this once-daily DAA regimen for 12 weeks is highly effective with minimal adverse effects, the AASLD included Epclusa as part of the simplified treatment recommendations.[13] Patients with decompensated Child-Pugh B or C cirrhosis should take Epclusa with weight-based ribavirin for 12 weeks, if tolerated, and those not able to take ribavirin may receive monotherapy for 24 weeks.[13]

Sofosbuvir, Velpatasvir, and Voxilaprevir (Vosevi) is a pangenotypic FDC tablet that contains drugs targeting three different sites to inhibit HCV viral replication. Similar to Epclusa, Vosevi also includes a NS3/4A protease inhibitor, voxilaprevir. The once-daily FDC tablet is taken daily with food for 12 weeks for adults with or without compensated cirrhosis (Child-Pugh A) who have been previously treated with an HCV regimen that included an NS5A inhibitor or sofosbuvir. This triple therapy has SVR rates above 95%, particularly in DAA-experienced patients. There are no dosage recommendations for patients with renal insufficiency or ESRD.

Glecaprevir and Pibrentasvir (Mavyret) is the first pangenotypic FDC tablet containing an NS3/4A protease inhibitor (glecaprevir 300 mg) and an NS5A inhibitor (pibrentasvir 120 mg). It is approved for patients 12 years and older weighing at least 45 kg with or without compensated cirrhosis (Child-Pugh A) or patients who are treatment experienced with either an HCV NS3/4A or NS5A inhibitor. It may be administered for 8, 12, or 16 weeks. The 8-week DAA treatment is effective for all HCV genotypes in: (a) noncirrhotic naïve-treated patients, (b) patients with compensated cirrhosis (Child-Pugh A), (c) patients coinfected with HIV, and (d) patients with renal insufficiency. Because this once-daily DAA regimen for eight weeks is highly effective with minimal adverse effects, the AASLD includes Mavyret as part of the simplified treatment recommendations for treatment-naïve patients with compensated (Child-Pugh A) or no cirrhosis.[13] For treatment-experienced patients, the duration of retreatment may be as short as 8 weeks or as long as 16 weeks.

▶ *Cost of HCV Treatment*

The new generation of HCV agents is associated with improved SVR rates and side effect profiles. However, their high cost may prevent some patients from receiving HCV treatment. Typically, 8 to 12 weeks of DAA therapy has a wholesale acquisition price of $27,000 to $95,000. The price has steadily declined as more DAA regimens became available generically. In an ideal world, all patients infected with HCV would be treated to decrease morbidity and mortality associated with cirrhosis and HCC. In an analysis performed by Chhatwal et al., it was projected that 1.85 million Americans would be treated between 2014 and 2030.[35] The unfortunate reality is that only 5 million had been treated worldwide by the end of 2017.[10] The high cost of HCV regimens and lack of linkage to care may explain the difficulty in treating everyone.

The AASLD recommends that all patients be treated regardless of severity of the liver disease, except those with short life expectancies.[32] With the simplified treatment recommendations, and now having generic DAAs available in the United States, it is hoped that all infected with hepatitis C will be treated with ultimately eradication of HCV worldwide.

Hepatitis D Prevention and Treatment

Hepatitis D infection is possible only if the patient is also infected with HBV; therefore, hepatitis B vaccination can indirectly prevent hepatitis D infections. The recommended treatment for HDV is pegIFN for 48 weeks with several adverse effects (Table 25–10).[20,30] For patients with mild liver disease (low HBV DNA levels, elevated ALT levels, and elevated HDV RNA levels), pegIFN for 48 weeks is recommended. Monotherapy with oral HBV antiviral agents should only be considered in patients with cirrhosis since there is minimal effect on HDV RNA concentrations. Coadministration of oral HBV agents (TDF, TAF, or entecavir) and pegIFN may be recommended in patients with elevated HBV DNA and HDV RNA levels.[20] HBV DNA and HDV RNA levels are not strong treatment endpoints, considering that 40% of patients may have viral suppression at the end of treatment but may rebound after several years.[20] A loss of HBsAg may be a better endpoint; however, only about 25% of patients achieve this with at least 5 years of pegIFN therapy.[20] Due to a lack of effective HDV regimens, several investigational therapies are being evaluated.[36]

Hepatitis E Prevention and Treatment

Because hepatitis E is transmitted via the fecal–oral route, good personal hygiene and proper disposal of sanitary waste are the most effective ways to prevent viral acquisition. There are no commercially available vaccines in the United States to prevent hepatitis E. However, a hepatitis E vaccine has been licensed in China since 2012 and may become available for countries with high HEV infection incidence rates.[15] In rare cases, HEV may lead

Patient Encounter Part 3

Sodium 138 mEq/L (mmol/L)
Potassium 4.4 mEq/L (mmol/L)
Chloride 98 mEq/L (mmol/L)
CO2 19 mEq/L (mmol/L)
BUN 20 mg/dL (7.1 mmol/L)
SCr 1.2 mg/dL (106 μmol/L)
Glucose 103 mg/dL (5.7 mmol/L)

Hct 39.9% (0.399)
Plt 201 × 10^3/mm^3 (201 × 10^9/L)

What questions should you ask the patient?

What action should you take based on the patient's week 4 HCV RNA level?

to chronic hepatitis. PegIFN treatment has been successful, primarily in the solid organ transplantation population. However, there are many adverse effects (Table 25–10), and it is considered a contraindication in several solid organ transplants (kidney, pancreas, heart, and lung) because it may induce rejection. Ribavirin monotherapy had been evaluated in organ transplant recipients with promising SVR rates of 78%.[37]

OUTCOME EVALUATION

Monitoring for efficacy in patients treated for chronic hepatitis B or C includes evaluating aminotransferase levels and hepatitis B or C viral levels and serologies.

Hepatitis B

- Obtain an ALT at baseline and then every 3 to 6 months during hepatitis B treatment.
- Monitor HBV DNA levels every 3 to 6 months to determine treatment response.
- Monitor HBeAg and anti-HBe every 6 months to determine if seroconversion to anti-HBe occurred or HBeAg was lost in HBeAg-positive CHB patients after achieving undetectable HBV DNA levels.[20]
- Monitor HBsAg every 6 to 12 months to determine if HBsAg was lost or anti-HBs developed in CHB HBeAg-negative patients with persistently undetectable serum HBV DNA levels.[20]
- Continue treatment in CHB HBeAg-positive patients until HBeAg seroconversion has been attained along with undetectable HBV DNA levels. Once anti-HBe appears, complete an additional 12 months of hepatitis B therapy.[20]
- Continue treatment in CHB HBeAg-negative patients. Medication discontinuation may be considered if HBsAg is lost, but the risk versus benefit must be weighed when doing so.[20]
- Monitor ALT, HBV DNA levels, seroconversion, and signs and symptoms of hepatic decompensation every 3 months for at least 1 year when discontinuing hepatitis B therapy.[20]
- For patients receiving TDF, TAF, or adefovir, monitor serum creatinine, phosphorus, urine glucose, and urinary protein for nephrotoxicity at baseline then yearly (more frequently in patients with baseline renal insufficiency).[20]
- Monitor WBC, absolute neutrophil count (ANC), and platelets either weekly or biweekly during the first month of therapy and monthly thereafter if stable while on pegIFN (Table 25–10).
- Monitor thyroid-stimulating hormone (TSH) and fasting lipid panel every 12 weeks while receiving pegIFN.

Patient Encounter Part 4

The patient has completed her HCV treatment and the HCV RNA level is detectable at 502,113 IU/mL (kIU/L) 12 weeks off of HCV medications.

What action should you take based on this HCV RNA level?

What other information should you counsel the patient about in addition to the side effects associated with the hepatitis C therapy?

Hepatitis C

- Evaluate the patient's HAV and HBV status. If not yet immune, then vaccinate. If positive for CHB, then have the hepatologist evaluate the patient for HBV treatment.
- Test for HIV before initiating HCV therapy. If positive, then refer to an infectious diseases specialist.
- Conduct a thorough medication reconciliation of prescription and over-the-counter medications and dietary supplements prior to and during HCV therapy for drug interactions.
- Evaluate for signs and symptoms of decompensated liver disease prior to initiating DAA therapies containing an HCV NS3 protease inhibitor. Patients with Child-Pugh B or C should not receive NS3 protease inhibitors (Table 25–11).
- Evaluate for the presence of RAS prior to initiating HCV therapy (Table 25–11).
- The ultimate goal of HCV therapy is to achieve SVR, defined as having undetectable HCV RNA levels for at least 3 months posttreatment; this indicates virological cure.[13] Ensure that a baseline HCV RNA level had been obtained any time prior to starting a DAA for comparison.

Patient Encounter Part 5

The patient's daughter visits the doctor today because she tested positive on a home pregnancy test last week. Labs were obtained a week ago and she returns for results.
SH: marijuana—started using at age 17.
All laboratory test results are normal except for the following:

AST 28 IU/L (0.47 mckat/L)
ALT 32 IU/L (0.53 μkat/L)
Anti-HAV IgM (–)
Anti-HAV IgG (–)
Anti-HBs (+)
Anti-HBc titer < 10

hCG 4316 mIU/mL (IU/L)
Anti-HBc IgG (–)
Anti-HBc IgM (–)
HBsAg (–)
Anti-HCV (–)

Based on the information presented:

(a) create a detailed care plan for the patient;

(b) create a detailed viral hepatitis vaccination care plan for the patient's newborn

- Obtain a CBC, INR, and complete metabolic panel at baseline within 6 months before initiating DAA therapy.
- Monitor ALT levels every 4 weeks. Biochemical response is defined as the normalization of ALT. If elevated, obtain an HCV RNA level.
- Monitor hemoglobin weekly or biweekly during the first month and monthly thereafter if stable while on ribavirin (Table 25–10).
- Monitor for fatigue, shortness of breath, chest pain, and dermatological complications while on ribavirin; discontinue treatment if complaints are significant.
- Monitor serum creatinine in patients receiving ribavirin to detect renal insufficiency that may result in ribavirin accumulation and toxicity (eg, hemolytic anemia).
- Monitor for pregnancy while on ribavirin therapy and 6 months after completing therapy.

Patient Care Process

Collect Information:

- Speak with the patient to identify risk factors for acquiring viral hepatitis (Table 25–1).
- Review social history to determine if any practices may contribute to or worsen the severity of liver disease (ie, alcohol, high-fat food intake).
- Review past medical history focusing on hepatic and renal disorders.
- Review physical assessment findings focusing on mental status changes, edema, and color of skin and eyes (ie, jaundice).
- Perform a medication history (prescription, over-the-counter drugs, dietary supplements) to identify drug interactions (may refer to hep-druginteraction.org) or drug-induced liver toxicity.
- Review the use of any drugs in the past for the treatment of hepatitis B or C.
- Obtain a vaccination history to determine which vaccines have been given.
- Review laboratory tests to determine severity of liver disease. Review hepatitis serologies to determine if vaccination is needed (Table 25–2).
- Speak with the patient and review insurance coverage records for medical and medication history.

Assess the Information:

- Determine if treatment is indicated by reviewing laboratory values, liver serologies, and liver biopsy report (if available) or imaging (CT, Fibroscan, ultrasound).
- If the patient does not qualify for hepatitis therapy, then schedule return visits every 3 to 6 months to monitor health condition and laboratory tests.
- If the patient qualifies for treatment, assess for uncontrolled medical conditions, and if present, treat or refer to an appropriate medical specialty for evaluation (eg, HIV, diabetes, renal disease, HBV).
- Determine which vaccines need to be administered.
- For patients with HCV, assess severity of liver disease to recommend appropriate anti-HCV regimen (Table 25–12).
- Document, trend, and review laboratory values to determine severity of liver disease (platelet counts, AST, ALT, INR, albumin).
- Assess the efficacy, safety, and patient adherence of current pharmacotherapy.
- Assess current medications before initiating hepatitis therapy to identify potential drug–drug interactions and ensure that doses are appropriate based on organ function.
- Assess laboratory values and medications with potential for drug interactions or adherence problems for patients currently on treatment.

Develop a Care Plan:

- Refer to AASLD HBV guidelines for CHB treatment recommendations.
- Refer to www.hcvguidelines.org for HCV treatment guidelines.
- Refer to https://www.hepatitisc.uw.edu/ for HCV treatment regimens.
- Obtain a pregnancy test in women of childbearing potential who are prescribed ribavirin-based therapies.

Implement the Care Plan:

- Educate the patient about the hepatitis drug regimen, potential side effects, and duration of therapy.
- Inform the patient about the importance of drug adherence to minimize the risk of developing resistance.
- Educate the patient to avoid alcohol and illicit drug use during treatment and after completion of therapy.
- Work with the local specialty pharmacy to ensure that medications are covered by insurance and continued without disruption in treatment.
- Educate all men and women who are of childbearing age and are receiving ribavirin to use two forms of birth control during treatment and for 6 months after treatment.
- Address any patient concerns about the liver disease and its management.
- Discuss the importance of lifestyle modification to reduce the progression of liver disease.

Follow-up: Monitor and Evaluate:

- At each clinic visit, review the medication list, assess for medication adverse effects and drug interactions, and review laboratory tests to assess efficacy and toxicity.
- Confirm adherence and number of missed doses to minimize drug resistance.
- Obtain laboratory test results every week to every 2 to 4 weeks until complete treatment if ribavirin is prescribed.
- Assess for decompensated liver disease while on HCV therapy (Table 25–12).
- Follow up with a hepatologist every 6 months for cirrhosis surveillance in patients with advanced liver disease.

- For patients taking medications for diabetes, monitor symptoms of hypoglycemia during and after treatment.
- For patients taking warfarin, monitor INR during and after treatment.

Abbreviations Introduced in This Chapter

ALT	Alanine aminotransferase
ANC	Absolute neutrophil count
Anti-HAV	Hepatitis A virus antibody
Anti-HBc	Hepatitis B core antibody
Anti-HBe	Hepatitis B envelope antibody
Anti-HBs	Hepatitis B surface antibody
Anti-HCV	Hepatitis C antibody
Anti-HDV	Hepatitis D antibody
Anti-HEV	Hepatitis E antibody
AST	Aspartate aminotransferase
CHB	Chronic hepatitis B infection
CHC	Chronic hepatitis C infection
CrCl	Creatinine clearance
DAA	Direct-acting antiviral
ESLD	End-stage liver disease
ESRD	End-stage renal disease
FDC	Fixed-dose combination
HAART	Highly active antiretroviral therapy
HAV	Hepatitis A virus
HBcAg	Hepatitis B core antigen
HBeAg	Hepatitis B envelope antigen
HBIG	Hepatitis B immunoglobulin
HBsAg	Hepatitis B surface antigen
HBV	Hepatitis B virus
HBV DNA	Hepatitis B deoxyribonucleic acid
HCV	Hepatitis C virus
HCV RNA	Hepatitis C virus ribonucleic acid
HDV	Hepatitis D virus
HDVAg	Hepatitis D antigen
HDV RNA	Hepatitis D virus ribonucleic acid
HEV	Hepatitis E virus
IgG	Immunoglobulin G
IgG anti-HD	IgG antibodies to hepatitis D virus antigen
IgM	Immunoglobulin M
IgM anti-HD	IgM antibodies to hepatitis D virus antigen
IG	Immune globulin
IGIM	Immune globulin for intramuscular administration
pegIFN	Pegylated interferon
PWID	People who inject drugs
RAS	Resistance-associated substitutions
SVR	Sustained virologic response
WBC	White blood cell count

Acute Kidney Injury

Mary K. Stamatakis

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Assess a patient's kidney function based on clinical presentation, laboratory results, and urinary indices.
2. Identify pharmacotherapeutic outcomes and endpoints of therapy in patients with acute kidney injury (AKI).
3. Apply knowledge of the pathophysiology of AKI to develop a treatment plan.
4. Develop strategies to minimize the occurrence of drug-induced AKI.
5. Monitor and evaluate the safety and effectiveness of the treatment plan.

INTRODUCTION

Acute kidney injury (AKI) is a potentially life-threatening syndrome that occurs primarily in hospitalized patients and frequently complicates the course of those who are critically ill. It is characterized by a rapid decrease in glomerular filtration rate (GFR) and the resultant accumulation of nitrogenous waste products (eg, creatinine), with or without a decrease in urine output. AKI often coexists with other clinical syndromes such as shock and sepsis.

KEY CONCEPT AKI is defined as an increase in serum creatinine (SCr) of at least 0.3 mg/dL (27 μmol/L) within 48 hours, a 50% increase in baseline SCr within 7 days, or a urine output of less than 0.5 mL/kg/h for at least 6 hours. Only one of the three criteria needs to be met for diagnosis of AKI.[1]

Kidney disease is being increasingly viewed as a continuum.[2] Once kidney disease persists longer than 90 days, patients have progressed to chronic kidney disease (CKD).[2]

EPIDEMIOLOGY

Approximately 7% to 18% of all hospitalized patients and more than half of critically ill patients develop AKI, and mortality increases with greater AKI severity.[2,3] Despite improvements in the medical care of individuals with AKI, in-hospital mortality is greater than 40% when AKI is not resolved.[4]

Community-acquired AKI occurs outside the hospital setting. Its incidence is 20 to 200 cases per 1 million population,[2] and it accounts for 1% to 4% of hospital admissions.[5]

ETIOLOGY AND PATHOPHYSIOLOGY

There are three categories of causes of AKI that share some pathophysiologic mechanisms: prerenal, intrinsic, and postrenal AKI. Specific syndromes within these categories have unique pathophysiologic features and treatment strategies.

Prerenal AKI

Prerenal AKI occurs in approximately 10% to 25% of patients with AKI. Renal hypoperfusion can occur secondary to systemic vasodilation or intravascular volume depletion due to conditions such as hemorrhage, dehydration, GI fluid losses, and fluid depletion related to major surgery. Early preventive measures, such as fluid resuscitation, can prevent progression and improve recovery because it can restore renal blood flow before structural kidney damage occurs.[4] Conditions of reduced cardiac output (eg, heart failure [HF], myocardial infarction) can decrease effective circulation or increase central venous pressure. Sepsis and liver disease can also reduce effective circulatory blood flow, resulting in decreased glomerular perfusion and prerenal AKI.[4]

Drugs may cause a functional AKI when they interfere with autoregulatory mechanisms in the glomerulus. This often occurs when the offending drugs are administered to patients dependent on autoregulation to maximize intraglomerular pressure (ie, dilation of afferent arterioles [arteries supplying blood to the glomerulus] or constriction of efferent arterioles [arteries removing blood from the glomerulus]). Nonsteroidal anti-inflammatory drugs (NSAIDs) interfere with prostaglandin-mediated dilation of afferent arterioles, resulting in decreased intraglomerular pressure.[6] Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) decrease intraglomerular pressure by inhibiting angiotensin II–mediated efferent arteriole vasoconstriction.[6] The calcineurin inhibitors cyclosporine and tacrolimus are potent renal vasoconstrictors, particularly in high doses. These drugs can reduce intraglomerular pressure in at-risk patients, with a resultant decrease in GFR. Prompt discontinuation of the offending drug can often return kidney function to normal.

Other causes of prerenal AKI are renovascular obstruction (eg, renal artery stenosis), hyperviscosity syndromes (eg, multiple myeloma), and systemic vasoconstriction (eg, hepatorenal syndrome).

Intrinsic AKI

Intrinsic renal failure is caused by diseases that can affect the nephron structure, such as the tubules, glomerulus, interstitium, or blood vessels. Acute tubular necrosis (ATN) is a term that is often used synonymously with intrinsic AKI but relates more specifically to necrosis of tubular epithelial cells resulting from nephrotoxins (eg, aminoglycosides, contrast agents, amphotericin B), sepsis, or ischemia. ATN accounts for 50% of all cases of AKI.[7] In addition, prerenal AKI can progress to intrinsic AKI if the underlying cause is not promptly corrected.

Glomerular, interstitial, and blood vessel diseases may also lead to intrinsic AKI but occur with a much lower incidence. Examples include glomerulonephritis, systemic lupus erythematosus, acute interstitial nephritis, and vasculitis.

Postrenal AKI

Postrenal AKI is due to obstruction of urinary outflow and increased intratubular pressure, impaired renal blood flow, and inflammation. Causes include benign prostatic hyperplasia, pelvic tumors, and precipitation of renal calculi.[7] Rapid resolution of postrenal AKI without structural kidney damage can occur depending on the severity of the obstruction and if the underlying obstruction is promptly corrected. Postrenal AKI accounts for less than 10% of AKI cases.

CLINICAL PRESENTATION AND DIAGNOSIS

The definition and categorization of AKI has evolved over the past decade. The most widely accepted AKI classification is from the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guidelines for Acute Kidney Injury (Table 26–1).[1] The KDIGO definition is based on either an increase in SCr or a decrease in urine output and includes 3 stages. Stage 1 includes either a 1.5 to 1.9 increase in SCr from baseline within 7 days or an absolute increase in SCr of 0.3 mg/dL (27 μmol/L) over 48 hours. Thus, even small increases in SCr indicate AKI, and this highlights the importance of early detection.

Decreased urine output may be a more sensitive marker than increased SCr in early AKI; however, urine output will not always be decreased. Oliguria and anuria are defined as daily urine outputs of less than 400 mL and 50 mL, respectively. Reduced urine output is associated with increased mortality and may represent a more severe form of AKI.

As kidney function declines, SCr and blood urea nitrogen (BUN) rise. Monitoring SCr and BUN and comparing them to baseline values can help determine if a patient's kidney function is worsening or improving. BUN is a less sensitive marker for evaluation of AKI than SCr. Urea is a product of amino acid metabolism; other conditions that can increase BUN are excessive protein intake and GI bleeding (because of blood breakdown to amino acids in the gut). Although urea is eliminated via glomerular filtration, it also undergoes significant reabsorption in the proximal tubules. Increased urea reabsorption occurs at lower urine flow rates, such as that which occurs in prerenal AKI, leading to increased BUN through enhanced reabsorption. In comparison, creatinine does not undergo reabsorption and is not affected by a low urine flow rate; thus, an increase in the ratio of BUN to Scr in the blood (> 20:1; when both are expressed in mg/dL) occurs in prerenal AKI because urea is preferentially reabsorbed compared to creatinine. A BUN:SCr ratio greater than 20 can assist in diagnosing prerenal AKI.

Some clinical and laboratory findings assist in the diagnosis of AKI, whereas others are used to differentiate between prerenal, intrinsic, and postrenal AKI. For example, patients with prerenal AKI typically demonstrate enhanced sodium reabsorption, which is reflected by a low urine sodium concentration and a low fractional excretion of sodium (FENa). The FENa is calculated by the following equation:

$$\text{Fractional excretion of sodium (FENa)} =$$

$$100 \times \frac{(\text{Urinary sodium concentration} \times \text{Plasma creatinine concentration})}{(\text{Plasma sodium concentration} \times \text{Urinary creatinine concentration})}$$

FENa is a measure of the percentage of sodium excreted by the kidney. Ordinarily, 1% to 2% of sodium intake is excreted by the kidneys. A FENa less than 1% may indicate prerenal AKI because it represents the response of the kidney to decreased renal perfusion by enhancing sodium reabsorption. Loop diuretics such as furosemide enhance sodium excretion and increase FENa and can limit the utility of this parameter in patients treated with loop diuretics.

Urine is typically more concentrated with prerenal AKI, and there is a higher urine osmolality and BUN-to-Scr ratio (> 20:1 for units of mg/dL) compared to intrinsic and postrenal AKI. Other factors, such as patient symptoms, laboratory test results, urinary indices, and results of diagnostic procedures, aid in the diagnosis and assessment of disease severity.

Early Detection of AKI

SCr lacks sensitivity in detecting AKI; thus, identifying novel biomarkers that identify stress and that are released within hours of injury would aid in early detection of AKI.[8] Nephrocheck is a commercially available point-of-care test for critically ill patients with cardiovascular or respiratory compromise that measures urine concentrations of insulin growth factor (IGF)-binding protein 7 and tissue inhibitor of metalloproteinase-2. The test identifies stress to the kidney and provides a positive risk score to indicate risk for moderate-to-severe kidney injury within 12 hours.[9] A positive score could trigger an early nephrology consult, avoidance of nephrotoxic medications, fluid resuscitation, and other therapies to prevent progression.

The furosemide stress test is being investigated to predict the development of Stage 3 AKI in early AKI. Initial studies have

Table 26–1

Staging System for AKI

Stage	Change in Serum Creatinine from Baseline		Urine Output	Need for Renal Replacement Therapy
1	0.3 mg/dL (27 μmol/L) or greater increase from baseline	150%–199% (1.5–1.9-fold)	Less than 0.5 mL/kg/hour for 6–12 hours	No
2	—	200%–299% (2–2.9-fold)	Less than 0.5 mL/kg/h for 12 hours or longer	No
3	Increase to 4 mg/dL (354 μmol/L) or greater	300% or greater (greater than 3-fold)	Less than 0.3 mL/kg/hour for 24 hours or anuria for > 12 hours	Initiation of renal replacement therapy indicates stage 3 regardless of serum creatinine or urine output

Based on the KDIGO staging system for AKI. Only one of the three criteria needs to be met to qualify for the higher stage.

found that a urine volume of less than 200 mL at 2 hours following a one-time furosemide dose of 1 mg/kg in furosemide-naïve patients or 1.5 mg/kg in patients with prior furosemide exposure is predictive of severe AKI.[10] Additional studies to validate the test, used alone and in combination with other biomarker tests, are needed to aid in the early detection of AKI.

Early alert systems in electronic health records that flag patients with an increase in SCr from baseline for nephrology consultation

Clinical Presentation and Diagnosis of AKI

Clinical presentation is variable depending on the etiology. A clinician must interpret kidney function in combination with the clinical picture. Listed below are symptoms and other findings that may occur in AKI. A clinical presentation that reflects volume depletion may occur with patients in prerenal AKI, while symptoms of volume overload may occur with intrinsic AKI.

Symptoms of AKI

Nonspecific

- Decreased urination
- Nausea, vomiting, diarrhea, anorexia
- Fatigue
- Pruritus

More specific

- Orange, concentrated urine (prerenal AKI)
- Weight loss (prerenal AKI)
- Brown urine (may indicate blood in the urine associated with acute glomerulonephritis)
- Weight gain (several pounds over a few days may indicate fluid retention)
- Shortness of breath (may indicate fluid retention)
- Anuria alternating with **polyuria** (postrenal AKI)
- Colicky abdominal pain radiating from flank to groin (postrenal AKI)

Physical Examination Findings

Nonspecific

- Change in mental status

More specific

- Hypotension or orthostatic hypotension (prerenal AKI)
- Rash (intrinsic AKI due to acute interstitial nephritis)
- Bladder distention (postrenal bladder outlet obstruction)
- Prostatic enlargement (postrenal AKI)

Findings suggesting fluid overload

- Increased blood pressure
- Peripheral edema
- Jugular venous distention (JVD)
- Pulmonary edema
- Crackles
- Asterixis
- Pericardial or pleural friction rub

Laboratory Tests

- Elevated SCr (reference range ~0.6–1.2 mg/dL [53–106 μmol/L])
- Elevated BUN (reference range ~8–25 mg/dL [2.9–8.9 mmol/L])
- BUN:SCr ratio greater than 20:1 for units of mg/dL (prerenal AKI); (100:1 for units of μmol/L)
- Hyperkalemia
- Metabolic acidosis

Urinalysis

- Sediment
- Scant or bland (prerenal or postrenal AKI)
- Brown, muddy granular casts (intrinsic ATN)
- Proteinuria (glomerulonephritis or allergic interstitial nephritis)
- Eosinophiluria (acute interstitial nephritis)
- Hematuria or red blood cell casts (glomerular disease or bleeding in urinary tract)
- WBCs or casts (acute interstitial nephritis or severe pyelonephritis)

Urinary Indices	Prerenal AKI	Intrinsic and Postrenal AKI
Urine osmolality (solute concentration in the urine in mOsm/kg or mmol/kg)	Greater than 500	Less than 350
Urine sodium concentration (mEq/L or mmol/L)	Less than 20	Greater than 40
Specific gravity	Greater than 1.020	Less than 1.015
Urine-to-plasma creatinine ratio	Greater than 40:1	Less than 20:1
Fractional excretion of sodium (FENa)	Less than 1%	Greater than 1%–2%

Diagnostic Procedures

- Urinary catheterization is performed to rule out urethral obstruction; increased urine output may occur if postrenal obstruction is present.
- Renal ultrasound can assist in differentiating AKI (normal-sized kidneys) from CKD (small kidneys). It can also show urinary tract obstruction and **hydronephrosis**, which indicates postrenal AKI.
- Computed tomography (CT) provides similar information as renal ultrasound but with greater spatial resolution. It assists in diagnosing masses, stones, and pyelonephritis.
- Magnetic resonance imaging (MRI) can be an alternative to CT scanning to avoid administering radiocontrast media.
- Renal angiography can be useful in identifying conditions such as renal artery stenosis and renal vein thrombosis.
- **Retrograde pyelography** is used to localize the site of urinary tract obstruction.
- Kidney biopsy may aid in the diagnosis of glomerular and interstitial diseases.

may also improve early detection of AKI and ultimately improve patient outcomes.[11]

TREATMENT

Desired Outcomes

A primary goal in caring for patients with AKI is ameliorating identifiable underlying causes of AKI such as hypovolemia, nephrotoxic drugs, or ureter obstruction. Prerenal and postrenal AKI can be reversed if the underlying problem is promptly identified and corrected, whereas treatment of intrinsic renal failure is primarily supportive until kidney function recovers. **KEY CONCEPT** There is no evidence that drug therapy hastens patient recovery, decreases length of hospitalization, or improves survival in intrinsic AKI.

Pharmacologic Therapy

▶ *Hydration in Patients with Hypovolemia*

Isotonic crystalloid solutions such as 0.9% normal saline and balanced crystalloid solutions (eg, Lactated Ringer's, Normosol-R, Plasma-Lyte A) are used to expand intravascular volume and return volume status to neutral fluid balance (euvolemia) in volume depleted patients.[12] Crystalloids are preferred over colloidal solutions (eg, albumin, hydroxyethyl starch) for fluid resuscitation.[12] Albumin is just as effective as crystalloids but is more costly. Hydroxyethyl starch has a risk for kidney injury, and the FDA issued a black box warning against its use in critically ill patients.

Crystalloid solutions vary in pH and chloride composition as indicated in Table 26–2.

The chloride concentration in normal saline is significantly higher than that of the plasma and can cause hyperchloremic metabolic acidosis. High chloride concentrations in the distal tubule may induce tubuloglomerular feedback, where the kidney interprets the distal tubule chloride load as an increase in GFR and responds by decreasing renal blood flow.

Normal saline may be associated with greater adverse effect on the kidney compared to the balanced crystalloid solutions. Normal saline was associated with a small, but significant, higher final SCr compared to a group that received balanced crystalloid solutions.[13] Although the cost of balanced crystalloid solutions is roughly double that of normal saline, evidence from these studies favor their use.

Caution must be taken with hydration because overzealous fluid resuscitation can result in pulmonary edema, increased postoperative complications, and ultimately, increased mortality.[14] Some evidence suggests that too much fluid can worsen AKI; thus, the goal of treatment is to return to a state of euvolemia or slightly negative fluid balance.[14] Blood transfusions may be indicated when there is acute blood loss.

In addition to fluids, vasopressors (ie, norepinephrine, dopamine, vasopressin) may be needed in patients with shock to restore adequate organ perfusion. There are no definitive data to support one agent as superior over another; however, more arrhythmic events have been reported with dopamine than with norepinephrine.[15]

Table 26–2

pH and Chloride Content of Various Replacement Fluids

Fluid	Chloride Content	pH
0.9% normal saline	154 mEq/L	5.5
Balanced electrolyte solution in water (eg, Plasma-Lyte A, Normosol-R)	98 mEq/L	7.4
Lactated Ringer's solution	109 mEq/L	6.5

▶ *Loop Diuretics in Patients with Volume Overload*

Most studies evaluating loop diuretics (eg, furosemide, bumetanide, torsemide, and ethacrynic acid) for preventing or treating AKI demonstrated improved urine output but no improvement in survival or need for dialysis.[16] There are some reports that loop diuretics may worsen kidney function and may be harmful if given for prevention of AKI. Thus, loop diuretics should be reserved for treating volume overload and should not be given to prevent AKI or hasten recovery of kidney function in euvolemic or hypovolemic individuals.[17]

Although bumetanide and torsemide are more potent than furosemide on a weight basis, all loop diuretics are equally effective in fluid removal when given in equipotent IV doses (40 mg furosemide = 10–20 mg torsemide = 1 mg bumetanide).

Patient Encounter Part 1

A 62-year-old man presents to the clinic with complaints of pain in the back of his left leg. In addition, he has increased dizziness and drowsiness and has "generally not been feeling well" over the past week. He has a past medical history of stage 2 chronic kidney disease (CKD) with proteinuria (baseline SCr 1.3 mg/dL [115 µmol/L]), hypertension, depression, and obesity. He reports that he has been trying to make lifestyle changes to better manage his medical problems, including dieting, vigorous walking to lose weight, and using a pill organizer to ensure he doesn't miss doses of his medications. He went to a walk-in urgent care medical clinic 1 week ago for left leg pain. He was diagnosed with Achilles tendonitis secondary to power walking. He received a boot to immobilize his left foot and was started on naproxen for pain and inflammation. Today, he states that his left foot feels better in the boot after wearing it for 7 days, but he has little energy, he has been going to the bathroom less often, and his urine is dark. His weight is usually 220 pounds (100 kg), and today he weighs 215 lb (97.5 kg). His blood pressure was 115/60 and heart rate was 118 beats per minute.

Current Medications:

Losartan 100 mg orally once daily
Furosemide 40 mg orally twice daily
Simvastatin 40 mg orally daily in the evening
Metformin 500 mg orally twice daily
Glyburide 5 mg orally daily
Metoprolol 25 mg orally twice daily
Paroxetine 20 mg orally daily
Naproxen 275 mg orally every 8 hours as needed for pain and inflammation

What information is suggestive of acute kidney injury (AKI)?

What risk factors does he have for developing AKI?

What additional laboratory information do you need to fully assess the patient?

What additional information would you elicit from him regarding his pharmacotherapy before creating a treatment plan?

Therefore, selection is based on the side-effect profile, cost, and pharmacokinetic differences. Ototoxicity is a well-established side effect of ethacrynic acid and limits its use; it occurs rarely with bumetanide and torsemide. The risk of ototoxicity with furosemide is significant when administered by the IV route at a rate exceeding 4 mg/min. Bioavailability is lower and more variable for furosemide compared to bumetanide and torsemide; therefore, the IV-to-oral ratio for furosemide is about 1:2.[18] Furosemide, bumetanide, and torsemide all contain a sulfa moiety; however, a previous sulfonamide antimicrobial allergy does not prohibit loop diuretic administration. In the rare instance of a sulfonamide-like allergic reaction to one of the commonly used loop diuretics, ethacrynic acid could be given because it does not contain a sulfa moiety.

Loop diuretics exert their effect from the luminal (urinary) side of the tubule. Decreased tubular secretion of loop diuretics occurs in kidney disease and reduces drug concentration at the active site in the tubule lumen. Therefore, large doses of loop diuretics are often necessary in kidney disease to ensure that adequate drug reaches the nephron lumen. Loop diuretics also have a ceiling effect where maximal **natriuresis** occurs.[19] Thus, very large doses of furosemide (eg, 1 g) are not necessary and may unnecessarily increase the risk of ototoxicity.

Several adaptive mechanisms by the kidney limit effectiveness of loop diuretic therapy. As the concentration of diuretic in the loop of Henle decreases, postdiuretic sodium retention can occur. This effect can be minimized by decreasing the dosage interval (ie, dosing more frequently) or by administering a continuous IV infusion.[18]

Prolonged administration of loop diuretics can lead to a second type of diuretic resistance. Hypertrophy of distal convoluted tubule cells can occur because of enhanced sodium delivery to the distal tubule.[19] Subsequently, increased sodium chloride absorption occurs in the distal tubule, which diminishes the effect of the loop diuretic on overall sodium excretion. Combining a distal convoluted tubule diuretic, such as metolazone or hydrochlorothiazide, with a loop diuretic can result in a synergistic increase in urine output. There are no data demonstrating greater efficacy of one distal convoluted tubule diuretic over another. It is common practice to administer these diuretics 30 to 60 minutes prior to the loop diuretic to inhibit sodium reabsorption at the distal convoluted tubule first. However, the effectiveness of this strategy has not been studied.

KEY CONCEPT Loop diuretics are the diuretics of choice for managing volume overload in AKI. The usual starting dose of IV furosemide for treatment of AKI ranges from 40 to 80 mg (Figure 26–1). Reasonable starting doses for bumetanide and torsemide are 1 and 20 mg, respectively.[19] Efficacy of diuretic administration can be determined by assessing a patient's hourly fluid balance. Other methods to minimize volume overload, such as fluid restriction and concentration of IV medications, should be initiated as needed. If urine output does not increase to about 1 mL/kg/hour, the diuretic dosage can be increased to a ceiling dose of 160 to 200 mg of furosemide or its equivalent (Figure 26–1). Dosing frequency is based on the patient's response, the ability to restrict sodium intake, and the duration of action of the diuretic. Methods to improve diuresis can be initiated sequentially, such as (a) shortening the dosing interval, (b) adding hydrochlorothiazide or metolazone, and (c) switching to a continuous infusion. Continuous infusion loop diuretics may be easier to titrate than bolus dosing, require less nursing administration time, and lead to fewer adverse reactions. The hemodynamic and fluid status of the patient should be monitored closely when loop diuretics are administered in high doses or with a continuous infusion, particularly in combination with distal convoluted tubule diuretics. Additionally, the electrolyte status of the patient should be monitored at least daily to prevent profound diuresis and electrolyte abnormalities, such as hypokalemia.

▶ *Other Agents*

Thiazide diuretics, when used as single agents, are generally not effective for fluid removal in patients with AKI. Mannitol is also not recommended for treating volume overload associated with AKI. In patients with renal dysfunction, mannitol excretion is decreased, resulting in expanded blood volume and hyperosmolality. Potassium-sparing diuretics, which inhibit sodium reabsorption in the distal nephron and collecting duct, are not sufficiently effective in removing fluid. In addition, they increase the risk of hyperkalemia in patients already at risk.

Low-dose dopamine, in doses ranging from 0.5 to 3 mcg/kg/min, predominantly stimulates dopamine-1 receptors, leading to renal vasodilation and increased renal blood flow. Although this effect has been substantiated in healthy euvolemic individuals with normal kidney function, there are no conclusive efficacy data in patients with AKI. Thus, it is not indicated for treatment of AKI. Fenoldopam, a selective dopamine-1 receptor agonist, lacks convincing data to support its use and it is not recommended for prevention or treatment of AKI.[1]

Nonpharmacologic Treatment

▶ *Renal Replacement Therapy*

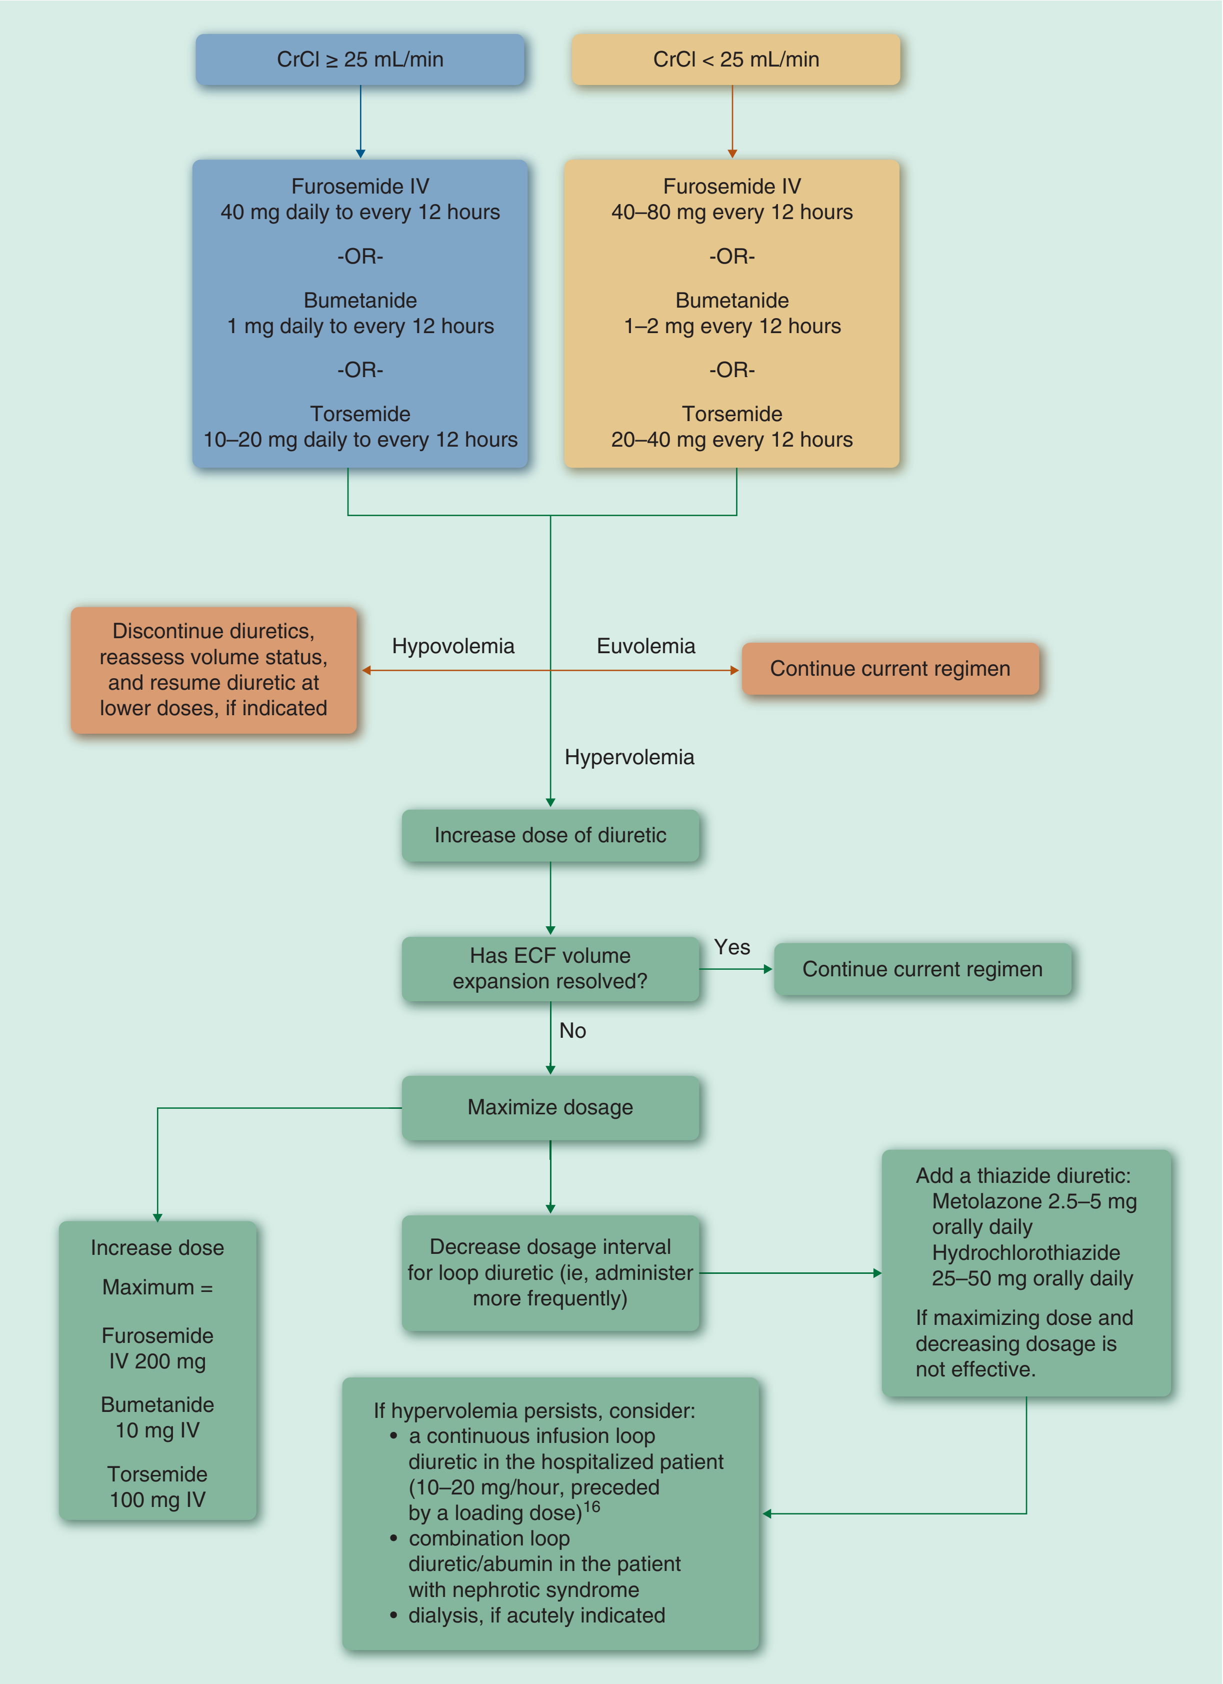
RRT may be necessary in patients with established AKI to treat pulmonary edema and volume overload that is unresponsive to diuretics, minimize accumulation of nitrogenous waste products, and correct electrolyte and acid–base abnormalities (eg, hyperkalemia, metabolic acidosis) while renal function recovers. There is wide variation in practice on indications for RRT, timing of initiation and discontinuation of RRT, intensity of treatment, and optimal type of RRT. Common criteria include:

- Anuria or severe oliguria
- Potassium greater than 6.5 mEq/L (mmol/L)
- Metabolic acidosis with a pH less than 7.2
- Pronounced elevations in BUN and SCr
- Symptoms of uremia
- Diuretic-resistant fluid overload.[20]

Approximately 10% to 30% of patients with AKI treated with RRT will not have recovery of kidney function and will need to remain on long-term dialysis.[21]

Two types of RRT modalities are used in AKI: intermittent hemodialysis (IHD) and continuous renal replacement therapy (CRRT). IHD is a higher efficiency form of dialysis that results in fluid removal by ultrafiltration and solute removal by diffusion that is provided for several hours a day at a variable frequency (usually daily or three to five times per week). CRRT is a form of dialysis that provides slow fluid and/or solute removal on a continuous (up to 24 hours) basis. The characteristics of the different types of CRRTs and their associated fluid and solute removal are described In Table 26–3.

The primary advantage of CRRT is hemodynamic stability and better volume control, particularly in patients who are unable to tolerate rapid fluid removal. The primary disadvantages of CRRT are continuous nursing requirements, the potential need for continuous anticoagulation, frequent clotting of the dialyzer, patient immobility, and increased cost. There is no conclusive evidence



CrCl ≥ 25 mL/min
CrCl < 25 mL/min
Furosemide IV
40 mg daily to every 12 hours
-OR-
Bumetanide
1 mg daily to every 12 hours
-OR-
Torsemide
10–20 mg daily to every 12 hours
Furosemide IV
40–80 mg every 12 hours
-OR-
Bumetanide
1–2 mg every 12 hours
-OR-
Torsemide
20–40 mg every 12 hours
Discontinue diuretics, reassess volume status, and resume diuretic at lower doses, if indicated
Hypovolemia
Euvolemia
Continue current regimen
Hypervolemia
Increase dose of diuretic
Has ECF volume expansion resolved?
Yes
Continue current regimen
No
Maximize dosage
Increase dose
Maximum =
Furosemide IV 200 mg
Bumetanide 10 mg IV
Torsemide 100 mg IV
Decrease dosage interval for loop diuretic (ie, administer more frequently)
Add a thiazide diuretic:
Metolazone 2.5–5 mg orally daily
Hydrochlorothiazide 25–50 mg orally daily
If maximizing dose and decreasing dosage is not effective.
If hypervolemia persists, consider:
• a continuous infusion loop diuretic in the hospitalized patient (10–20 mg/hour, preceded by a loading dose)16
• combination loop diuretic/abumin in the patient with nephrotic syndrome
• dialysis, if acutely indicated

FIGURE 26–1. Algorithm for treatment of extracellular fluid expansion. (CrCl, creatinine clearance; ECF, extracellular fluid; HCTZ, hydrochlorothiazide; po, oral.)

Table 26–3

Modalities for Continuous Renal Replacement Therapy

		Technique		Process of Solute Removal		
Type of CRRT	Abbreviation	Filtration	Dialysis	Convection	Diffusion	Description
Slow **C**ontinuous **U**ltra**f**iltration	SCUF	√		√ (limited)		Low rate of fluid removal without significant solute removal.
Continuous **V**eno**v**enous **H**emofiltration	CVsH	√		√		Higher rate of fluid removal and solute removal (small and large molecule).
Continuous **V**eno**v**enous **H**emo**d**ialysis	CVsHD		√		√	Diffusive removal of solutes (small molecule) with limited fluid removal.
Continuous **V**eno**v**enous **H**emo**d**ia**f**iltration	CVsHDF	√	√	√	√	Fluid removal and removal of solutes (small and large molecule) via diffusion (dialysis).

that one type of dialysis is preferred over another in terms of mortality and recovery of renal function. Thus, selection of dialysis type is often governed by the critical illness of the patient and by the comfort level of the institution with one type of dialysis. KDIGO Clinical Practice Guidelines suggest CRRT in hemodynamically unstable patients.[1] Mortality in critically ill patients receiving CRRT is 44% to 65%.[22]

▶ *Supportive Therapy*

Supportive therapy in AKI includes adequate nutrition, correction of electrolyte and acid–base abnormalities (particularly hyperkalemia and metabolic acidosis), fluid management, and correction of any hematologic abnormalities. Because AKI can be associated with multiorgan failure, treatment may include medical management of infections, cardiovascular and GI conditions, and respiratory failure. See Table 26–4 for treatment of electrolyte abnormalities in AKI.

Historically, patients were often placed on a protein-restricted diet to avoid the production of uremic toxins and minimize the rise in BUN. However, adequate protein intake should be administered to maintain metabolic balance. Protein intake of 0.8 to 1 g/kg/day is recommended in patients with AKI who are not undergoing dialysis, and higher protein intake in patients undergoing RRT or who are hypercatabolic.[1] Some studies have shown

Patient Encounter Part 2: Medical History and Physical Examination

PMH: Type 2 diabetes mellitus for 15 years (labs from 3 months ago: A1C 7.7% [0.077; 61 mmol/mol Hb], SCr 1.3 mg/dL [115 μmol/L])

Dyslipidemia for 10 years

Hypertension for 20 years

Depression for 5 years

Obesity

FH: Father with history of type 2 diabetes and CKD; mother with history of hypertension

SH: No smoking, no alcohol use

PE:

VS: BP 115/60 mm Hg, pulse 118 bpm, RR 15/min, temperature 99.5°F (37.5°C), weight 97.5 kg (215 lb), ht 5′11″ (180 cm)

Chest: lungs clear to auscultation and percussion

CV: RRR, S_1 and S_2, normal

MS/Ext: Achilles tendon swollen and red 6 cm from its insertion on to the back of the heel bone

Urinalysis: Color, dark yellow; character, cloudy; glucose (–); ketones (–); specific gravity 1.022; pH 5; (+) protein; no bacteria; nitrite (–); blood (–); osmolality 525 mOsm/kg (mmol/kg); urinary sodium 15 mEq/L (mmol/L); creatinine 86 mg/dL (7602 μmol/L)

Laboratory values: Sodium 137 mEq/L (mmol/L), potassium 5.1 mEq/L (mmol/L), chloride 104 mEq/L (mmol/L), bicarbonate 21 mEq/L (mmol/L), BUN 47 mg/dL (16.8 mmol/L), SCr 1.9 mg/dL (168 μmol/L), magnesium 1.6 mg/dL (0.66 mmol/L), glucose 118 mg/dL (6.5 mmol/L), WBC 7.9 × 10^3/mm^3 (7.9 × 10^9/L), hemoglobin 14.3 g/dL (143 g/L; 8.88 mmol/L), hematocrit 41.5% (0.42).

Interview information: Patient takes all his medications as prescribed. He has been taking them for years, except for naproxen. He started taking it for Achilles tendonitis 8 days ago and has been taking it around the clock. He says it upsets his stomach, and he feels he has not been eating and drinking as much in the past week. He has also vomited on several occasions. He states he has been taking it on an empty stomach. He checks his fasting glucose each morning, and it ranges from 110 to 125 mg/dL (6.1–6.9 mmol/L). He also checks it in the afternoon, and it runs low 4 to 5 times per week (in the range of 60–70 mg/dL [3.3–3.9 mmol/L]). He checks his blood pressure several times a week and it is usually in the range of 140 to 150/80 to 90 mm Hg.

Given this additional information, what is your assessment of the patient's condition?

Identify your treatment goals for the patient.

Table 26–4

Treatment of Electrolyte Abnormalities in AKI

Hyperkalemia	• Restrict dietary potassium intake. • Discontinue potassium-sparing diuretics, ACE inhibitors, ARBs, NSAIDs. • Loop diuretics to promote urinary potassium loss. • Potassium binding ion-exchange resin (sodium polystyrene sulfonate, sodium zirconium cyclosilicate, patiromer) for non–life-threatening treatment. • Insulin (10 units regular) and glucose (50 mL of 50% dextrose) to promote entry of potassium intracellularly. • Inhaled beta-agonists therapy to promote entry of potassium intracellularly. • Calcium gluconate or calcium chloride (1 g) to stabilize the myocardium. • Renal replacement therapy.
Metabolic Acidosis	• Sodium bicarbonate (if pH < 7.2 to keep serum bicarbonate > 15 mEq/L [mmol/L]). • Renal replacement therapy.
Hyperphosphatemia	• Restrict dietary phosphate intake. • Phosphate binding agents (calcium acetate, sevelamer hydrochloride—taken with meals).
Hypocalcemia	• Calcium carbonate or calcium gluconate if symptomatic.
Hypermagnesemia	• Discontinue magnesium-containing antacids.

a beneficial effect of tight glycemic control in decreasing the incidence and severity of AKI, whereas others have shown a higher incidence of hypoglycemia. Thus, glycemic control in the range of 110 to 149 mg/dL (6.1–8.3 mmol/L) is recommended.[1]

PREVENTION OF ACUTE KIDNEY INJURY

KEY CONCEPT It is critically important to identify patients at high risk for developing AKI and to implement preventive methods to decrease its occurrence or severity.

Avoidance of Nephrotoxic Medications

The best preventive measure for AKI, especially in high-risk individuals, is to avoid medications known to precipitate AKI. Drug therapy may contribute to AKI in about 20% of cases.[20] Nephrotoxicity is a significant side effect of aminoglycosides, ACE inhibitors, ARBs, amphotericin B, NSAIDs, calcineurin inhibitors, and radiographic contrast agents.[20] It is also reported with cisplatin, carboplatin, antiviral agents (acyclovir, foscarnet, tenofovir, indinavir), and vancomycin (particularly when combined with piperacillin-tazobactam).[6,23] Unfortunately, an effective, nonnephrotoxic alternative may not always be appropriate for a given patient, and the risks and benefits of selecting a drug with nephrotoxic potential must be considered. For example, serious gram-negative infections may require double antibiotic coverage, and an aminoglycoside may be necessary based on culture and sensitivity reports. Monitoring of serum aminoglycoside concentrations is warranted in these situations.

▶ *Drug-Induced AKI*

Aminoglycosides Aminoglycosides (gentamicin, tobramycin, and amikacin) cause nonoliguric intrinsic AKI in about 10% to 25% of treated patients.[6] Injury is due to binding of positively charged aminoglycoside molecules to negatively charged phospholipids in proximal tubular epithelial cells within the renal cortex, cellular uptake with formation of reactive oxygen species, and alterations in cell membrane transporters and cell death.[24] Gentamicin, tobramycin, and amikacin have comparable nephrotoxicity; thus, similar precautions should be used for all of the agents. Risk factors for aminoglycoside-induced AKI include high cumulative drug exposure, prolonged course of therapy (typically after 7–10 days), preexisting CKD, increased age, and concurrent administration of other nephrotoxic drugs. There is conflicting evidence as to whether the combination of vancomycin and an aminoglycoside increases the risk of AKI compared to aminoglycoside therapy alone.[23] Individualized pharmacokinetic monitoring to achieve specific serum concentrations or alternative antibiotics should be selected in individuals at high risk for developing AKI.

Traditional aminoglycoside dosing entails a loading dose followed by multiple daily doses (eg, gentamicin 1–2.5 mg/kg IV every 8 hours). Methods to minimize drug exposure with traditional dosing include maintaining trough concentrations less than 2 mcg/mL (mg/L; 4.2 µmol/L) for gentamicin and tobramycin and less than 10 mcg/mL (mg/L; 17.1 µmol/L) for amikacin, minimizing length of therapy, avoiding repeated courses of aminoglycosides, and minimizing concurrent exposure to other nephrotoxic medications. Renal recovery occurs in about half of patients.[25]

The principle behind extended-interval aminoglycoside administration (eg, gentamicin 5–7 mg/kg IV every 24 hours) is that large doses are given less frequently, which provides both high peak concentrations of drug that saturate proximal tubule uptake sites and a drug-free period. Once saturated, the remaining aminoglycoside molecules pass through the proximal tubule and are excreted in the urine. Thus, less drug is available for cellular uptake during a 24-hour period. Aminoglycosides also demonstrate concentration-dependent bactericidal activity, with optimal activity when the peak drug concentration is 8 to 10 times greater than the MIC.[26] Bacterial growth is also suppressed after concentrations decrease below the MIC due to its postantibiotic effect. Thus, extended-interval aminoglycoside dosing can maximize efficacy while minimizing nephrotoxicity. Extended-interval aminoglycoside dosing is as effective or superior to conventional dosing and is not more nephrotoxic; some studies have shown it to be less nephrotoxic. Extended-interval dosing is not recommended for patients with preexisting kidney disease (CrCl $<$ 20 mL/min [0.33 mL/s]), conditions where high concentrations are not needed (eg, urinary tract infections), hyperdynamic patients who may demonstrate increased drug clearance (eg, burn patients), gram-positive infections where aminoglycoside is used for synergy, suspected altered pharmacokinetics (eg, morbid obesity, significant liver disease, pregnancy), or increased risk of ototoxicity.

Amphotericin B The reported incidence of amphotericin B–induced AKI varies widely in the literature, ranging from 12% to 53% with the conventional desoxycholate formulation.[27] Nephrotoxicity is due to renal arterial vasoconstriction and renal tubule cell damage. Risk factors for development of AKI include high daily dosage, large cumulative dose ($>$ 2–3 g), preexisting kidney dysfunction, dehydration, and concomitant use of other nephrotoxic drugs. Tubular abnormalities manifesting as hypomagnesemia and hypokalemia often occur within the first 2 weeks of treatment, followed by overt development of AKI.

Three lipid-based formulations of amphotericin B have been developed in an attempt to improve efficacy and limit toxicity, particularly nephrotoxicity: (a) amphotericin B lipid complex, (b) liposomal amphotericin B, and (c) amphotericin B cholesteryl sulfate (no longer available in the United States). These formulations have a significantly lower incidence of nephrotoxicity compared to the conventional formulation.[27,28] The mechanism for decreased nephrotoxicity is thought to be due to preferential delivery of amphotericin B to the site of infection, with less affinity for cells in the kidney.[27] Costs for lipid-based formulations are significantly higher than for the conventional formulation; thus, lipid-based formulations are typically recommended for individuals with risk factors for AKI. Administration of IV normal saline (1 L during therapy) may also attenuate nephrotoxicity associated with amphotericin B.

It is unclear whether there are significant differences in nephrotoxicity among the lipid-based formulations. No differences in incidence of nephrotoxicity or other endpoints of therapy, such as new-onset dialysis, length of hospital stay, or mortality have been identified.[27,29] However, large prospective studies are needed to definitively ascertain differences in nephrotoxicity among liposomal formulations.

Radiocontrast Agents Radiocontrast agents are administered during radiologic studies and are associated with a risk of contrast-induced AKI (CI-AKI). Although definitions vary, CI-AKI is frequently defined as a rise in SCr of at least 0.5 mg/dL (44 μmol/L) or a 25% increase in SCr within 48 hours of contrast administration. More recent studies suggest that the incidence may be lower than earlier reports, and that the term "postcontrast AKI" may be more indicative when it is not clear that the nephropathy is due to the contrast agent.[30] Patient-related risk factors are CKD, diabetes, dehydration, older age, concomitant nephrotoxic drug administration, and high doses of contrast dye.[31]

Contrast agents are water-soluble, triiodinated, benzoic acid salts. Nephrotoxicity results from both ischemia and direct proximal tubule toxicity, with a resultant decrease in GFR and increased SCr within 24 to 48 hours of the damage.[32] The incidence of nephrotoxicity with ionic and nonionic agents is similar in patients at low risk for developing AKI; however, in high-risk patients, nephrotoxicity is significantly greater when high ionic, high osmolar contrast agents are used. The cost of nonionic agents is approximately 10-fold higher, and their use is usually limited to high risk patients.

Therapeutic measures to decrease the incidence of CI-AKI include extracellular volume expansion with isotonic solution, judicious use of contrast media, and use of nonionic contrast agents in high-risk patients. Treatment with oral acetylcysteine has produced mixed results. Theophylline, fenoldopam, furosemide, mannitol, dopamine, statins, vitamins C and E, and calcium antagonists have been studied but with no strong evidence that they prevent CI-AKI.[31,33]

KEY CONCEPT The most effective therapeutic maneuver to decrease the incidence of CI-AKI is extracellular volume expansion with an isotonic solution.[33] Hydration with normal saline or sodium bicarbonate is recommended.[34] Sodium bicarbonate may have the theoretical benefit of alkalinizing renal tubule fluid, which is thought to reduce the formation of oxygen free radicals. However, a large, multicenter trial found no benefit of sodium bicarbonate compared to sodium chloride, or a benefit of oral acetylcysteine over placebo at 90 days for a decrease in kidney function, need for dialysis, or death.[35] The KDIGO Clinical Practice Guidelines workgroup recommends either agent until more definitive data are available.[1] The infusion should begin from 3 to 12 hours before the procedure and continue for 6 to 12 hours afterward to achieve a urine flow rate of at least 150 mL/hour.[1] Fluid should be administered cautiously to patients with HF, left ventricular dysfunction, and significant renal dysfunction.

Because production of reactive oxygen species has been implicated in the pathophysiology of contrast-induced AKI, prophylactic administration of the antioxidant acetylcysteine has been investigated, usually in combination with hydration. Acetylcysteine doses in clinical studies ranged from 600 to 1200 mg orally every 12 hours for 2 days, with the first one or two doses administered prior to the contrast procedure. Many studies have evaluated the efficacy of oral acetylcysteine with mixed results.[36,37] The KDIGO Clinical Practice Guidelines suggest that oral acetylcysteine can be used in combination with IV fluids in patients at risk for CI-AKI due to its low risk of adverse effects and low cost.[1] However, other organizations, such as the American College of Cardiology, do not advocate its routine use.

Cyclosporine and Tacrolimus The calcineurin inhibitors cyclosporine and tacrolimus are administered as part of immunosuppressive regimens in solid organ and bone marrow transplant recipients. They are also used in autoimmune disorders such as psoriasis and multiple sclerosis. The pathophysiologic mechanism for AKI is renal afferent arteriole vasoconstriction and ATN.[38,39] AKI often occurs within the first 6 to 12 months of treatment and can be reversible with dose reduction or drug discontinuation.[38] Risk factors include high dose, elevated trough blood concentrations, increased age, and concomitant therapy with other nephrotoxic drugs.[39] Cyclosporine and tacrolimus are extensively metabolized by the liver through the cytochrome P450 3A pathway; drugs that inhibit their metabolism (eg, erythromycin, clarithromycin, fluconazole, ketoconazole, verapamil, diltiazem, nicardipine) can increase blood concentrations of cyclosporine and tacrolimus and precipitate AKI. Pharmacogenetic variability in drug absorption and metabolism can also alter blood concentrations.

Careful monitoring of cyclosporine or tacrolimus trough concentrations and maintaining them in the target range can reduce the occurrence of AKI; however, AKI can still occur with therapeutic or even low blood concentrations. Calcium channel blockers may have a renoprotective effect through dilation of afferent arterioles and are often used preferentially as antihypertensive agents in kidney transplant recipients.[40] However, the calcineurin inhibitor dose would need to be reduced to avoid high blood concentrations because of reduced metabolism.

It is often difficult to differentiate AKI from acute organ rejection in kidney transplant recipients, because the conditions may present with similar symptoms and physical examination findings. However, fever and graft tenderness are more likely to occur with rejection, whereas neurotoxicity is more likely to occur with cyclosporine or tacrolimus toxicity. Kidney biopsy is often needed to confirm the diagnosis of rejection.

ACE Inhibitors and ARBs In instances of decreased renal blood flow (eg, kidney disease, renal artery stenosis, HF, volume depletion), production of angiotensin II increases, causing efferent arteriole vasoconstriction and maintenance of glomerular capillary pressure and GFR. However, ACE inhibitors decrease angiotensin II synthesis, and ARBs block the action of angiotensin II at the receptor, which results in dilation of efferent arterioles, a reduction in glomerular capillary pressure, and decreased GFR.[6]

When initiating therapy with an ACE inhibitor or ARB for management of hypertension or prevention of CKD progression, a modest increase in SCr should be anticipated within the first week of starting therapy.[41] However, an increase of greater than 30% in patients with SCr concentrations greater than 1.4 mg/dL (124 μmol/L) and that does not plateau after several weeks of therapy suggests AKI, and the drug should be discontinued.[41] Risk factors for developing AKI are preexisting renal dysfunction, severe atherosclerotic renal artery stenosis, volume depletion, and severe HF. Discontinuation of the drug usually results in return to baseline kidney function. Initiating therapy with low doses of a short-acting agent such as captopril is recommended for patients at risk of developing AKI. If tolerated, patients can later be converted to a longer-acting agent.

Nonsteroidal Anti-inflammatory Drugs Traditional nonselective NSAIDs (eg, ibuprofen, naproxen, sulindac) and the cyclooxygenase-2 (COX-2) selective inhibitor celecoxib can cause prerenal AKI through inhibition of prostaglandin-mediated renal vasodilation.[6] Risk factors are similar to those for ACE inhibitors and ARBs. Concurrent use of NSAIDS in patients on diuretics and ACE inhibitors or ARBs results in increased risk of AKI, particularly within the first 30 days of coadministration.[42]

The onset of AKI is often within days of initiating therapy, and patients typically present with oliguria, which is usually reversible with drug discontinuation. COX-2 selective inhibitors and traditional nonselective NSAIDs pose similar risk for AKI.

Drug-induced Acute Interstitial Nephritis Unexplained AKI with a temporal relationship to new drug therapy may be due to acute interstitial nephritis. A variety of drugs have been implicated, most commonly penicillin and cephalosporin antibiotics, NSAIDs, and proton pump inhibitors. Less than 10% of patients will present with nonrenal symptoms such as rash, fever, and eosinophilia, making the diagnosis difficult.[43] A kidney biopsy may aid in the diagnosis. Primary treatment is discontinuation of the offending drug. In addition, limited evidence suggests that early treatment with corticosteroids may hasten recovery.[43] However, this is supported primarily with case reports and nonrandomized studies. Potential benefits of corticosteroids must be weighed against risks, such as hyperglycemia in patients with diabetes or an increased risk of infection.

OUTCOME EVALUATION

Goals of therapy are to maintain a state of euvolemia with good urine output (at least 0.5–1 mL/kg/hour), to return SCr to baseline, and to correct electrolyte and acid-base abnormalities. Additional goals include appropriate drug dosages based on kidney function and avoidance of nephrotoxic drugs. Assess vital signs, weight, fluid intake, urine output, BUN, creatinine, and electrolytes daily in unstable patients.

Patient Encounter Part 3: Follow-Up

The patient is admitted to the hospital for treatment of AKI.

Based on the information available, create a care plan for this patient's AKI and provide overall recommendations for his drug therapy. The plan should include (a) a statement of the drug related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

In patients with volume overload, monitoring includes body weight changes, fluid input compared to urine output, signs of pulmonary and peripheral edema, and blood pressure.

DRUG DOSING CONSIDERATIONS IN AKI

Assessment of Kidney Function

Appropriate drug dosing in kidney disease requires an accurate assessment of kidney function. The best index of overall kidney function is GFR. Defined as the volume of plasma filtered across the glomerulus per unit time, GFR correlates with the excretory, endocrine, and metabolic functions of the kidney. The CrCl is routinely used as a measure of kidney function for purposes of drug dosing; however, equations to estimate CrCl (eg, Cockcroft–Gault equation) are not accurate or reliable in AKI, particularly in critically ill patients because they tend to overestimate CrCl.[44,45] Use of such equations should be limited to instances when SCr is at steady state, with no more than a 10% to 15% change in SCr within 24 hours. Measurement of 24-hour urinary creatinine clearance may be more accurate and is calculated by the following formula:

$$\text{Measured CrCl (mL/min)} = \frac{[\text{Urine creatinine concentration (mg/dL)} \times \text{urine volume (mL)}]}{[\text{Plasma creatinine concentration (mg/dL)} \times \text{time (minutes)}]}$$

or

$$\text{Measured CrCl (mL/s)} = \frac{[\text{Urine creatinine concentration } (\mu\text{mol/dL}) \times \text{urine volume (mL)}]}{[\text{Plasma creatinine concentration } (\mu\text{mol/dL}) \times \text{time (seconds)}]}$$

As part of kidney function test results, many laboratories report an estimated GFR (eGFR), typically calculated from the Modification of Diet in Renal Disease Study (MDRD) equation. However, the equation has not been validated in AKI. This estimation is not accurate in AKI because non–steady-state conditions for SCr are present, leading to inaccurate estimates.

Factors Influencing Drug Dosing in AKI

Determining the optimal dose of drugs in AKI is challenging. A variety of factors influence drug dosing, such as (a) alterations in drug pharmacokinetics that occur during AKI, (b) difficulties in accurately quantifying kidney function in AKI, (c) the influence of intermittent or continuous RRT on drug clearance, and (d) challenges in interpreting information from the literature and applying it to a specific patient. See Table 26–5 for a more complete list of considerations when dosing medications in patients with AKI.

For drugs with a narrow therapeutic window, serum drug concentration monitoring may be available to guide drug dosing. If this is not available, dosing based on an eGFR is recommended, with frequent reassessment of kidney function and evaluation of the patient's status to assess efficacy and adverse effects of therapy. Selection of a drug with hepatic elimination rather than renal excretion is a reasonable alternative, if possible.

In critically ill septic patients, interpatient variability in pharmacokinetics renders dosing of antibiotics difficult. Underdosing a critically ill patient may be a greater risk than potential adverse effects attributed to higher plasma concentrations, particularly with antibiotics such as beta lactams, quinolones, and carbapenems, for which therapeutic drug monitoring is not available.[46] Thus, the risk of undertreatment of the infection needs to be balanced with the risk of adverse effects from the antimicrobial agent.

Table 26–5

Drug Dosing Considerations in AKI

Alteration in drug pharmacokinetics	• Increase in volume of distribution due to fluid retention may occur. • Reduction in excretion of both drugs and metabolites eliminated by the kidney. • Nonrenal clearance of some drugs may be reduced.
Difficulty in quantifying an accurate assessment of kidney function in AKI	• Cockcroft–Gault and MDRD equations are not meant for AKI population; equations are based on a single SCr. • SCr as a marker for kidney function is influenced by nonrenal factors (such as nutritional status and liver function). • Equations to estimate kidney function in cases of changing kidney function have not been well studied.
AKI patients undergoing dialysis	• Different types of dialysis modalities result in differences in drug removal (eg, IHD vs. CRRT). • Differences in intensity of dialysis dose may affect drug removal (eg, length of dialysis treatment, blood, and dialysate flow rate). • Populations studied in the literature are likely to be different than the specific patient being treated (eg, different types of dialysis, length of treatment).
Textbook dosing and literature recommendations	• Studies in patients with AKI are sparse. • Many drug information resource recommendations on dosing are based on the manufacturer's original pharmacokinetics information, often in patients with chronic kidney disease. • Most drug dosing guidelines were developed prior to standardization of SCr measurements between labs; thus, today's SCr measurements are 5% to 10% higher than those reported prior to 2010.[48] • There is growing support for incorporating the MDRD equation in future pharmacokinetic studies and to guide drug dosing, although use of this equation is limited to chronic kidney disease.

MDRD, Modification of Diet in Renal Disease equation; SCr, serum creatinine.

DRUG DOSING CONSIDERATIONS IN DIALYSIS

Several characteristics of a drug influence its removal during dialysis: percentage of drug eliminated by the kidney, volume of distribution, and protein binding. Drug elimination is greater when renal clearance accounts for 30% or more of total body clearance of the drug, volume of distribution is less than 1 L/kg, and protein binding is less than 50%.[47] Other factors that affect drug clearance include type of RRT (ie, IHD, CVVH, CVVHD); permeability of

The Patient Care Process

Collect Information:

- Perform a thorough and accurate drug history including use of nonprescription drugs that may affect kidney function, such as NSAIDs.

Assess the Information:

- Assess kidney function by evaluating a patient's signs and symptoms, physical exam findings, laboratory test results (eg, SCr, BUN, electrolytes), and urinary indices; CrCl, if possible.
- Assess whether current medications may be contributing to AKI. Consider not only drugs that can directly cause AKI (eg, aminoglycosides, amphotericin B, NSAIDs, cyclosporine, tacrolimus, ACE inhibitors, ARBs) but also drugs that can predispose a patient to nephrotoxicity or prerenal AKI (ie, diuretics and antihypertensive agents). The risk of AKI increases when potential nephrotoxic medications are not discontinued.[49]
- Based on physical exam and review of systems, determine whether the patient is experiencing hypervolemia or hypovolemia.

Develop a Care Plan:

- Determine if any drugs should be discontinued, or alternative drugs selected, to prevent worsening of kidney function based on kidney function assessment.
- Determine if any drugs undergo significant kidney elimination and require dosage reduction or specific monitoring during AKI.
- Determine if additional therapy is warranted. For example, determine if a patient should receive hydration (for volume depletion) or a loop diuretic (for volume overload).

Implement the Care Plan:

- Adjust drug dosages based on estimated kidney function or evidence of adverse drug reactions or interactions.
- Provide supportive therapy, including adequate nutrition, correction of electrolyte and acid–base abnormalities (particularly hyperkalemia and metabolic acidosis), fluid management, and correction of hematologic abnormalities.
- Implement preventative strategies to decrease the risk of AKI, such as administration of normal saline when contrast media are administered.
- Educate the patient and/or caregiver about changes in drug therapy, potential adverse effects related to new medications, and how to manage them if they occur.

Follow-up: Monitor and Evaluate:

- Monitor the patient's weight, urine output, electrolytes (such as potassium), and blood pressure to assess efficacy of the medication regimen.
- Monitor SCr to evaluate whether kidney function is worsening or improving.
- Review and encourage medication adherence.

the dialysis membrane; and blood, ultrafiltrate, and dialysate flow rates. Higher permeable filters result in greater drug elimination than lower permeable membranes, particularly for middle molecular weight drugs, such as vancomycin, that can pass through the pores of higher permeable filters.[48] Supplemental doses postdialysis may be indicated when significant drug is removed during dialysis.

CRRT procedures that rely on convection for solute removal (eg, CVVH, CVVHDF) result in greater solute removal than procedures utilizing diffusion (eg, CVVHD, IHD). In the case of antibiotics, residual renal function, the seriousness of the infection, the minimum inhibitory concentration (MIC) of the organism, and the clinical status of the patient must also be considered to avoid underdosing the patient.

Drug information references provide drug dosing recommendations in IHD and CRRT; however, they must be interpreted cautiously due to the variability in dialysis techniques used. Referring to more than one drug information resource is recommended due to variability in published recommendations.[48]

Abbreviations Introduced in This Chapter

ACE	angiotensin-converting enzyme
AKI	acute kidney injury
ARB	angiotensin II receptor blocker
ATN	acute tubular necrosis
BUN	blood urea nitrogen
CI-AKI	contrast-induced acute kidney injury
CKD	chronic kidney disease
CI-AKI	contrast-induced AKI
CrCl	creatinine clearance
CT	computed tomography
CRRT	continuous renal replacement therapy
CVVH	continuous venovenous hemofiltration
CVVHD	continuous venovenous hemodialysis
CVVHDF	continuous venovenous hemodiafiltration
FENa	fractional excretion of sodium
GFR	glomerular filtration rate
HF	heart failure
IHD	intermittent hemodialysis
JVD	jugular venous distention
KDIGO	Kidney Disease: Improving Global Outcomes
MDRD	Modification of Diet in Renal Disease Study
MRI	magnetic resonance imaging
NSAIDs	nonsteroidal anti-inflammatory drugs
RRT	renal replacement therapy
SCr	serum creatinine

Chronic and End-Stage Kidney Disease

Kristine S. Schonder and Alicia Lichvar

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the risk factors that increase susceptibility for chronic kidney disease (CKD).
2. Explain the mechanisms associated with progression of CKD.
3. Outline the desired outcomes for treatment of CKD.
4. Develop a therapeutic approach to slow progression of CKD including lifestyle modifications and pharmacologic therapies.
5. Identify specific consequences associated with CKD.
6. Design an appropriate therapeutic approach for specific consequences associated with CKD.
7. Recommend an appropriate monitoring plan to assess the effectiveness of pharmacotherapy for CKD and specific consequences.
8. Educate patients with CKD about the disease state, the specific consequences, lifestyle modifications, and pharmacologic therapies used for treatment of CKD.

INTRODUCTION

The kidney is made up of approximately 2 million **nephrons** that are responsible for filtering, reabsorbing, and excreting solutes and water. The kidney has three primary functions: excretory (excrete fluid, electrolytes, and solutes); metabolic (metabolize vitamin D and some drugs, such as insulin and some beta-lactams); and endocrine (produce **erythropoietin**). As the number of functioning nephrons declines, the primary functions of the kidney that are affected include:

- Production and secretion of erythropoietin (EPO)
- Activation of vitamin D
- Regulation of fluid and electrolyte balance
- Regulation of acid–base balance

Chronic kidney disease (CKD) is defined as abnormalities in the structure or function of the kidney, present for 3 months or more, with implications for health.[1] Markers of structural abnormalities include albuminuria (30 mg/24 hours or more or an albumin:**creatinine** ratio (ACR) of more than 30 mg/g [or 3.5 mg/mmol for female and 2.5 mg/mmol for male, but varies between different guidelines and location]); hematuria or casts in urine sediment; electrolyte and other abnormalities caused by renal tubular disorders; abnormalities detected by histology or imaging; or history of kidney transplantation. Functional abnormalities are indicated by a decline in **glomerular filtration rate (GFR)** less than 60 mL/min/1.73 m^2 (0.58 mL/s/m^2). Generally, CKD is a progressive decline in kidney function (number of functioning nephrons) that occurs over several months to years. A rapid decline in kidney function over days to weeks is known as acute kidney injury (AKI), which is discussed in Chapter 26. Because the decline in kidney function in CKD is often irreversible, treatment of CKD is aimed at slowing the progression to end-stage kidney disease (ESKD).

EPIDEMIOLOGY AND ETIOLOGY

The United States Renal Data System (USRDS), using data from the National Health and Nutrition Examination Survey (NHANES), estimates the prevalence of CKD in the United States in 2016 is 14.2%, corresponding to nearly 46 million people.[2] CKD is more common in people over age 60 years and African American patients.[3] Diabetes, hypertension, cardiovascular disease, and higher body mass index (≥ 30 kg/m^2) are associated with CKD.[3] Furthermore, mortality is three times higher in people with CKD compared to those without CKD.[3]

KEY CONCEPT The Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group developed a classification system for CKD.[1] The staging system defines the stages of CKD based on GFR and albuminuria categories (Tables 27–1 and 27–2). The estimated GFR (or eGFR) is calculated using the abbreviated Modification of Diet in Renal Disease (MDRD) study equation:[4]

$$\text{eGFR} = 175 \times (\text{SCr})^{-1.154} \times (\text{age})^{-0.203} \times (0.742 \text{ if female}) \\ \times (1.21 \text{ if African American})$$

Alternatively, eGFR can be calculated using the Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI):[1]

$$\text{eGFR} = 141 \times \min\,(S_{Cr}/\kappa, 1)\alpha \times \max\,(S_{Cr}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \\ \times 1.018\ [\text{if female}] \times 1.159\ [\text{if African American}],$$

where κ is 0.7 for females and 0.9 for males, α is –0.329 for females and –0.411 for males, min indicates the minimum of S_{cr}/κ or 1, and max indicates the maximum of S_{Cr}/κ or 1.

Note: serum creatinine expressed in units of μmol/L should be divided by 88.4 to express in units of mg/dL prior to calculation using either MDRD or CKD-EPI equations presented here.

KEY CONCEPT CKD is a progressive disease that eventually leads to ESKD. The prevalence of ESKD has increased every year since

Table 27–1

GFR Categories in CKD[1]

GFR Category	GFR		Terms
	(mL/min/1.73m^2)	(mL/s/m^2)	
G1[a]	≥ 90	≥ 0.87	Normal or high
G2[a]	60–89	0.58–0.86	Mildly decreased
G3a	45–59	0.43–0.57	Mildly-to-moderately decreased
G3b	30–44	0.29–0.42	Moderately-to-severely decreased
G4	15–29	0.14–0.28	Severely decreased
G5	<15	<0.14	Kidney failure

[a] Kidney damage must be present to meet criteria of CKD.

Abbreviations: CKD, chronic kidney disease; GFR, glomerular filtration rate. Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group. KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease. Kidney Int Suppl. 2013;3:1–50.

1980 to over 700,000 people in 2016 with over 124,000 new cases of ESKD diagnosed in 2016.[3] The prevalence of ESKD is related to ethnicity, affecting 9.5 times more American Indians/Alaska Natives, 3.7 times more African Americans, 1.3 times more Asians, and 1.4 more Hispanics as Whites.[3]

Risk Factors for CKD

Identifying risk factors for CKD is difficult because CKD progresses slowly and is often not diagnosed until late in the disease. Disease states and factors that can increase susceptibility to CKD are listed in Table 27–3. These factors can be used to identify targets for CKD screening programs. For example, older patients, those with low kidney mass or birth weight, or those with a family history of kidney disease should be routinely screened for CKD. Minority and low socioeconomic communities may be targets for more widespread CKD screening programs.

The three most common causes of CKD in the United States are diabetes mellitus (DM), hypertension, and glomerulonephritis. These are discussed in further detail below. Other causes of CKD include polycystic kidney disease, Wegener's granulomatosis, vascular diseases, human immunodeficiency virus (HIV) nephropathy, and AKI.

Table 27–2

Albumin Categories in CKD[1]

Category	AER (mg/24 hours)	ACR (approximate equivalent)		Terms
		(mg/mmol)	(mg/g)	
A1	< 30	< 3	< 30	Normal to mildly increased
A2	30–300	3–30	30–300	Moderately increased
A3	> 300	> 30	> 300	Severely increased

Abbreviations: CKD, chronic kidney disease; AER, albumin excretion ratio; ACR, albumin-to-creatinine ratio. From Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group. KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease. Kidney Int Suppl. 2013;3:1–50.

Table 27–3

Risk Factors that Increase Susceptibility for CKD

- Diabetes mellitus
- Hypertension
- Autoimmune disease
- Polycystic kidney disease
- Human immunodeficiency virus (HIV)
- Drug toxicity
- Urinary tract abnormalities (infections, obstruction, stones)
- Advanced age
- Reduced kidney mass
- Low birth weight
- Racial/ethnic minority
- Family history of kidney disease
- Low income or education
- Systemic inflammation
- Dyslipidemia

▶ *Diabetes*

DM is the most common cause of CKD, causing 36% of all CKD.[3] The risk of developing diabetic kidney disease (DKD) associated with DM is closely linked to hyperglycemia and is similar for both type 1 (T1D) and type 2 (T2D). Structural changes appear in the glomerulus as early as 2 years after diagnosis of T1D. Changes in GFR can occur as early as 5 to 7 years after diagnosis.[5] Similar changes occur in T2D, but the timing of onset of T2D and presentation of kidney disease is more difficult to determine. Albuminuria develops in 40% of patients with T2D and GFR decreases below 30 mL/min/1.73 m^2 (0.29 mL/s/m^2) within 15 years of diagnosis of T2D.[5]

▶ *Hypertension*

The second most common cause of CKD is hypertension, accounting for 31% of cases of CKD.[3] It is more difficult to determine the true risk of developing CKD in patients with hypertension because the two are so closely linked, with CKD also being a cause of hypertension. The prevalence of hypertension is correlated with the degree of kidney dysfunction (decreased GFR) with 36% of patients with CKD G1, 48% of patients with CKD G2, and 85% of patients with CKD G3 presenting with hypertension.[6] The risk of developing ESKD increases with the degree of hypertension and is linked to both systolic and diastolic blood pressure.[6]

▶ *Glomerulonephritis*

The term *glomerulonephritis* includes many specific diseases that can affect glomerular function. These include such diseases as IgA nephropathy and glomerulonephritis associated with systemic lupus erythematosus and streptococcal disease, among many others. The etiologic and pathophysiologic features of glomerular diseases vary with the specific disease, making it difficult to extrapolate the risk for progression of CKD in patients affected by glomerular diseases. Certain glomerular diseases are known to rapidly progress to ESKD; others progress more slowly or may be reversible.

Risk Factors for Progression of CKD

Several factors increase the progression of CKD, or rate of decline in GFR. The most important risk factors for progression of CKD include proteinuria, elevated blood pressure, hyperglycemia, hyperlipidemia, and AKI. Smoking tobacco also plays a role in progression of CKD.

▶ *Proteinuria*

The presence of protein in the urine is a marker of structural damage to the glomerulus and some tubulointerstitial diseases. The degree of proteinuria correlates with the risk for progression of CKD.[7] Proteinuria causes more significant effects in patients with milder stages of CKD. Compared with patients with no proteinuria in the same GFR category, patients with CKD G3 who have proteinuria are 15 times more likely to double serum creatinine within 5 years; patients with CKD G4 who have proteinuria are 8 times more likely to double serum creatinine within the same timeframe.[7] The mechanisms by which proteinuria potentiates CKD are discussed later.

▶ *Elevated Blood Pressure*

Systemic blood pressure correlates with glomerular pressure, and elevations in both independently contribute to glomerular damage. The rate of GFR decline is related to elevated systolic blood pressure and mean arterial pressure. The decline in GFR is estimated to be 14 mL/min/year (0.23 mL/s/year) in patients with diabetes with a sustained systolic blood pressure of 180 mm Hg. Conversely, the decline in GFR decreases to 2 mL/min/year (0.03 mL/s/year) with a systolic blood pressure of 135 mm Hg.[8]

▶ *Elevated Blood Glucose*

The reaction between glucose and protein in the blood produces advanced glycation end products (AGEs), which are metabolized in the proximal tubules. Hyperglycemia increases the synthesis of AGEs, which affects glomerular, tubular, and vascular function in the kidney. AGEs are known to affect activity of podocytes, the epithelial cells responsible for filtering blood in the glomerulus, which contributes to proteinuria, and, in turn, damages tubules.[9]

▶ *Hyperlipidemia*

Dyslipidemia can promote kidney injury and subsequent progression of CKD.[10] The dyslipidemia in CKD is manifested primarily as elevated triglycerides and lipoprotein(a) levels and decreased high-density lipoprotein cholesterol (HDL-C) levels. Total cholesterol and low-density lipoprotein cholesterol (LDL-C) levels generally remain within normal limits, but LDL-C particles are smaller, denser, and more atherogenic. Furthermore, kidney disease alters lipid metabolism, allowing lipoproteins to remain in blood circulation longer.[10] In contrast, patients with nephrotic syndrome, characterized by urine protein rates that exceed 3 g/24 hours, often have elevated total cholesterol and LDL-C.[10]

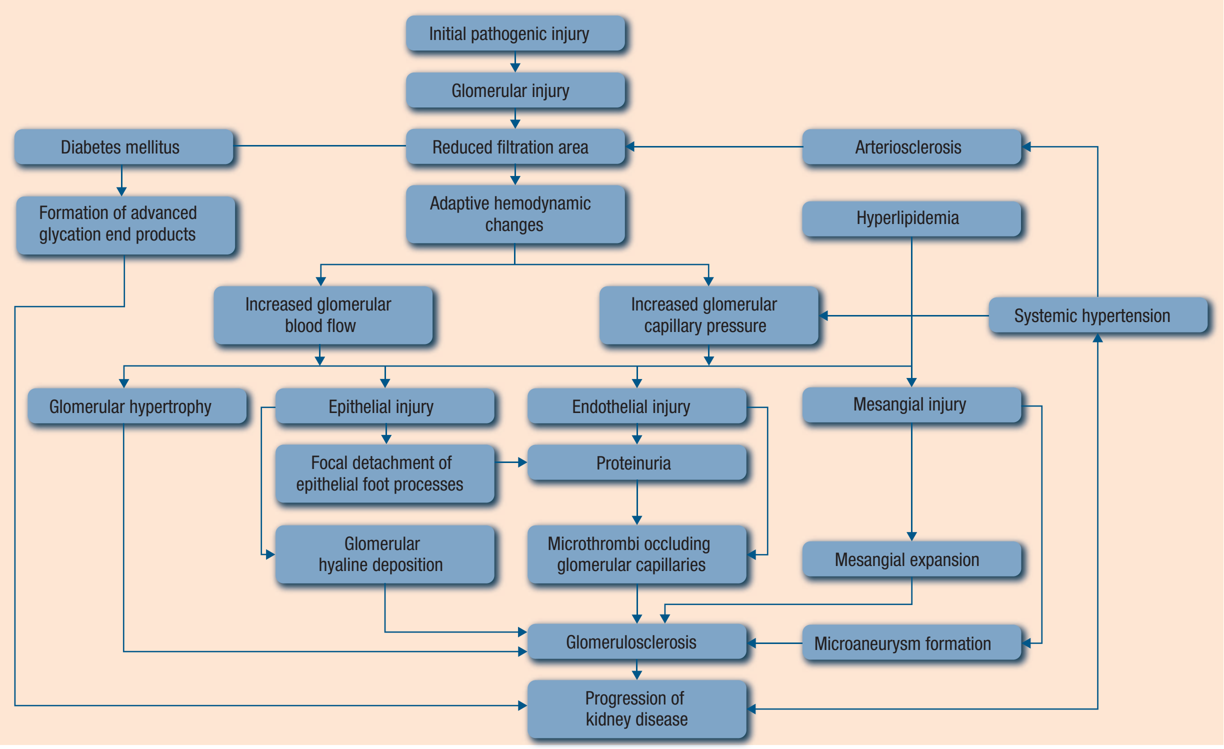
▶ *Acute Kidney Injury*

Nephron damage that results from AKI increases the risk of developing CKD, even if renal function recovers.[11] The most predictive risk factor of whether patients will develop CKD is the severity of AKI. Severe AKI is associated with a 28-fold increased risk of developing CKD, but even mild AKI is associated with a 2-fold increased risk. Older age also increases the risk of developing CKD after AKI. The cause of AKI may also affect the risk of CKD.[11]

PATHOPHYSIOLOGY

A number of factors can cause initial damage to the kidney. The resulting sequelae, however, follow a common pathway that promotes progression of CKD and results in irreversible damage leading to ESKD (Figure 27–1).

Regardless of the initial cause of kidney damage, the result is a decrease in the number of functioning nephrons. The remaining nephrons hypertrophy to increase glomerular filtration and



Initial pathogenic injury
Glomerular injury
Diabetes mellitus
Reduced filtration area
Arteriosclerosis
Formation of advanced glycation end products
Adaptive hemodynamic changes

Clinical Presentation and Diagnosis of CKD

General

The development of CKD is usually subtle in onset, often with no noticeable symptoms.

Symptoms

CKD G1 and G2 are generally asymptomatic.

CKD G3a to 3b and G4 may be associated with minimal symptoms.

CKD G5 can be associated with pruritus, dysgeusia, nausea, vomiting, constipation, muscle pain, fatigue, and bleeding abnormalities.

Signs

Cardiovascular: Worsening hypertension, edema, dyslipidemia, left ventricular hypertrophy, electrocardiographic changes, and chronic heart failure.

Musculoskeletal: Cramping.

Neuropsychiatric: Depression, anxiety, impaired mental cognition.

Gastrointestinal (GI): Gastroesophageal reflux disease, GI bleeding, and abdominal distention.

Genitourinary: Changes in urine volume and consistency, "foaming" of urine (indicative of proteinuria), and sexual dysfunction.

Laboratory Tests

CKD G1 and G2: Blood urea nitrogen (BUN) and serum creatinine (SCr) are generally within normal limits, despite mildly decreased GFR.

CKD G3a to G3b, G4, and G5: Increased BUN and SCr; decreased GFR.

Advanced stages: Increased potassium, phosphorus, and magnesium; decreased bicarbonate (metabolic acidosis); calcium levels are generally low in earlier stages of CKD and may be elevated in CKD G5, secondary to the use of calcium-containing phosphate binders.

Decreased albumin, if inadequate nutrition intake in advanced stages.

Decreased red blood cell (RBC) count, hemoglobin (Hgb), and hematocrit (Hct); Decreased iron stores (decreased iron level, increased total iron binding capacity [TIBC], decreased serum ferritin level, and decreased transferrin saturation [TSat]). Erythropoietin levels are not routinely monitored and are generally normal to low. Urine positive for albumin or protein.

Increased parathyroid hormone (PTH) level; decreased vitamin D levels (CKD G4 or G5).

Stool may be Hemoccult-positive if GI bleeding occurs from uremia.

Other Diagnostic Tests

Structural abnormalities of kidney may be present on diagnostic examinations.

tubular function, both reabsorption and secretion, in an attempt to compensate for the loss of kidney function. Initially, these adaptive changes preserve many of the clinical parameters of kidney function, including **creatinine** and electrolyte excretion. However, as time progresses, angiotensin II is required to maintain the hyperfiltration state of the functioning nephrons. Angiotensin II is a potent vasoconstrictor of both the afferent and efferent arterioles but has a preferential effect to constrict the efferent arteriole, thereby increasing the pressure in the glomerular capillaries. Increased glomerular capillary pressure expands the pores in the glomerular basement membrane, altering the size-selective barrier and allowing proteins to be filtered through the glomerulus.[12]

Proteinuria increases nephron loss through various complex mechanisms. Filtered proteins are reabsorbed in the renal tubules, which activates the tubular cells to produce inflammatory and vasoactive cytokines and triggers complement activation. These cytokines cause interstitial damage and scarring in the renal tubules, leading to damage and loss of more nephrons. Ultimately, the process leads to progressive loss of nephrons to the point where the number of remaining functioning nephrons is too small to maintain clinical stability, and kidney function declines.

ASSESSMENT

Because CKD often presents without symptoms, assessment for CKD relies on appropriate screening strategies in all patients with risk factors for developing CKD. Evaluation for CKD and the subsequent treatment strategies depend on the diagnosis, comorbid conditions, severity and complications of disease, and risk factors for the progression of CKD. KEY CONCEPT Early treatment of CKD and the associated complications of CKD are the most important factors to decrease morbidity and mortality associated with CKD. Screening for CKD should be performed in all people with an increased risk for developing CKD including patients with DM, hypertension, genitourinary abnormalities, autoimmune disease, increased age, a family history of kidney disease, or following AKI. Assessment for CKD includes measurement of SCr, measurement of creatinine clearance (ie, 24-hour urine collection) or estimation of GFR (ie, MDRD or CKD-EPI), urinalysis, blood pressure, serum electrolytes, and/or imaging studies. It is important to note that SCr should be stable when estimating GFR or measuring creatinine clearance in patients with CKD. In patients with known CKD, the presence and assessment of CKD-related complications, including anemia and bone and mineral disorders, should be performed.

A key part of CKD assessment is analysis for proteinuria, which is the primary marker of structural kidney damage, even in patients with normal GFR. Protein excretion can be assessed by measuring urine ACR, urine protein-to-creatinine ratio, or urinalysis with a reagent strip test. A urinary protein excretion of 30 mg/day or more or an ACR of 30mg/g (or 3.5 mg/mmol for female and 2.5 mg/mmol for male, but varies between different guidelines and locations) or more on a random untimed urine sample is considered to be significant in the context of CKD. Albuminuria should be assessed with GFR at least annually in people with CKD, and more frequently as GFR declines.[1]

Complications

KEY CONCEPT The decline in kidney function is associated with a number of complications, which are discussed later in the chapter, including:

- Hypertension
- Fluid and electrolyte disorders
- Anemia
- Metabolic bone disease

TREATMENT

Desired Outcomes

The primary goal is to prevent and slow the progression of CKD to prevent a cardiovascular event, CKD complications, and the need for renal replacement therapy (RRT). This requires early identification of patients at risk for CKD to initiate interventions as early as possible in the course of the disease.

Nonpharmacologic Therapy

▶ *Nutritional Management*

In people with diabetic CKD G3-5 without dialysis, protein intake should be lowered to 0.8 g/kg/day in adults reduces the accumulation of by-products of protein catabolism in CKD and hyperfiltration associated with protein intake, which may delay the progression of CKD and the need for **dialysis**.[13] On the contrary, the recommended protein intake for people on dialysis is 1 to 1.2 g/kg/day to decrease the risk for nutritional abnormalities.[13] Malnutrition is common in patients with ESKD for various reasons, including decreased appetite, protein catabolism due to protein losses in the **dialysate**, and nutrient losses through dialysis. Overall caloric intake should be maintained at 25 to 35 kcal/kg/day (105–146 kJ/kg/day) for people at all stages of CKD.[13]

Limiting salt intake to less than 2 g (90 mmol) of sodium per day (equivalent to 5 g sodium chloride) will help to control blood pressure and reduce water retention in CKD. Patients with CKD should be encouraged to increase physical activity, with a goal of at least 30 minutes 5 times per week, to achieve a healthy weight, with a goal BMI of 20 to 25 kg/m^2.[1]

Pharmacologic Therapy

▶ *CKD with Diabetes*

The KDIGO guidelines recommend that the target hemoglobin A1c (HbA1c) should be less than 6.5% (0.065; 48 mmol/mol Hgb) to less than 8% (0.08; 64 mmol/mol Hgb) for patients with DM who are not receiving dialysis.[14] This generally involves intensive insulin therapy for T1D or insulin-dependent T2D or optimizing doses of oral hypoglycemic agents in patients with non–insulin-dependent T2D. The choice of oral hypoglycemic agents can impact CKD progression and cardiovascular outcomes in people with CKD. Sodium glucose cotransporter 2 (SGLT2) inhibitors have been demonstrated to decrease progression of CKD and cardiovascular disease. This effect is seen at all stages of CKD.[14] The KDIGO guidelines recommend using metformin or a sodium glucose cotransporter 2 (SGLT2) inhibitor with GFR 30 to 60 mL/min/1.73 m^2 (0.29–0.58 mL/s/m^2) as first-line agents for T2D.[14] Higher A1c targets should be considered for patients with limited life expectancy with late stages of DM and CKD to minimize the risk of hypoglycemia and associated complications.

▶ *Optimal Blood Pressure Control*

Reductions in blood pressure are associated with a decrease in proteinuria, leading to a decrease in the rate of progression of kidney disease. The 2017 High Blood Pressure Clinical Practice Guideline recommends targeting a goal blood pressure of less than 130/80 mm Hg for all patients with CKD without dialysis.[15]

KEY CONCEPT Angiotensin-converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARBs) are the antihypertensive agents of choice in patients with CKD with an albumin excretion ratio (AER) of 30 mg/day or more because of their greater effect on lowering proteinuria, compared with other antihypertensive agents.[15] ACEIs and ARBs should be started at a low dose and the dose should be titrated upward slowly to minimize the risk of AKI (see Chapter 26). Ideally, the dose of ACEIs and ARBs should be increased to achieve a 30% to 50% reduction in urinary albumin excretion, but this may be limited by side effects, such as hyperkalemia, in patients with CKD. Thiazide diuretics have complementary effects when added to ACEIs and ARBs.[16] While many clinicians feel that thiazide diuretics are ineffective with GFR less than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2), some evidence suggests that thiazide diuretics may be effective in lowering blood pressure with lower GFR.[17] Other drug classes should be considered when compelling indications warrant or if blood pressure goals are not achieved.

In patients with CKD G5 who are receiving hemodialysis (HD), cardiovascular mortality is affected by blood pressure both before and after HD.[18] Predialysis blood pressure has a U-shaped association between systolic blood pressure and mortality. Systolic blood pressures less than 120 mm Hg and greater than 150 mm Hg are both associated with increased mortality.[18] Furthermore, as many as 20% to 30% of people can experience hypotension during dialysis, which can cause ischemia to the heart, GI tract, and the brain, increase clotting of venous access, and increase mortality.[18] Current guidelines do not define a specific blood pressure goal before or after dialysis due to lack of clinical evidence.[19] Some evidence suggests that blood pressure on non-HD days may be a more appropriate measure and correlates better with cardiovascular outcomes.[18]

Because hypertension and kidney dysfunction are linked, blood pressure control can be more difficult to attain in patients with CKD compared with patients with normal kidney function. All antihypertensive agents have similar effects on reducing blood pressure. However, two or more agents are generally required to achieve the blood pressure goal of less than 130/80 mm Hg in CKD patients.[15] Timing of blood pressure medications may also be important. Studies suggest that administration of antihypertensive medications at bedtime can decrease proteinuria by more than 30% and decrease cardiovascular risk by 14% in people with CKD compared with taking all antihypertensive medications in the morning.[20]

▶ *Reduction in Proteinuria*

Proteinuria refers to the presence of general protein in the urine. Albumin is the most common type or protein lost in the urine in patients with CKD. While older studies refer to reductions in proteinuria, new guidelines focus specifically on albuminuria. Throughout this chapter, the two terms are used interchangeably. Albuminuria in CKD predicts long-term renal and cardiovascular prognosis.[17] The ability of antihypertensive agents to reduce protein excretion differs. ACEIs and ARBs decrease glomerular capillary pressure and volume because of their effects on angiotensin II. This, in turn, reduces the amount of protein filtered through the glomerulus, independent of the reduction in blood pressure,[17] which ultimately decreases the progression of CKD. The ability of ACEIs and ARBs to reduce proteinuria is greater than that of other antihypertensives, up to 35% to 40%,[17] making ACEIs and ARBs the antihypertensive agents of choice for all patients with CKD with an AER of 30 mg/day or more, unless contraindicated. ACEIs and ARBs have been demonstrated to slow the progression of CKD with GFR less than 50 mL/min/1.73 m^2 (0.49 mL/s/m^2).[16] Studies investigating combination of ACEIs and ARBs have shown a wide variety of results compared to monotherapy with either agent. Some studies show the combination reduces proteinuria more than monotherapy, but this does not appear to reduce the progression of CKD. Current guidelines recommend avoiding combination of ACEIs and ARBs because of increased risks of hyperkalemia and AKI.[21]

The nondihydropyridine calcium channel blockers (CCBs, eg, diltiazem, verapamil) have been shown to also decrease protein excretion and decrease the progression of CKD. Dihydropyridine CCBs (eg, amlodipine, nifedipine, felodipine) however, do not have the same effects on protein excretion and should only be used in combination with ACEIs and ARBs.[16]

▸ *Hyperlipidemia Treatment*

Hyperlipidemia plays a role in the development of cardiovascular disease (CVD) in patients with CKD. Because data do not support the use of LDL-C levels to guide treatment of hyperlipidemia, the KDIGO guidelines recommend starting statins for all patients with non–dialysis-dependent CKD aged 50 years and older, regardless of GFR category.[22] Ezetimibe should be considered when GFR is less than 60 mL/min/1.73 m^2 (0.58 mL/s/m^2). Statins should also be used for patients aged 18 to 49 years who have known coronary artery disease, DM, prior ischemic stroke, or more than a 10% estimated 10-year incidence of coronary death or nonfatal myocardial infarction.[22] However, because of the lack of efficacy in reducing cardiovascular events and the risk of adverse effects associated with statins in patients with ESKD, statins should not be initiated in patients on dialysis, unless they were receiving statins prior to starting dialysis.[22]

Outcome Evaluation

The KDIGO guidelines recommend intervals for monitoring GFR and albuminuria in patients with CKD, based on the CKD stage and the degree of albuminuria.[1] In general, patients should be monitored more frequently as CKD stage and the severity of albuminuria increase.

Patients with CKD G3a should be monitored every 12 months until albuminuria is detected, then the frequency of monitoring should be increased to every 4 to 6 months, based on the severity of albuminuria. As CKD progresses, the frequency of monitoring should be increased to every 3 to 6 months.

Monitor SCr and potassium levels and blood pressure within 1 week after initiating ACEI or ARB therapy. Discontinue the medication and switch to another agent if a sudden increase in SCr greater than 30% occurs, uncontrollable hyperkalemia develops, or the patient becomes hypotensive. Titrate the dose of the ACEI or ARB every 1 to 3 months to effect using the maximum tolerable dose. If blood pressure is not reduced to goal, add another agent to the regimen. Refer the patient to a nephrologist to manage complications associated with CKD. As kidney function declines to CKD G4, begin discussion to prepare the patient for RRT.

Patient Encounter 1

A 38-year-old Asian female presents to the clinic for a routine checkup. She has no complaints today.

PMH: Hypertension, diagnosed 8 years ago; type 2 diabetes mellitus, diagnosed 5 years ago

SH: no history of smoking; drinks alcohol occasionally (socially)

Meds: Amlodipine 10 mg orally daily; atenolol 50 mg orally daily; atorvastatin 20 mg orally daily; glipizide 5 mg orally two times daily

ROS: Unremarkable.

PE:

VS: BP 158/98 mm Hg; P 82 bpm; T 98.8°F (37.1°C); ht 5′6″ (168 cm); wt 170 lb (77.1 kg)

CV: RRR, normal S_1, S_2; no murmurs, rubs or gallops; lungs clear

Abd: No organomegaly, bruits or tenderness, (+) bowel sounds; heme (–) stool

Exts: negative for pedal edema bilaterally; no lesions

Labs (Fasting): Sodium 145 mEq/L (mmol/L); potassium 4.3 mEq/L (mmol/L); chloride 105 mEq/L (mmol/L); carbon dioxide 23 mEq/L (mmol/L); blood urea nitrogen (BUN) 28 mg/dL (10 mmol/L); serum creatinine (SCr) 1.8 mg/dL (159 μmol/L); fasting glucose 201 mg/dL (11.2 mmol/L); total cholesterol 260 mg/dL (6.72 mmol/L); low-density lipoprotein cholesterol (LDL-C) 176 mg/dL (4.55 mmol/L); high-density lipoprotein cholesterol (HDL-C) 24 mg/dL (0.62 mmol/L); triglycerides 300 mg/dL (3.39 mmol/L); urine albumin:creatinine 52 mg/g creatinine (5.9 mg/mmol creatinine)

What signs and symptoms are consistent with CKD?

How would you classify her CKD?

What lifestyle modifications would you recommend for this patient with CKD?

What pharmacologic alternatives are available for this patient for treatment of CKD?

CONSEQUENCES OF CKD AND ESKD

Anemia of CKD

The progenitor cells of the kidney produce 90% of the hormone EPO, which stimulates red blood cell (RBC) production. **KEY CONCEPT** Reduction in the number of functioning nephrons decreases renal production of EPO, which is the primary cause of anemia in patients with CKD. The development of anemia of CKD results in decreased oxygen delivery and utilization, leading to increased cardiac output and left ventricular hypertrophy (LVH), which increase the cardiovascular risk and mortality in patients with CKD. A decline in hematocrit (Hct) from 30% (0.3) to 27% (0.27) results in an increased relative risk (RR) for mortality of 1.33.[23]

▸ *Epidemiology and Etiology*

The World Health Organization defines anemia as an Hgb level less than 13 g/dL (130 g/L; 8.07 mmol/L) in males and less than 12 g/dL (120 g/L; 7.45 mmol/L) in females. In addition to

Clinical Presentation and Diagnosis of Anemia of CKD

General

Anemia of CKD generally presents with fatigue and decreased quality of life.

Symptoms

Anemia of CKD is associated with symptoms of cold intolerance, shortness of breath, and decreased exercise capacity.

Signs

Cardiovascular: Left ventricular hypertrophy, ECG changes, congestive heart failure.

Neurologic: Impaired mental cognition.

Genitourinary: Sexual dysfunction.

Laboratory Tests

Decreased RBC count, Hgb, and Hct.

Decreased serum iron level, TSat and serum ferritin, and increased TIBC.

Patient Encounter 2, Part 1

A 54-year-old African American man with a history of diabetes presents to your clinic for a routine checkup. He complains of getting fatigued easily at work. He works in a bank and notes that he is not able to keep up with his work. He notes that he feels winded when he walks even short distances between his desk and the fax machine and printer. He notes his shoes are fitting tightly and his socks leaves indentations on his legs.

Current meds: Lisinopril 20 mg orally daily; furosemide 20 mg orally daily; levothyroxine 125 mcg orally daily; glipizide 10 mg po BID, ferrous sulfate 325 mg orally two times daily.

ROS: Fatigue daily throughout the day with minimal exertion; otherwise unremarkable.

PE:

VS: BP 127/82 mm Hg; P 88 bpm; T 97.5°F (36.4°C); ht 5′10″ (178 cm); wt 264 lb (120 kg)

CV: RRR, normal S_1, S_2

Abd: No organomegaly, bruits or tenderness; (+) bowel sounds; heme (–) stool

Ext: 2+ pedal edema bilaterally

Labs: Sodium 138 mEq/L (mmol/L); potassium 4.1 mEq/L (mmol/L); chloride 101 mEq/L (mmol/L); carbon dioxide 21 mEq/L (mmol/L); BUN 18 mg/dL (6.4 mmol/L); Scr 2.2 mg/dL (194 μmol/L); glucose 140 mg/dL (7.8 mmol/L); white blood cell (WBC) count 4.8×10^3 cells/mm^3 (4.8×10^9/L); red blood cell (RBC) count 2.5×10^6 cells/mm^3 (2.5×10^{12}/L); Hgb 8.2 g/dL (82 g/L; 5.09 mmol/L); Hct 25% (0.25); platelets 278×10^3 cells/mm^3 (278×10^9/L)

What signs and symptoms are consistent with anemia of CKD?

What additional information could you request to determine other causes of anemia in this patient?

decreased EPO production, a number of factors contribute to the development of anemia including deficiencies in iron, vitamin B_{12} or folate, hemolysis, bleeding, or bone marrow resistance to EPO. Many of these can be detected by alterations in RBC indices, which should be included in the evaluation for anemia (see Chapter 69). A complete blood cell count is also helpful in evaluating anemia to determine overall bone marrow function. The prevalence of anemia correlates with the degree of kidney dysfunction. Only 8.7% of patients with CKD G1 have anemia, whereas the number increases to 54.2% with CKD G5 without dialysis.[23]

▶ *Pathophysiology*

The primary cause of anemia in patients with CKD is a decrease in EPO production. With normal kidney function, as Hgb, Hct, and tissue oxygenation decrease, the plasma concentration of EPO increases exponentially. As the number of functioning nephrons decrease, EPO production also decreases. Thus, as Hgb, Hct, and tissue oxygenation decrease in patients with CKD, plasma EPO levels remain constant within the normal range but low relative to the degree of hypoxia present. The result is a normochromic, normocytic anemia.

Several other factors contribute to the development of anemia in patients with CKD. Uremia, the accumulation of toxins that results from declining kidney function, decreases the lifespan of RBCs from a normal of 120 days to as low as 60 days in patients with CKD G5. Iron deficiency and blood loss from frequent regular laboratory testing and HD also contribute to the development of anemia in patients with CKD.

▶ *Treatment*

Patients with CKD should be evaluated for anemia when the GFR falls below 60 mL/min (1.0 mL/s) or if the SCr rises above 2 mg/dL (177 μmol/L). An anemia workup should be performed if the Hgb is less than 13 g/dL (130 g/L; 8.07 mmol/L) in males or less than 12 g/dL (120 g/L; 7.45 mmol/L) in females. The workup for anemia should rule out other potential causes for anemia (see Chapter 69). Abnormalities found during the anemia workup should be corrected before initiating erythropoiesis-stimulating agents (ESAs), particularly iron deficiency, because iron is an essential component of RBC production. If Hgb is below 10 g/dL (100 g/L; 6.21 mmol/L) when all other causes of anemia have been corrected, EPO deficiency should be assumed. EPO levels are not routinely measured and have little clinical significance in monitoring progression and treatment of anemia in patients with CKD.

Nonpharmacologic Therapy Approximately 1 to 2 mg of iron is absorbed daily from the diet. This small amount is generally not adequate to preserve adequate iron stores to promote RBC production in patients with CKD-related anemia. RBC transfusions have been used in the past as the primary means to maintain Hgb and Hct levels in patients with anemia of CKD. This treatment is still utilized today in patients with severe anemia, when rapid Hgb correction is needed, especially for patients with cardiovascular disease, or if patients have contraindications to ESAs.

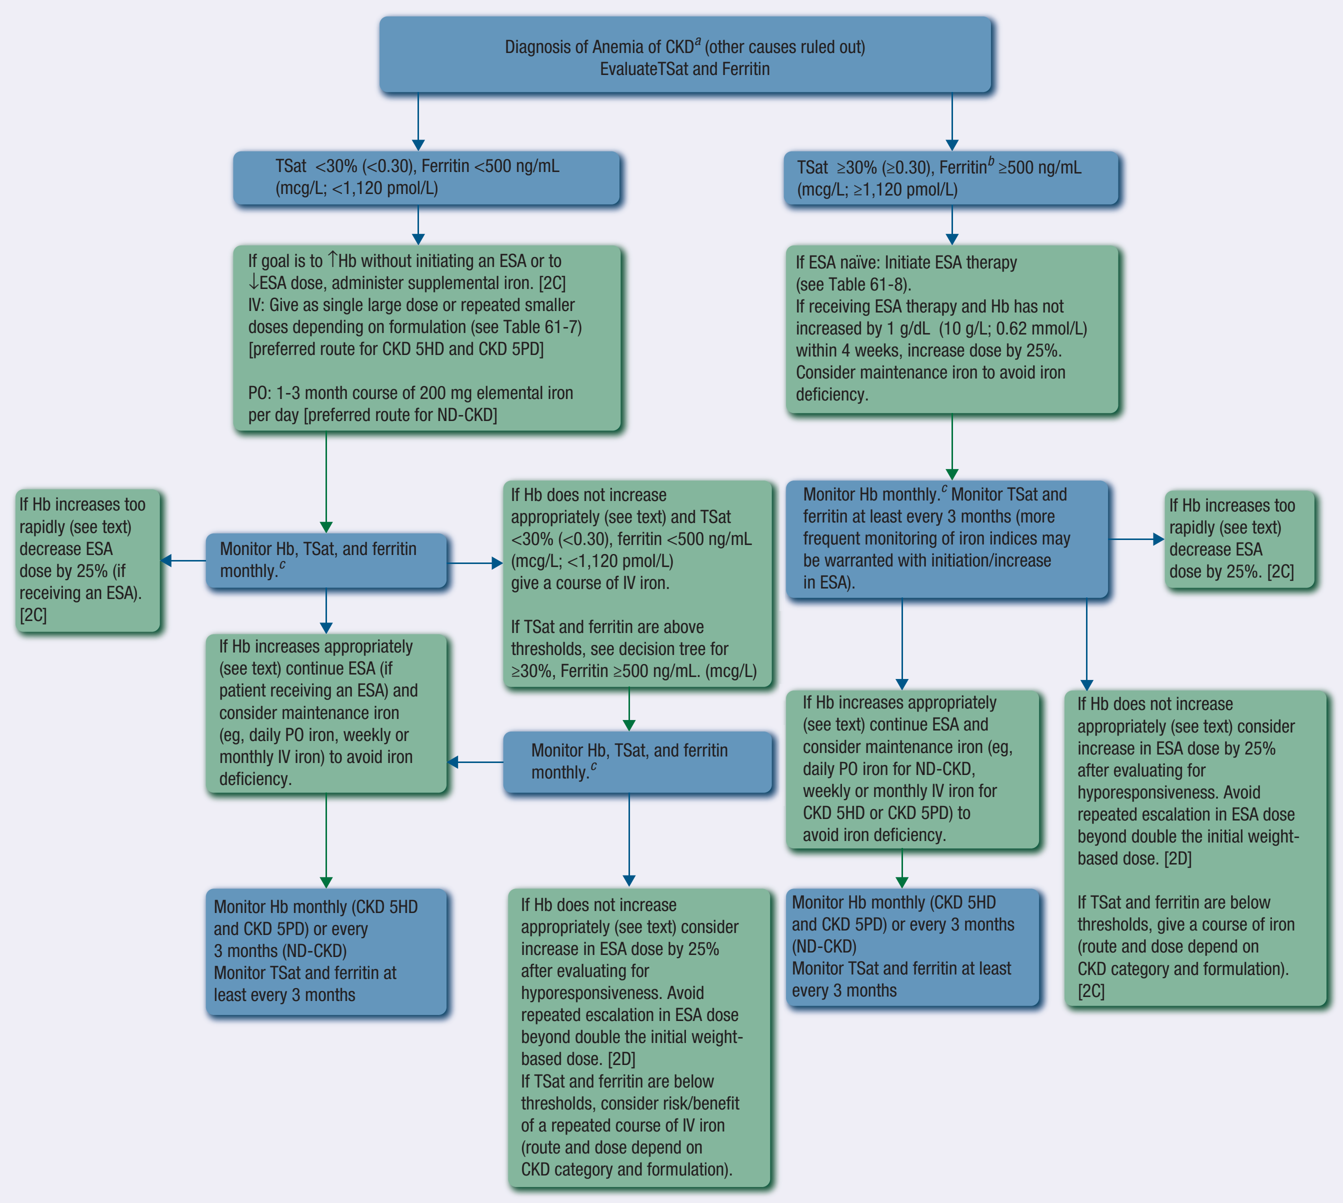
Pharmacologic Therapy The first-line treatment for anemia of CKD involves replacement of iron stores with iron supplements. When iron supplementation alone is not sufficient to increase Hgb levels, ESAs are necessary to replace EPO. ESAs are synthetic formulations of EPO produced by recombinant human DNA technology. Use of ESAs increases the iron demand for RBC production and iron deficiency is common, requiring iron supplementation to correct and maintain adequate iron stores to promote RBC production. The approach to the management of anemia of CKD with iron supplementation and ESAs is illustrated in Figure 27–2.

Iron Supplementation. Iron deficiency is a common cause of anemia in CKD. Use of ESAs can lead to iron deficiency if iron stores are not adequately maintained. The markers of iron stores that are used to determine iron deficiency include serum ferritin levels and transferrin saturation (TSat). Ferritin is an intracellular protein that stores iron and is used as an indirect marker of the total amount of iron stored in the body. Transferrin is the primary transport protein for iron in the bloodstream. The saturation of transferrin reflects how much serum iron is bound to transferrin.

According to the KDIGO guidelines, iron supplementation should be considered when:

- Serum ferritin levels are less than 500 ng/mL (mcg/L; 1124 pmol/L)
- Transferrin saturation (TSat) is less than 30% (0.30).[24]

Serum ferritin is an acute phase reactant that may become elevated with inflammation and infection. Thus, when serum ferritin is normal or elevated in conjunction with TSat levels less than 30% (0.30), treatment should be based on the clinical picture of the patient. Iron supplementation may be indicated if Hgb levels are below the goal level but avoided if the patient has an active infection.



Diagnosis of Anemia of CKD[a] (other causes ruled out)
EvaluateTSat and Ferritin

TSat <30% (<0.30), Ferritin <500 ng/mL (mcg/L; <1,120 pmol/L)

If goal is to ↑Hb without initiating an ESA or to ↓ESA dose, administer supplemental iron. [2C]
IV: Give as single large dose or repeated smaller doses depending on formulation (see Table 61-7) [preferred route for CKD 5HD and CKD 5PD]

PO: 1-3 month course of 200 mg elemental iron per day [preferred route for ND-CKD]

Monitor Hb, TSat, and ferritin monthly.[c]

If Hb increases too rapidly (see text) decrease ESA dose by 25% (if receiving an ESA). [2C]

If Hb does not increase appropriately (see text) and TSat <30% (<0.30), ferritin <500 ng/mL (mcg/L; <1,120 pmol/L) give a course of IV iron.

If TSat and ferritin are above thresholds, see decision tree for ≥30%, Ferritin ≥500 ng/mL. (mcg/L)

If Hb increases appropriately (see text) continue ESA (if patient receiving an ESA) and consider maintenance iron (eg, daily PO iron, weekly or monthly IV iron) to avoid iron deficiency.

Monitor Hb, TSat, and ferritin monthly.[c]

Monitor Hb monthly (CKD 5HD and CKD 5PD) or every 3 months (ND-CKD)
Monitor TSat and ferritin at least every 3 months

If Hb does not increase appropriately (see text) consider increase in ESA dose by 25% after evaluating for hyporesponsiveness. Avoid repeated escalation in ESA dose beyond double the initial weight-based dose. [2D]
If TSat and ferritin are below thresholds, consider risk/benefit of a repeated course of IV iron (route and dose depend on CKD category and formulation).

TSat ≥30% (≥0.30), Ferritin[b] ≥500 ng/mL (mcg/L; ≥1,120 pmol/L)

If ESA naïve: Initiate ESA therapy (see Table 61-8).
If receiving ESA therapy and Hb has not increased by 1 g/dL (10 g/L; 0.62 mmol/L) within 4 weeks, increase dose by 25%.
Consider maintenance iron to avoid iron deficiency.

Monitor Hb monthly.[c] Monitor TSat and ferritin at least every 3 months (more frequent monitoring of iron indices may be warranted with initiation/increase in ESA).

If Hb increases too rapidly (see text) decrease ESA dose by 25%. [2C]

If Hb increases appropriately (see text) continue ESA and consider maintenance iron (eg, daily PO iron for ND-CKD, weekly or monthly IV iron for CKD 5HD or CKD 5PD) to avoid iron deficiency.

Monitor Hb monthly (CKD 5HD and CKD 5PD) or every 3 months (ND-CKD)
Monitor TSat and ferritin at least every 3 months

If Hb does not increase appropriately (see text) consider increase in ESA dose by 25% after evaluating for hyporesponsiveness. Avoid repeated escalation in ESA dose beyond double the initial weight-based dose. [2D]

If TSat and ferritin are below thresholds, give a course of iron (route and dose depend on CKD category and formulation). [2C]

FIGURE 27–2. Algorithm for management of anemia of CKD. (CKD, chronic kidney disease; ESA, erythropoiesis-stimulating agent; Hb, hemoglobin; ND-CKD, nondialysis CKD patients; TSat, transferrin saturation.) [a]Clinical judgement should be used to determine if iron supplementation should be given when ferritin > 500 ng/mL (mcg/L; 1,124 pmol/L). [c]Weekly monitoring of Hb may be warranted. Wait at least 1 week after an IV dose of iron to measure TSat and ferritin. (From Hudson JQ, Wazny LD, Komenda P. Chronic kidney disease. In: DiPiro JT, Yee GC, Posey M, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill Education; 2020, with permission.)

Oral iron supplements are less costly than IV supplements and are generally the first-line treatment for iron supplementation for patients with CKD not receiving HD. When administering iron by the oral route, 200 mg of elemental iron should be delivered daily in divided doses to increase iron stores.[24]

When oral iron is not effective to increase iron stores or for patients receiving HD, IV iron should be administered. Table 27–4 lists the FDA-approved doses of the currently available IV iron products. Patients receiving HD have ongoing blood losses with each HD session, which can lead to iron losses of 1 to 2 g/year. For HD, IV iron may be administered episodically based on routine surveillance of iron stores as a total of 1 g of IV iron, administered in small sequential doses to replete iron stores. An alternative method to administer IV iron is to give smaller maintenance doses of iron weekly or with each dialysis session (eg, iron sucrose 20–100 mg/week; sodium ferric gluconate 62.5–125 mg/week). The latter approach of giving smaller maintenance doses may result in lower cumulative doses of iron and lower doses of ESAs.[24]

IV iron preparations are equally effective in increasing iron stores. Anaphylaxis may occur with all IV preparations, but most notably with iron dextran, which can also cause delayed reactions,

Table 27–4

IV Iron Products

Iron Formulation (Product)	FDA-Approved Indications	FDA-Approved Dosing	Warnings	Dose Ranges[a]	How Supplied
Ferric carboxymaltose (Injectafer®)	Adults with non–dialysis-dependent CKD	IV push: 750 mg over 10 minutes IV infusion: 750 mg in 100–250 mL of 0.9% NaCl over at least 15 minutes	General	1500 mg (2 doses of 750 mg separated by at least 7 days)	15-mL vials containing 750 mg elemental iron
Ferric derisomaltose (Monoferric®)	Adults with non–dialysis-dependent CKD	IV infusion: Patients ≥ 50 kg: 1000 mg; Patients < 50 kg: 20 mg/kg actual body weight	General	1000 mg (single dose)	1-mL, 5-mL, 10-mL vials (100 mg iron/mL)
Ferric gluconate (Ferrlecit®, Sodium ferric gluconate)	Adult and pediatric HD patients age 6 years and older receiving ESA therapy	IV push (adult): 125 mg over 10 minutes	General	6.25–500 mg	5-mL ampules containing 62.5 mg elemental iron (12.5 mg/mL)
		IV infusion (adult): 125 mg in 100 mL of 0.9% NaCl over 60 minutes			
		IV infusion (pediatric): 1.5 mg/kg in 25 mL of 0.9% NaCl over 60 minutes; maximum dose 125 mg			
Ferumoxytol (Feraheme”)	Adults with iron-deficiency anemia associated with CKD	infusion: 510 mg (17 mL) in 50–200 mL 0.9% NaCl or 5% Dextrose over at least 15 minutes, followed by a second 510-mg infusion 3–8 days after the initial infusion	Black box (risk of anaphylactic reactions)	1020 mg (2 doses of 510 mg separated by 3–8 days)	17 mL vials containing 510 mg (0 mg/mL)
Iron dextran (INFeD®, Dexferrum®)	Patients with iron deficiency in whom oral iron is unsatisfactory	IV push: 100 mg over 2 minutes (25 mg test dose required)	Black box (risk of anaphylactic reactions)	25–1000 mg	2-mL vials containing 50 mg elemental iron per mL
Iron sucrose (Venofer®)	HD patients with CKD receiving ESA therapy	IV push: 100 mg over 2–5 minutes	General	25–500 mg	5-mL single-dose vials containing 100 mg elemental iron (20 mg/mL)
		IV infusion: 100 mg in maximum of 100 mL of 0.9% NaCl over 15 minutes			
	Nondialysis-CKD patients receiving or not receiving ESA therapy	IV push: 200 mg over 2–5 minutes on five different occasions within 14-day period			
	PD patients receiving ESA therapy	IV infusion: 2 infusions 14 days apart, of 300 mg in maximum of 250 mL of 0.9% NaCl over 1.5 hour, followed by 1 infusion 14 days later, of 400 mg in maximum of 250 mL of 0.9% NaCl over 2.5 hours			

CKD, chronic kidney disease; ESA, erythropoietin-stimulating agent; HD, hemodialysis; PD, peritoneal dialysis.

[a] Small dosing ranges (eg, 25–100 mg/week) generally used for maintenance regimens. Larger doses (eg, 1 g) should be administered in divided doses.

such as arthralgias and myalgias. A test dose of 25 mg iron dextran should be administered 30 minutes before the full dose to monitor for potential anaphylactic reactions, although anaphylactic reactions can occur in patients who safely received prior doses of iron dextran. Ferumoxytol also carries a warning for serious allergic reactions and should be closely monitored, but does not require a test dose. Sodium ferric gluconate, iron sucrose, and ferric carboxymaltose are associated with fewer severe reactions and a much lower risk of anaphylaxis and do not require a test dose, making them the preferred agents in CKD. The most common side effects seen with these preparations include hypotension, flushing, nausea, and injection site reactions.

After administering a 1g course of IV iron, iron status should be monitored to determine the effectiveness of the treatment. Serum ferritin and TSat should be monitored no sooner than 1 week after the last dose of IV iron. If Hgb does not increase after a course of IV iron or serum ferritin is not greater than 500 ng/mL (mcg/L; 1124 pmol/L) and TSat greater than 30% (0.30), an additional 1 g of IV iron may be administered, based on the clinical situation.

Erythropoiesis-Stimulating Agents. ESAs may be considered if Hgb levels remain persistently low to improve symptoms of anemia. In patients not receiving dialysis, the decision to initiate ESAs should be based on the rate of Hgb decline, prior response to anemia treatment, risks associated with ESAs and the patient's symptoms. The KDIGO guidelines recommend considering initiating ESAs when Hgb is less than 10 g/dL (100 g/L; 6.21 mmol/L).[24] However, the target for Hgb is unclear because use of ESAs to increase Hgb levels beyond 12 g/dL (120 g/L; 7.45 mmol/L) is associated with increased mortality.[24] The ESAs currently available in the United States are listed in Table 27–5. Epoetin α and epoetin β (which is available outside the United States) have the same biological activity as endogenous EPO. Darbepoetin alfa has 2 additional carbohydrate side chains that increase the half-life compared with epoetin alfa and endogenous EPO, allowing for less frequent dosing than that of epoetin alfa. Methoxy PEG-epoetin beta has the addition of an amide bond that produces a longer half-life than the other ESAs and is referred to as a continuous EPO receptor activator (CERA). All ESAs are equivalent in their efficacy and have a similar adverse-effect profile.

The most common adverse effect seen with ESAs is increased blood pressure, which may require antihypertensive agents to control blood pressure. Caution should be used when initiating an ESA in patients with very high blood pressures (> 180/100 mm Hg). If blood pressures are refractory to antihypertensive agents, ESAs may need to be withheld. Seizures and pure red cell aplasia have also been reported in patients initiating ESA therapy, and has been reported more with the CERA product.

Subcutaneous (SC) administration of ESA is the preferred route of administration for all agents because it produces a more predictable and sustained response than IV administration, and lower doses of ESAs are generally needed. IV administration is often utilized in patients who have established IV access or are receiving HD. Starting doses of ESAs depend on the Hgb level, the target Hgb level, the rate of Hgb increase, and clinical circumstances. The initial increase in Hgb should be 1 to 2 g/dL (10–20 g/L; 0.62–1.24 mmol/L) per month.[24] The recommended starting dose of the ESAs are listed in Table 27–5.

When prescribing ESAs, clinicians should not attempt to target "normal" Hgb levels (ie, > 13 g/dL [130 g/L; 8.07 mmol/L] in males; > 12 g/dL [120 g/L; 7.45 mmol/L] in females). Several clinical trials have demonstrated that targeting Hgb levels greater than 13 g/dL (130 g/L; 8.07 mmol/L) resulted in more cardiovascular complications or death, compared with target Hgb levels less than 11 g/dL (110 g/L; 6.83 mmol/L).[23] Further studies are needed to evaluate the appropriate target level for Hgb. Nonetheless, based on these findings, the US FDA recommended addition of a black box warning to the product information for all ESAs indicating the maximum target Hgb should not exceed 11 g/dL (110 g/L; 6.83 mmol/L) and requires a medication guide be given to patients who are receiving ESAs. However, KDIGO suggests a maximum threshold of 11.5 g/dL (115 g/L; 7.14 mmol/L).[23]

▶ *Outcome Evaluation*

The outcomes to monitor for anemia of CKD include Hgb, iron status, and the need for blood transfusions. Hemoglobin should be monitored every 3 months in patients with CKD not on dialysis and those receiving PD and monthly in patients receiving HD. Evaluate Hgb monthly when ESA therapy is initiated or the dose is adjusted to ensure Hgb does not exceed 11.5 g/dL (115 g/L; 7.14 mmol/L).[24] The ESA dose can increase monthly if Hgb is below goal. Once a stable Hgb is attained, evaluate Hgb every 3 months thereafter. When a patient begins or increases the dose of ESA therapy, monitor iron stores monthly to ensure

Table 27–5

Erythropoiesis Stimulating Agents in Chronic Kidney Disease[a]

Drug	Brand Name	Starting Dose	Route of Administration	Half-Life (Hours)
Epoetin alfa Epoetin alfa-epbx	Epogen®, Procrit® Retacrit®	Adults: 50–100 U/kg three times per week Pediatrics: 50 U/kg three times per week	IV or SC	8.5 (IV) 24 (SC)
Darbepoetin alfa	Aranesp®	ND-CKD: 0.45 mcg/kg once every 4 weeks Dialysis: 0.45 mcg/kg once per week or 0.75 mcg/kg once every 2 weeks Pediatrics: 0.45 mcg/kg once weekly; may give 0.75 mcg/kg once every 2 weeks for nondialysis	IV or SC	25 (IV) 48 (SC)
Methoxy PEG-epoetin beta	Mircera®	0.6 mcg/kg every 2 weeks; once Hgb stabilizes, double the dose and administer monthly (eg, if administering 0.6 mcg/kg every 2 weeks, give 1.2 mcg/kg every month)	IV or SC	134 (IV) 139 (SC)

Patient Encounter 2, Part 2

The patient returns to your clinic in 1 week and states that his symptoms have not changed. He is asking about the results of his laboratory studies.

Labs: WBC 4.2 × 10^3 cells/mm^3 (4.2 × 10^9/L); red blood cell (RBC) count 2.6 × 10^6 cells/mm^3 (2.6 × 10^{12}/L); Hgb 8.4 g/dL (84 g/L; 5.21 mmol/L); Hct 27% (0.27); mean corpuscular volume (MCV) 86 fL; mean corpuscular hemoglobin concentration (MCHC) 31 g/dL (310 g/L); platelets 298 × 10^3 cells/mm^3 (298 × 10^9/L); iron 131 mcg/dL (23.4 μmol/L); total iron binding capacity (TIBC) 390 mcg/dL (69.8 μmol/L); ferritin 662 ng/mL (mcg/L; 1487 pmol/L); transferrin saturation (TSat) 36% (0.36); stool guaiac negative × 3

What treatment would you recommend for this patient for treatment of anemia?

How would you evaluate the effectiveness of treatment of anemia?

adequate iron stores are present for erythropoiesis and limit dosing of ESAs. When the goal Hgb is reached, monitor iron stores every 3 months. Serum ferritin and TSat should be monitored no sooner than 1 week after the last dose of IV iron is administered.

CKD-Mineral and Bone Disorder and Secondary Hyperparathyroidism

▶ *Epidemiology and Etiology*

Increases in parathyroid hormone (PTH) occur early as kidney function begins to decline. The actions of PTH on bone turnover lead to CKD-mineral and bone disorders (CKD-MBD). The majority of patients with CKD G3-G5 have CKD-MBD.[25]

▶ *Pathophysiology*

As kidney function declines in patients with CKD, decreased phosphorus excretion disrupts the balance of calcium and phosphorus homeostasis. Fibroblast growth factor 23 (FGF-23) is a hormone produced by osteocytes and osteoblasts that is stimulated by increased phosphate and calcitriol. In CKD, elevated phosphate concentrations increase expression of FGF-23, which promotes phosphorus excretion and downregulates vitamin D activation in the kidney.[25] Decreased vitamin D activation in the kidney also decreases calcium absorption from the GI tract. Each of these stimulates the parathyroid glands to secrete parathyroid hormone. KEY CONCEPT The parathyroid glands release PTH in response to decreased serum calcium and increased serum phosphorus levels. The actions of PTH include the following:

- Increasing calcium resorption from bone
- Increasing calcium reabsorption from the proximal tubules in the kidney
- Decreasing phosphorus reabsorption in the proximal tubules in the kidney
- Stimulating activation of vitamin D by 1-α-hydroxylase to calcitriol (1,25-dihydroxyvitmin D_3) to promote calcium absorption in the GI tract and increased calcium mobilization from bone

All of these actions are directed at increasing serum calcium levels and decreasing serum phosphorus levels, although the activity of calcitriol also increases phosphorus absorption in the GI tract and mobilization from the bone, which can worsen hyperphosphatemia. Calcitriol also decreases PTH levels through a negative feedback loop. These measures are sufficient to correct serum calcium and phosphorus levels in the earlier stages of CKD. However, secondary hyperparathyroidism (sHPT) can still present in early stages of CKD, despite normal calcium and phosphorus levels, due to the effects of FGF-23.[25] As CKD worsens, increased FGF-23 and phosphorus and decreased calcitriol levels lead to excessive production of PTH, resulting in hyperplasia of the parathyroid glands, which decreases the sensitivity of the parathyroid glands to serum calcium levels and calcitriol feedback, further promoting sHPT. The most dramatic consequences of sHPT are vascular calcifications and alterations in bone turnover, which leads to renal osteodystrophy (ROD). The pathogenesis of sHPT and CKD-MBD are depicted in Figure 27–3.

Clinical Presentation and Diagnosis of sHPT and ROD

General

Onset of sHPT and ROD is subtle and may not be associated with symptoms.

Symptoms

sHPT and ROD are usually asymptomatic in early disease. Calcification in the joints can be associated with decreased range of motion.

Conjunctival calcifications are associated with a gritty sensation in the eyes, redness, and inflammation.

Signs

Cardiovascular: Increased stroke index, heart rate, and diastolic and mean arterial pressures.

Musculoskeletal: Bone pain, muscle weakness.

Dermatologic: Pruritus.

Laboratory Tests

Increased serum phosphorus levels.

Low to normal serum calcium levels.

Increased PTH levels.

Decreased vitamin D levels.

Diagnostic Tests

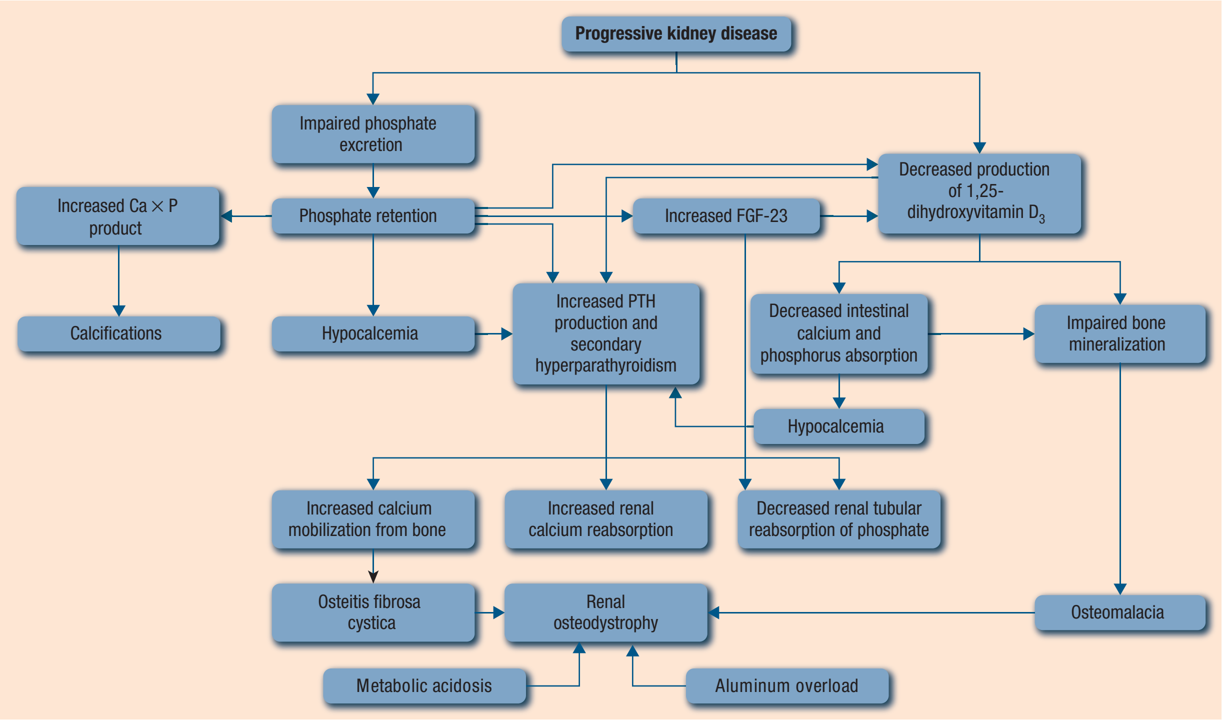
Radiographic studies show calcium–phosphate deposits in joints and/or cardiovascular system.

Bone biopsy of the iliac crest (not routinely performed)

▶ *Treatment*

General Approach KEY CONCEPT Diagnosis and management of bone disease in CKD is based on corrected serum levels of calcium and phosphorus, and intact PTH levels (iPTH). KDIGO guidelines recommend preventing hyperphosphatemia and avoiding hypercalcemia, while maintaining PTH levels as close to normal as possible in people with CKD.[26]

Current recommendations suggest that treatment of CKD-MBD should take into consideration evaluations of calcium, phosphorus, and PTH level collectively and trends over time.[26] When phosphorus levels remain elevated, phosphorus-lowering treatment should be started. Management of sHPT often requires



Progressive kidney disease
Impaired phosphate excretion
Decreased production of 1,25-dihydroxyvitamin D_3
Increased Ca × P product
Phosphate retention
Increased FGF-23
Calcifications
Hypocalcemia
Increased PTH production and secondary hyperparathyroidism
Decreased intestinal calcium and phosphorus absorption
Impaired bone mineralization
Hypocalcemia
Increased calcium mobilization from bone
Increased renal calcium reabsorption
Decreased renal tubular reabsorption of phosphate
Osteitis fibrosa cystica
Renal osteodystrophy
Osteomalacia
Metabolic acidosis
Aluminum overload

FIGURE 27–3. Pathogenesis of CKD-MBD. (Ca, calcium; FGF-23, fibroblast growth factor-23, PTH, parathyroid hormone.) [a]FGF-23 also increases in response to 1,25-dihydroxyvitamin D_3. [b]These adaptations are lost as kidney failure progresses. (From Hudson JQ, Wazny LD, Komenda P. Chronic kidney disease. In: DiPiro JT, Yee GC, Posey M, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill Education; 2020, with permission.)

treatment with vitamin D analogs or calcimimetics in addition to phosphorus management.

Nonpharmacologic Therapy The first-line treatment for the management of hyperphosphatemia is dietary phosphorus restriction to 800 to 1000 mg/day in patients with CKD G3 or higher who have phosphorus levels at the upper limit of the normal range or elevated iPTH levels.[26] Many foods high in phosphorus are also high in protein, which can make it difficult to restrict phosphorus intake while maintaining adequate protein intake to avoid malnutrition. HD and peritoneal dialysis (PD) can remove up to 2 to 3 g of phosphorus per week. However, this is usually insufficient to control hyperphosphatemia, and pharmacologic therapy is necessary in addition to dialysis treatment.

Other nonpharmacologic strategies to manage sHPT and CKD-MBD include restriction of aluminum exposure and parathyroidectomy. Chronic ingestion of aluminum-containing antacids and other aluminum-containing products should be avoided in patients with CKD G4 and G5 (GFR less than 30 mL/min/1.73 m^2 [0.29 mL/s/m^2]) because of the risk of aluminum toxicity and potential uptake into the bone

Parathyroidectomy is a treatment of last resort for sHPT, but should be considered in patients with persistently elevated iPTH levels above 800 pg/mL (ng/L; 85.6 pmol/L) that is refractory to medical therapy to lower serum PTH and/or phosphorus levels. A portion or all of the parathyroid tissue may be removed. After parathyroidectomy, serum calcium levels can decrease dramatically due to the low levels of PTH after the parathyroid tissue is removed, which decreases intestinal calcium absorption and bone resorption. Therefore, serum ionized calcium levels should be monitored frequently (every 4–6 hours for the first 48–72 hours) in patients receiving a parathyroidectomy. Calcium supplementation is usually necessary, administered IV initially, then orally (with vitamin D supplementation) once normal calcium levels are attained for several weeks to months after the procedure.

Pharmacologic Therapy

Phosphate-Binding Agents. When serum phosphorus levels cannot be controlled by restriction of dietary intake, phosphate-binding agents are used to bind dietary phosphate in the GI tract to form an insoluble complex that is excreted in the feces. Phosphorus absorption is decreased, thereby decreasing serum phosphorus levels. The drugs used for binding dietary phosphate are listed in Table 27–6. The selection of the phosphate binding agent should be on sequential assessment of calcium and PTH levels in addition to the phosphorus level. These agents should be administered with each meal and can be tailored to the amount of phosphorus that is typically ingested during each meal. For example, patients can take a smaller dose with smaller meals or snacks, and a larger dose with larger meals. Although phosphate binders are not FDA approved for patients with CKD who are not receiving dialysis, they are used clinically when phosphorus levels are elevated, regardless of the GFR category.

Sevelamer and lanthanum phosphate binders do not contain calcium, iron, or aluminum. These agents are particularly useful in patients with hyperphosphatemia who have elevated serum calcium levels or who have vascular or soft tissue calcifications. Sevelamer is a cationic polymer that is not systemically absorbed and binds to phosphate in the GI tract, and it prevents absorption and promotes excretion of phosphate through the GI tract via the feces. Sevelamer carbonate has an added benefit of reducing LDL-C levels,[25] and correction of metabolic acidosis. The most common side effects of sevelamer are GI complaints including nausea, constipation, and diarrhea.

Table 27–6

Phosphate-Binding Agents Used to Treat Hyperphosphatemia in CKD

Compound	Trade Name	Dosage Form	Compound Content (mg)	Elemental Compound Content (mg)	Starting Dose	Comments
Resin-based binders						
Sevelamer carbonate	Renvela®	Tablet, Powder for suspension	800		800 mg three times a day with meals	First-line agent; lowers LDL-C More expensive than calcium products; preferred in patients at risk for extraskeletal calcification May require large doses to control phosphorus levels
Elemental-based binders						
Lanthanum	Fosrenol®	Chewable tablet	500, 750, 1000	–	750–1500 mg three times a day with meals	Second-line agent; more expensive than calcium products; preferred in patients at risk for extraskeletal calcification Most patients require 1500–3000 mg/day to control phosphorus
Iron-based binders						
Ferric citrate	Auryxia®	Tablet	210	1 g ferric citrate	420 mg (2 tablets) three times a day with meals	Maximum dose is 12 tablets per day; iron is systemically absorbed
Sucroferric oxyhydroxide	Velphoro®	Chewable tablet	500	–	500 mg three times a day with meals	Do not use with levothyroxine; separate from doxycycline and alendronate by 1 hour
Calcium-containing binders						
Calcium carbonate (40% elemental calcium)	Tums®	Chewable tablet	500, 750, 1000, 1250	200, 300, 400, 500	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; dissolution characteristics and phosphorus-binding effect may vary from product to product; try to limit daily intake of elemental calcium to 1500 mg/day Approximately 39 mg phosphorus bound per 1 g calcium carbonate
	Oscal®-500	Tablet	1250	500		
	Caltrate® 600	Tablet	1500	600		
	Nephro-Calci”	Tablet	1500	600		
	LiquiCal”	Liquid gelcap	1200	480		
	Calci-Chew®	Chewable tablet	1250	500		
Calcium acetate (25% elemental calcium)	PhosLo®	Capsule, Tablet	667	167	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; comparable efficacy to calcium carbonate with one-half the dose of elemental calcium; do not exceed 1500 mg elemental calcium intake per day Approximately 45 mg phosphorus bound per 1 g calcium acetate By prescription only
	Phoslyra®	Solution	667/5 mL			
Aluminum-based binders						
Aluminum hydroxide	AlternaGel® Amphojel®	Suspension	Various	–	300–600 mg three times a day with meals	Third-line agents; do not use concurrently with citrate-containing products Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders

CKD, chronic kidney disease; LDL-C, low-density lipoprotein cholesterol.

Lanthanum is a naturally occurring trivalent rare earth element (atomic number 57). Lanthanum carbonate quickly dissociates in the acidic environment of the stomach, where the lanthanum ion binds to dietary phosphorus, forming an insoluble compound that is excreted in the feces. Lanthanum has been shown to be as effective as other phosphate binders and may improve bone turnover, compared with calcium-containing products. Side effects of lanthanum include nausea, peripheral edema, and myalgias.

Sucroferric oxyhydroxide and ferric citrate are iron-based phosphate binders that lower phosphate levels. Sucroferric oxyhydroxide is an insoluble form of iron that binds to phosphate in the GI tract and has been shown to be as effective as other phosphate binders but has a benefit of a lower pill burden.[27] Sucroferric oxyhydroxide is not absorbed from the GI tract, so it does not affect serum iron levels. Ferric citrate also lowers phosphate as effectively as other phosphate binders. Unlike sucroferric oxyhydroxide, ferric citrate is absorbed from the GI tract and can also increase serum ferritin and TSAT levels. The major side effects associated with both products are GI side effects, namely, diarrhea.[27]

Calcium-containing phosphate binders (CCPBs), including calcium carbonate and calcium acetate, are effective in decreasing serum phosphate levels, as well as in increasing serum calcium levels. Calcium acetate binds more phosphorus than the carbonate salt, making it a more potent agent for binding dietary phosphate. Calcium carbonate can also aid in the correction of metabolic acidosis, another complication of kidney failure. Calcium citrate is usually not used as a phosphate-binding agent because the citrate salt can increase aluminum absorption. However, use of CCPBs can cause hypercalcemia, even at low doses, which can lead to vascular calcification and cardiovascular events in people with CKD. Furthermore, studies have shown an increase in mortality associated with CCPBs compared to non-CCPBs in both predialysis and dialysis patients.[26] Therefore, current guidelines recommend restricting the dose of CCPBs in all stages of CKD.[26] The most common adverse effects of CCPBs are constipation and hypercalcemia.

Aluminum-containing phosphate-binding agents are not recommended for chronic use in patients with CKD to avoid aluminum accumulation, leading to encephalopathy, bone disease, and anemia. These agents may be used for a short course of therapy (< 4 weeks) for significantly elevated phosphorus levels in AKI or refractory hyperphosphatemia in patients with CKD.

Vitamin D Therapy. Vitamin D regulates many processes in the body, including calcium and phosphorus absorption from the GI tract and kidney, PTH secretion, maintaining muscle, cardiovascular, immune and brain function, and glucose control. Vitamin D is activated in various tissues, with the liver and kidney being primary sites. In CKD, a decrease in renal metabolism of vitamin D decreases circulating concentrations of the activated form of vitamin D, calcitriol (1,25-dihydroxyvitamin D) and its precursor 25-hydroxyvitamin D. Vitamin D deficiency begins early in CKD and increases as kidney function declines.[28] PTH levels rise as early as CKD G3 as a result of low calcitriol concentrations.

Exogenous vitamin D compounds that mimic the activity of calcitriol act directly on the parathyroid gland to decrease PTH secretion by upregulation of the vitamin D receptor in the parathyroid gland, which decreases parathyroid gland hyperplasia and PTH synthesis and secretion. This is particularly useful when reduction of serum phosphorus levels does not sufficiently reduce PTH levels.

Vitamin D supplements (Table 27–7) can be used to lower serum PTH levels in patients with CKD. Ergocalciferol, cholecalciferol, and calcifediol have been shown to be effective in lowering PTH secretion in patients with CKD G3, and are useful in later stages of CKD to maintain adequate 25-hydroxyvitamin D levels for extrarenal functions.[26,28] In CKD G4 and G5, renal 1α-hydroxylation of vitamin D decreases and thus activated vitamin D analogs must be used to decrease PTH secretion in severe hyperparathyroidism.[26] Synthetic calcitriol has the same biologic activity as endogenous calcitriol. Doxercalciferol (1-α-hydroxyvitamin D_2) is another vitamin D analog that is hydroxylated in the liver to 1,25-dihydroxyvitamin D_2, which has the same biologic activity as calcitriol. Both calcitriol and doxercalciferol upregulate vitamin D receptors in the intestines, which increases calcium and phosphorus absorption, increasing the risk of hypercalcemia and hyperphosphatemia. It is important that serum calcium and phosphorus levels are within the normal range for the stage of CKD prior to starting either of these therapies. Paricalcitol (19-nor-1,25-dihydroxyvitamin D_2) is a vitamin D analog that has equal efficacy to calcitriol. Alfacalcidol

Table 27–7

Available Treatments for Secondary Hyperparathyroidism

Generic Name	Trade Name	Dosage Range	Dosage Forms	Frequency of Administration
Vitamin D (prohormone)				
Ergocalciferol	Vitamin D_2	400–50,000 IU	PO	Daily (doses of 400–2000 IU) Weekly or monthly for higher doses (50,000 IU)
Cholecalciferol	Vitamin D_3			
Calcifediol	Rayaldee®	30–60 mcg	PO	Daily
Active vitamin D				
Calcitriol	Calcijex®	0.5–5 mcg	IV	Three times per week
	Rocaltrol®	0.25–5 mcg	PO	Daily, every other day, or three times per week
Vitamin D analogs				
Paricalcitol	Zemplar®	1–4 mcg	PO	Daily or three times per week
		2.5–15 mcg	IV	Three times per week
Doxercalciferol	Hectorol®	5–20 mcg	PO	Daily or three times per week
		2–8 mcg	IV	Three times per week
Calcimimetics				
Cinacalcet	Sensipar”	30–180 mg	PO	Daily
Etelcalcitide	Parsabiv”	2.5–15 mg	IV	3 times per week

Patient Encounter 3

A 52 year-old Hispanic female with a history of hypertension presents to your clinic for a routine follow-up. She has no complaints at this time.

PMH: hypertension, diagnosed 12 years ago; hyperlipidemia

Current meds: Aspirin 81 mg orally daily; atorvastatin 40 mg orally daily; carvedilol 12.5 mg orally twice daily; lisinopril 20 mg orally daily; sodium bicarbonate 1300 mg orally twice daily; Ergocalciferol 50,000 units orally once a week or calcitriol 0.5 mcg orally daily.

ROS: Unremarkable.

PE:

VS: BP 136/84 mm Hg; P 70 bpm; T 96.3°F (35.7°C); ht 5′7″ (170 cm); wt 178 lb (80.7 kg)

CV: RRR, normal S_1, S_2

Abd: No organomegaly, bruits, tenderness; (+) bowel sounds; heme (–) stool

Ext: 2+ edema bilaterally

Labs: Sodium 139 mEq/L (mmol/L); potassium 5.2 mEq/L (mmol/L); chloride 109 mEq/L (mmol/L); carbon dioxide 24 mEq/L (27 mmol/L); BUN 42 mg/dL (15 mmol/L urea); SCr 3.4 mg/dL (301 μmol/L); glucose 98 mg/dL (5.4 mmol/L); calcium 8.8 mg/dL (2.2 mmol/L); phosphate 7.4 mg/dL (2.39 mmol/L); intact parathyroid hormone (iPTH) 458 pg/mL (ng/L; 48.6 pmol/L); WBC 5.6×10^3 cells/mm^3 (5.6×10^9/L); RBC 3.9×10^6 cells/mm^3 (3.9×10^{12}/L); Hgb 9.8 g/dL (98 g/L; 6.08 mmol/L); Hct 29% (0.29); platelets 272×10^3 cells/mm^3 (272×10^9/L)

What signs are consistent with CKD mineral and bone disorder (MBD)?

What treatment would you recommend for CKD-MBD?

(1-α-hydroxyvitamin D_3), falecalcitriol, and 22-oxacalcitriol (maxacalcitol) are only available outside the United States.

Calcimimetics. Cinacalcet and etelcalcetide are calcimimetics that increase the sensitivity of receptors on the parathyroid gland to serum calcium levels to reduce PTH secretion but have no effect on intestinal absorption of calcium or phosphorus. Calcimimetics also reduce FGF-23 and serum calcium levels.[29] Thus, calcimimetics are beneficial for patients with elevated PTH levels who have increased calcium or phosphorus levels or cannot use vitamin D therapy. Cinacalcet is an oral calcimimetic that is most widely used for sHPT. Etelcalcetide is an injectable agent that lowers PTH levels and serum calcium levels to a greater degree than cinacalcet.[29] Gastrointestinal side effects, including nausea and vomiting, are the most common side effects for both agents. Hypocalcemia resulting from calcimimetics can result in QTc prolongation[29] and may lower the seizure threshold in patients with seizure disorders.

▶ *Outcome Evaluation*

KDIGO guidelines recommend monitoring serum calcium, phosphorus, and PTH levels early in CKD, with increasing frequency as renal function declines. Calcium and phosphorus levels should be monitored every 6 to 12 months in CKD G3a to G3b; every 3 to 6 months in CKD G4, and every 1 to 3 months in CKD G5. PTH levels should be monitored every 6 to 12 months for CKD G3-G4 and every 3 to 6 months in CKD G5.[26]

Monitor serum calcium and phosphorus levels regularly in patients receiving phosphate-binding agents. When initiating therapy, monitor serum levels every 1 to 4 weeks, depending on the severity of hyperphosphatemia. Titrate doses of phosphate binders to maintain phosphorus levels near normal. Once target levels are achieved, monitor phosphorus and corrected serum calcium or ionizsed calcium levels every 1 to 3 months. Monitor-iPTH levels monthly while initiating vitamin D therapy, then every 3 months once stable iPTH levels are achieved. When starting or increasing the dose of cinacalcet, monitor serum calcium and phosphorus levels within 1 week; iPTH levels should be monitored within 1 to 4 weeks. Once target levels are achieved, decrease monitoring to every 3 months.

Impaired Electrolyte and Acid-Base Homeostasis

The kidney is responsible for regulating homeostasis for sodium, potassium, water, and acid-base. Reductions in the number of functioning nephrons decrease glomerular filtration regulation of electrolytes and acid secretion.

▶ *Pathophysiology*

As the number of functioning nephrons decreases, the remaining nephrons are able to increase excretion of sodium, water, potassium, and hydrogen ions. However, this is limited and as the number of functioning nephrons decreases as CKD progresses, total excretion of electrolytes and fluid eventually decreases.

Sodium and water balance is maintained by natriuretic peptides, namely, atrial natriuretic peptide (ANP), which increases sodium excretion in the kidneys. The relative increase in sodium excretion by a smaller number of functioning nephrons results in an osmotic diuresis that promotes water excretion but impairs the ability of the kidneys to concentrate and dilute urine. Thus, urine becomes fixed at an osmolality close to that of the plasma, approximately 300 mOsm/kg (mmol/kg) and presents as nocturia. Sodium and fluid retention increases intravascular volume and raises systemic blood pressure, which can present as early as CKD G3a to G3b.[30]

Potassium excretion occurs in both the distal tubules of the kidney and in the GI tract, which is mediated by aldosterone stimulation. Aldosterone increases in response to rising serum potassium, which then increases potassium excretion in both the functioning nephrons and GI tract. This maintains serum potassium concentrations within the normal range through CKD G1 to G4. Hyperkalemia begins to develop when GFR falls below 20% of normal, when the number of functioning nephrons and renal potassium secretion is so low that the capacity of the GI tract to excrete potassium has been exceeded.[31]

Medications can increase the risk of hyperkalemia in patients with CKD, including ACEI and ARBs, used for the treatment of proteinuria and hypertension. Potassium-sparing diuretics, used for the treatment of edema and chronic heart failure, can also exacerbate the development of hyperkalemia, and they should be used with caution in patients with CKD G3 or higher.

Hydrogen ions are excreted at the same rate of production by the kidney via buffers in the urine created by ammonia generation and phosphate excretion to maintain the pH of body fluids within a very narrow range. As kidney function declines, bicarbonate reabsorption is maintained, but hydrogen excretion is decreased because the ability of the kidney to generate ammonia is impaired. The positive hydrogen balance leads to metabolic acidosis, which is characterized by a serum bicarbonate level of 15 to 20 mEq/L (mmol/L), and an elevated anion gap greater than 17 mEq/L (mmol/L), resulting in a pH less than 7.35. Metabolic acidosis generally presents when the GFR declines below 25 mL/min/1.73 m^2 (0.24 mL/s/m^2).[32]

Metabolic acidosis contributes to various complications associated with CKD. Metabolic acidosis can directly cause bone disease, particularly in children, and contribute significantly to the bone disease induced by secondary hyperparathyroidism, as discussed previously. Metabolic acidosis also decreases hepatic albumin synthesis, which contributes to hypoalbuminemia and muscle wasting. Furthermore, metabolic acidosis can accelerate progression of CKD by causing tubular injury. Reversal of metabolic acidosis has been demonstrated to decrease progression of CKD, improve bone disease and increase serum albumin concentrations.[32]

▶ *Treatment*

Nonpharmacologic Treatment The kidney is unable to adjust to abrupt changes in sodium and potassium intake in patients with severe CKD. Electrolyte disorders resulting from an acute increase in intake can be more severe and prolonged.

Clinical Presentation and Diagnosis of Electrolyte and Acid-Base Abnormalities

General

Alterations in sodium and water balance in CKD manifests as increased edema.

Hyperkalemia is generally asymptomatic in patients with CKD until serum potassium levels are greater than 5.5 mEq/L (mmol/L), when cardiac abnormalities present.

Metabolic acidosis is generally asymptomatic in patients with CKD.

Symptoms

Nocturia can present in CKD G3a-G3b.

Edema generally presents in CKD G4 or later.

Mild hyperkalemia and metabolic acidosis are generally not associated with overt symptoms.

Symptoms of hyperkalemia generally appear when GFR falls below 20 ml/min/1.73m^2 (0.19 ml/s/m^2), such as muscle weakness, fatigue, nausea, and paresthesias.

Symptoms of chronic metabolic acidosis present as bone abnormalities and growth retardation in children.

Signs

Cardiovascular:

Sodium: Worsening hypertension, edema.

Potassium: ECG changes (peaked T waves, widened QRS complex, loss of P wave).

Genitourinary: Sodium abnormalities result in change in urine volume and consistency.

Laboratory Tests

Sodium: Increased blood pressure; sodium levels remain within the normal range; urine osmolality is generally fixed at 300 mOsm/kg (mmol/kg).

Potassium: Increased serum potassium levels.

Metabolic acidosis: Decreased serum bicarbonate levels (CO_2); decreased pH.

Sodium and Water. Patients with CKD should be advised to refrain from adding salt to their diet but should not restrict sodium intake. Changes in sodium intake should occur slowly over a period of several days to allow adequate time for the kidney to adjust urinary sodium content. Sodium restriction produces a negative sodium balance, which causes fluid excretion to restore sodium balance. The resulting volume contraction can decrease perfusion of the kidney and hasten the decline in GFR. Saline-containing IV solutions should be used cautiously in patients with CKD because the salt load may precipitate volume overload.

Fluid restriction is generally unnecessary as long as sodium intake is controlled. The thirst mechanism remains intact in CKD to maintain total body water and plasma osmolality near normal levels. Fluid intake should be maintained at the rate of urine output to replace urine losses, usually fixed at approximately 2 L/day as urine concentrating ability is lost. Significant increases in free water intake orally or IV can precipitate volume overload and hyponatremia. Patients with CKD G5 require RRT to maintain normal volume status. Fluid intake is often limited in patients receiving HD to prevent fluid overload between dialysis sessions.

Diuretic therapy is often necessary to prevent volume overload in patients with CKD who still produce urine. When GFR falls below 30 mL/min/1.73 m^2 (0.29 mL/s/m^2), thiazide diuretics alone may not be effective in reducing fluid retention.[21] Loop diuretics are most frequently used to increase sodium and water excretion. As CKD progresses, higher doses, as much as 80 to 1000 mg/day of oral furosemide, or continuous infusion of loop diuretics may be needed, or combination therapy with loop and thiazide diuretics to increase sodium and water excretion.[17]

Potassium. Patients who develop hyperkalemia should restrict dietary intake of potassium to 50 to 80 mEq (mmol) per day. Potassium concentrations can also be altered in the dialysate for patients receiving HD and PD to manage hyperkalemia. Because GI excretion of potassium plays a large role in potassium homeostasis in patients with CKD G5, a good bowel regimen is essential to minimize constipation. Severe hyperkalemia is most effectively managed by HD.

Acute hyperkalemia can be managed medically until dialysis can be initiated. Loop diuretics, some potassium-binding agents, and fludrocortisone are useful in the management of hyperkalemia in patients with CKD. Acute hyperkalemia that results in cardiac abnormalities can be managed with calcium, insulin, and dextrose; sodium bicarbonate; or β_2-agonist. The management of hyperkalemia is discussed in more detail in Chapter 28. Potassium-binding agents are particularly useful in CKD to lower potassium levels. Potassium-binding agents decrease potassium levels by exchanging ions in the GI tract to enhance GI excretion of potassium. Sodium polystyrene sulfonate (SPS) exchanges potassium for sodium; however, it is poorly tolerated because of GI side effects. Newer agents are better tolerated and are preferred for managing potassium levels in CKD. Patiromer exchanges potassium for calcium, primarily in the colon. The recommended dose of patiromer is 8.4 g once daily and can be titrated up to 25.2 g/day. Doses of patiromer should be separated from other medications by at least 3 hours. Both SPS and patiromer have a longer onset of action and are not suitable for acute treatment of hyperkalemia. Sodium zirconium cyclosilicate (SZC) exchanges potassium for sodium and hydrogen ions in the lower intestines and colon. Potassium levels are reduced within 1 hour of administration, making it useful for acute management of hyperkalemia in addition to long-term management. The recommended dose of SZC is 10 g once daily for chronic hyperkalemia but can be administered more frequently for acute hyperkalemia. Patiromer and SZC are associated with GI side effects, including constipation, diarrhea, nausea, and abdominal discomfort, but side effects are more pronounced with patiromer. SZC can also cause edema, which can be managed with diuretics. Use of potassium-binding agents can reduce the hyperkalemic effects of ACEIs and ARBs and prolong their use in latter stages of CKD.[33]

Metabolic Acidosis. Pharmacologic therapy with sodium bicarbonate or citrate/citric acid preparations may be needed in patients with CKD G3 or higher to replenish body stores of bicarbonate. Calcium carbonate, used to bind phosphorus in sHPT, also aid in increasing serum bicarbonate levels, in conjunction with other agents. The management of acidosis is discussed in more detail in Chapter 29.

▶ *Outcome Evaluation*

Monitor serum electrolytes and bicarbonate levels regularly. Monitor edema after initiation of diuretic therapy. Monitor fluid intake to ensure obligatory losses are being met and avoid dehydration. If adequate diuresis is not attained with a single agent, consider combination therapy with another diuretic, such as a loop plus thiazide diuretic. In patients with cardiac abnormalities due to elevated potassium levels, monitor ECG continuously until serum potassium levels drop below 5 mEq/L (mmol/L) or cardiac abnormalities resolve. Evaluate serum potassium and glucose levels within 1 hour in patients who receive insulin and dextrose therapy. Evaluate serum potassium levels within 2 to 4 hours after treatment with patiromer, SPS or diuretics. Repeat doses of diuretics or SPS if necessary, until serum potassium levels fall below 5 mEq/L (mmol/L). Monitor blood pressure and serum potassium levels in 1 week after starting fludrocortisone. Correct metabolic acidosis slowly to prevent the development of metabolic alkalosis or other electrolyte abnormalities.

RENAL REPLACEMENT THERAPY

Patients who progress to ESKD require RRT. The modalities that are used for RRT are dialysis, including HD and PD, and kidney transplantation. The USRDS reported that the number of patients with ESKD was 726,331, with 124,675 new cases diagnosed in 2016.[3] The mortality rate of patients with ESKD was 134 per 1000-patient years in 2016, which is decreased from 190 per 1000-patient years in 2001.[3] The modality of RRT influences mortality considerably, with a mortality of 163 per 1000-patient years with dialysis, compared to 29 per 1000-patient years mortality with transplant.[3] The improved survival makes kidney transplantation the preferred method of RRT; however, organ availability limits the number of patients who can receive a kidney transplant. Only 2.5% of patients with newly diagnosed ESKD receive kidney transplants each year.[3] Therefore, the most common form of RRT is dialysis, accounting for more than 97% of all patients with ESKD.[3] The principles and complications associated with dialysis are discussed later. Chapter 55 discusses the principles of kidney transplantation.

Indications for Dialysis

KEY CONCEPT Planning for dialysis should begin when GFR falls less than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2) (CKD G4), when progression to ESKD is inevitable, to allow time to educate the patient and family on the treatment modalities for renal replacement and establish the appropriate access for the modality of choice.[34] Ideally, initiation of dialysis should be done at a point when the patient is ready to undergo treatment, rather than when the patient is in emergent need of dialysis.

Initiation of dialysis depends on the patient's clinical status and not based solely on laboratory values. Symptoms that may indicate the need for dialysis include persistent anorexia, nausea, vomiting, fatigue, and pruritus. Other criteria that indicate the need for dialysis include declining nutritional status, declining serum albumin levels, electrolyte abnormalities, particularly hyperkalemia, and volume overload, which may manifest as chronic heart failure and uncontrolled hypertension. Blood urea nitrogen (BUN) and SCr levels may be used as a guide for the initiation of dialysis, but they should not be the absolute indicator. Dialysis is initiated in most patients after the GFR falls below 15 mL/min/1.73 m^2 (0.14 mL/s/m^2).[34] Patients should determine which modality of dialysis to use based on their own preferences. Advantages and disadvantages of HD and PD are listed in Tables 27–8 and 27–9, respectively.

The goals of dialysis are to remove toxic metabolites to decrease uremic symptoms, correct electrolyte abnormalities, restore acid–base status, and maintain volume status to ultimately improve quality of life and decrease the morbidity and mortality associated with ESKD.

Table 27–8

Advantages and Disadvantages of Hemodialysis

Advantages

1. Higher solute clearance allows intermittent treatment
2. Parameters of adequacy of dialysis are better defined and therefore underdialysis can be detected early
3. The technique's failure rate is low
4. Even though intermittent heparinization is required, hemostasis parameters are better corrected with hemodialysis than peritoneal dialysis
5. In-center hemodialysis enables closer monitoring of the patient

Disadvantages

1. Requires multiple visits each week to the hemodialysis center, which translates into loss of control by the patient
2. Dysequilibrium, dialysis, hypotension, and muscle cramps are common. May require months before patient adjusts to hemodialysis
3. Infections in hemodialysis patients may be related to the choice of membranes; the complement-activating membranes are more deleterious
4. Vascular access is frequently associated with infection and thrombosis
5. Decline of residual renal function is more rapid compared with peritoneal dialysis

From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Yee GC, Posey M, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020, with permission.

Hemodialysis

HD is the most common method of RRT, initiated in 88% of US patients with newly diagnosed ESKD each year, with a total of 428,588 patients receiving HD in 2014.[3] Home HD is becoming increasingly more popular, but most patients continue to receive HD from a dialysis center.

Table 27–9

Advantages and Disadvantages of Peritoneal Dialysis

Advantages

1. More hemodynamic stability (blood pressure) due to slow ultrafiltration rate
2. Increased clearance of larger solutes, which may explain good clinical status in spite of lower urea clearance
3. Better preservation of residual renal function
4. Convenient intraperitoneal route of administration of drugs such as antibiotics and insulin
5. Suitable for elderly and very young patients who may not tolerate hemodialysis well
6. Freedom from the "machine" gives the patient a sense of independence (for continuous ambulatory peritoneal dialysis)
7. Less blood loss and iron deficiency, resulting in easier management of anemia or reduced requirements for erythropoietin and parenteral iron
8. Systemic heparin not required
9. Subcutaneous versus IV erythropoietin or darbepoetin is usual, which may reduce overall doses and be more physiologic

Disadvantages

1. Protein and amino acid losses through the peritoneum and reduced appetite owing to continuous glucose load and sense of abdominal fullness predispose to malnutrition
2. Risk of peritonitis
3. Catheter malfunction, and exit site and tunnel infection
4. Inadequate ultrafiltration and solute dialysis in patients with a large body size, unless large volumes and frequent exchanges are employed
5. Patient burnout and high rate of technique failure
6. Risk of obesity with excessive glucose absorption
7. Mechanical problems such as hernias, dialysate leaks, hemorrhoids, or back pain may occur
8. Extensive abdominal surgery may preclude peritoneal dialysis
9. No convenient access for IV iron administration

From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Yee GC, Posey M, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020, with permission.

▸ *Principles of Hemodialysis*

KEY CONCEPT Hemodialysis involves the exposure of blood to a semipermeable membrane (dialyzer) against which a physiologic solution (dialysate) is flowing (Figure 27–4). The dialyzer is composed of thousands of capillary fibers made up of the semipermeable membrane, which are enclosed in the dialyzer, to increase the surface area of blood exposure to maximize the efficiency of removing substances. The dialysate is composed of purified water and electrolytes, and it is run through the dialyzer countercurrent to the blood on the other side of the semipermeable membrane. The process allows for the removal of several substances from the bloodstream, including water, urea, creatinine, electrolytes, uremic toxins, and some drugs. Sterilization is not required for dialysate because the membrane prevents bacteria from entering into the bloodstream. However, if the membrane ruptures during HD, infection becomes a major concern for the patient.

Three types of membranes used for dialysis are classified by the size of the pores and the ability to remove solutes from the bloodstream: low flux, high efficiency, and high flux. Low flux membranes have small pores, which limit solute removal to relatively small molecules, such as creatinine and urea. High-efficiency membranes also have small pores but have a higher surface area

Patient Encounter 4, Part 1

A 33-year-old Caucasian male with a history of focal segmental glomerulosclerosis (FSGS) presents to the clinic with complaints that he "feels terrible and exhausted and foggy." He has not felt like eating for several weeks and has lost 12 lb (5.5 kg) in the last 2 months. As of yesterday, he is unable to keep any food down and has been very nauseous and vomiting.

PMH: FSGS; hypertension; anxiety

Current medications: Venlafaxine XR 150 mg orally daily; vitamin D_3 2000 international units orally daily; lisinopril 20 mg orally daily; metoprolol 50 mg orally twice daily; calcium acetate 1,334 mg orally three times daily with meals; pravastatin 40 mg orally daily.

ROS: Lethargic male in mild distress.

PE:

VS: BP 178/108 mm Hg; P 86 bpm; T 97.2°F (36.2°C); ht 5′10″ (178 cm); wt 150 lb (68 kg)

CV: RRR, normal S_1, S_2, present

Lungs: negative for crackles at bases; negative for inspiratory wheezes

Ext: 4+ bilateral lower extremity edema present to mid-thigh

Labs: Sodium 138 mEq/L (mmol/L); potassium 7.2 mEq/L (mmol/L); chloride 106 mEq/L (mmol/L); carbon dioxide 10 mEq/L (mmol/L); BUN 108 mg/dL (38.5 mmol/L); SCr 8.1 mg/dL (716 μmol/L); glucose 62 mg/dL (3.4 mmol/L); calcium 9.8 mg/dL (2.45 mmol/L); phosphate 5.6 mg/dL (1.81 mmol/L); iPTH 315 pg/mL (ng/L; 33.7 pmol/L); WBC 6.8×10^3 cells/mm^3 (6.8×10^9/L); RBC 4.0×10^6 cells/mm^3 (4.0×10^{12}/L); Hgb 10.4 g/dL (104 g/L; 6.46 mmol/L); Hct 30% (0.30); platelets 278×10^3 cells/mm^3 (278×10^9/L)

What indications does the patient have for dialysis?

What options for renal replacement therapy exist for the patient?

What are the advantages and disadvantages of each modality for renal replacement therapy?

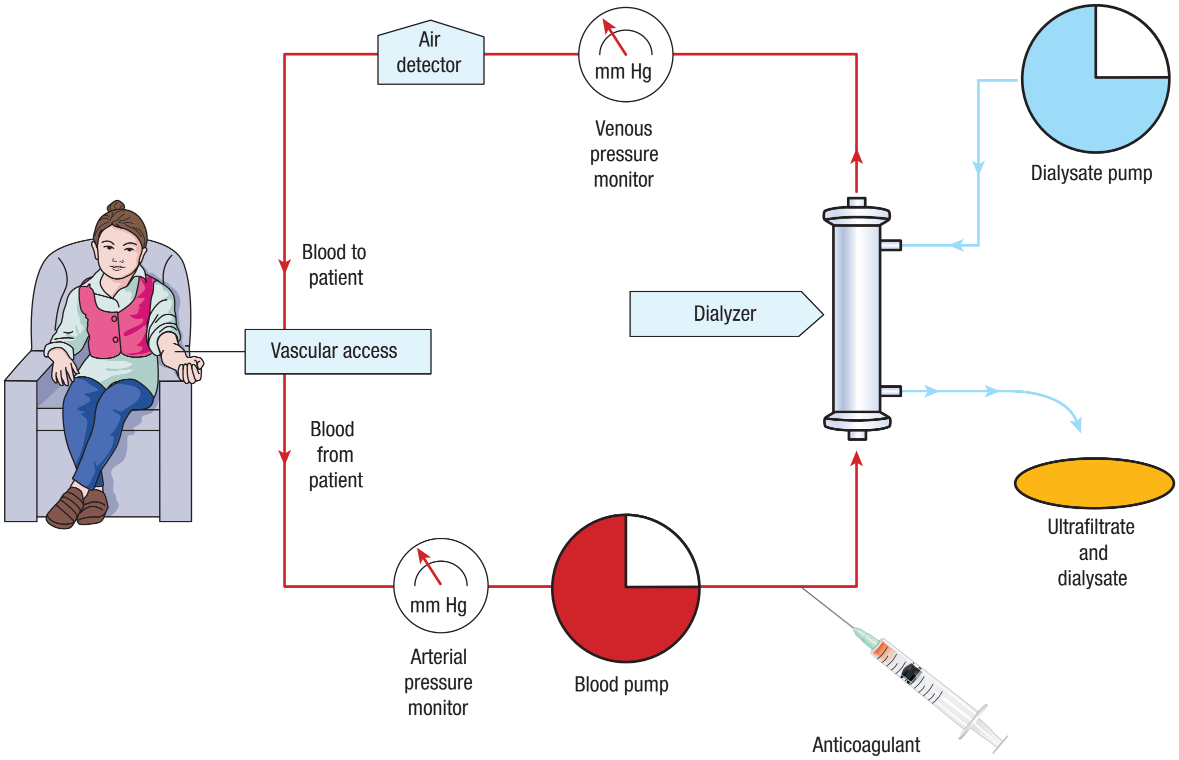


FIGURE 27–4. In hemodialysis, the patient's blood is pumped to the dialyzer at a rate of 300 to 600 mL/min. An anticoagulant (usually heparin) is administered to prevent clotting in the dialyzer. The dialysate is pumped at the rate of 500 to 1000 mL/min through the dialyzer countercurrent to the flow of blood. The rate of fluid removal from the patient is controlled by adjusting the pressure in the dialysate compartment. (From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Yee GC, Posey M, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020, with permission.)

that increases removal of small molecules, such as water, urea, and creatinine from the blood. The most widely used dialyzers are high-flux membranes which larger pores that allow for the removal of substances with higher molecular-weight, including some drugs, such as vancomycin.

Three primary processes are utilized for the removal of substances from the blood:

- Diffusion is the movement of a solute across the dialyzer membrane from an area of higher concentration (usually the blood) to a lower concentration (usually the dialysate). This process removes small molecules from the bloodstream, such as electrolytes. At times, solutes can be added to the dialysate that are diffused into the bloodstream. Changing the composition of the dialysate allows for control of the amount of electrolytes that are being removed.
- Ultrafiltration is the movement of solvent (plasma water) across the dialyzer membrane by applying hydrostatic or osmotic pressure, and it is the primary means for removing water from the bloodstream. Changing the hydrostatic pressure applied to the dialyzer or the osmotic concentration of the dialysate allows for control of the amount of water being removed.
- Convection is the movement of dissolved solutes across the dialyzer membrane by "dragging" the solutes along a pressure gradient with a fluid transport and is the primary means for larger molecules to be removed from the bloodstream. Changing the pore size of the dialyzer membrane alters the efficiency of convection and allows for control of the amount of water removed in relation to the amount of solute being removed.

▶ *Vascular Access*

Long-term permanent access to the bloodstream is a key component of HD. There are three primary techniques used to obtain permanent vascular access in patients receiving HD: arteriovenous fistulas (AVFs), arteriovenous grafts (AVGs), and central venous catheters. An AVF is the preferred access method because it has the longest survival rate and the fewest complications. An AVF is made by creating an **anastomosis** between an artery and a vein, usually in the forearm of the nondominant arm (Figure 27–5). An AVG results in a similar access site but uses a synthetic graft, usually made of polytetrafluoroethylene, to connect the artery and vein in the forearm (Figure 27–5). The advantages of the AVG are that it is able to be used within 2 to 3 weeks, compared with 2 to 3 months for an AVF. However, AVGs are complicated by stenosis, thrombosis, and infections, which lead to a shorter survival time of the graft. Double-lumen venous catheters, placed in the femoral, subclavian, or jugular vein, are often used as temporary access while waiting for the AVF or AVG to mature. The catheters are tunneled beneath the skin to an exit site to reduce the risk of infection. Venous catheters can also be used as permanent access in patients in whom arteriovenous access cannot be established. However, venous catheters carry the greatest risk of complications, namely, thrombosis and infections.

▶ *Complications of Hemodialysis*

Complications associated with HD include hypotension, muscle cramping, thrombosis, infection, and vitamin depletion. The physiology of these complications is described below and the management is listed in Table 27–10.

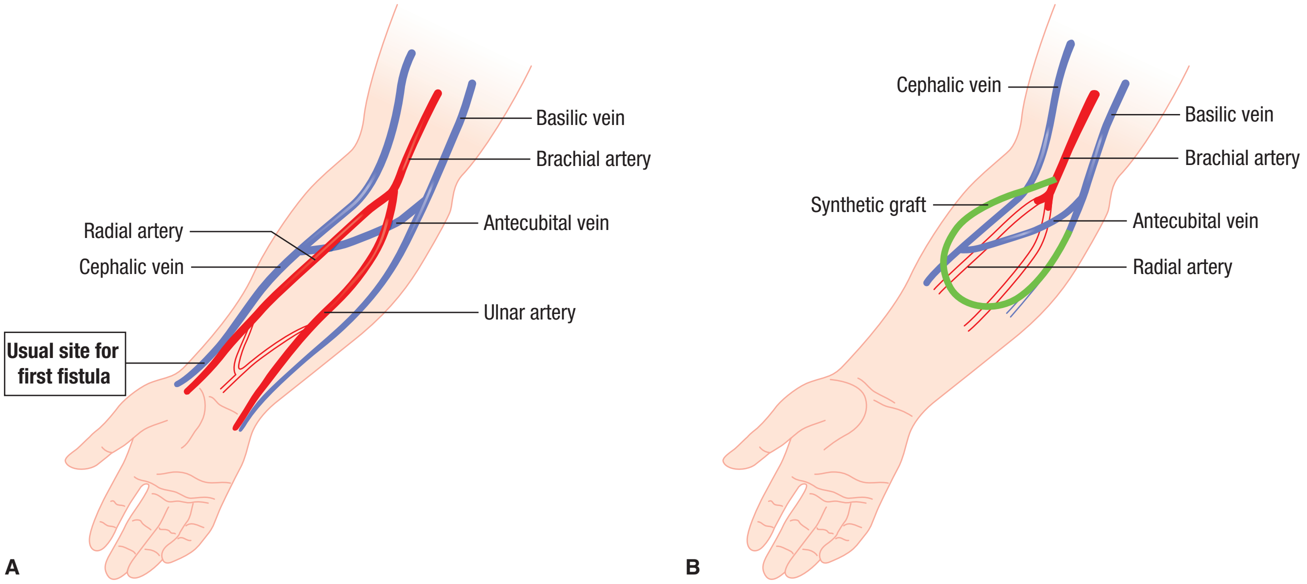

FIGURE 27–5. The predominant types of vascular access for chronic dialysis patients are (A) the arteriovenous fistula and (B) the synthetic arteriovenous forearm graft. The first primary arteriovenous fistula is usually created by the surgical anastomosis of the cephalic vein with the radial artery. The flow of blood from the higher-pressure arterial system results in hypertrophy of the vein. The most common AV graft (depicted in green) is between the brachial artery and the basilic or cephalic vein. The flow of blood may be diminished in the radial and ulnar arteries because it preferentially flows into the low pressure graft. (From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Yee GC, Posey M, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020, with permission.)

Table 27–10

Management of Complications Associated with Hemodialysis

Hypotension	Acute treatment	Decrease ultrafiltration rate Place in Trendelenburg position (head lower than feet) Normal saline 100–200 mL Hypertonic saline (23.4%) 10–20 mL Mannitol 12.5 g
	Prevention	Accurate determination of "dry weight" Midodrine 2.5–10 mg 30 minutes prior to HD Other options with limited evidence: Levocarnitine 20 mg/kg IV after HD Sertraline 50–100 mg daily Fludrocortisone 0.1 mg before HD
Muscle cramps	Acute treatment	Normal saline 100–200 mL Hypertonic saline (23.4%) 10–20 mL Dextrose 50% 50 mL (for nondiabetic patients)
	Prevention	Decrease ultrafiltration rate Accurate determination of "dry weight" Stretching exercises, massage, flexing, compression devices Vitamin E 400 IU daily
Central Venous Catheter Thrombosis	Acute treatment	Normal saline flush Alteplase 2 mg/2 mL per catheter lumen port Reteplase 0.4 U/0.4 mL per catheter lumen port
	Prevention	Heparin lock (1000–10,000 units/1 mL) Sodium citrate 4% lock
Vitamin depletion	Prevention	Multivitamin B complex with vitamin C supplement

Hypotension Hypotension is the most common complication seen during HD. It has been reported to occur with approximately 20% to 30% of dialysis sessions.[35]

Pathophysiology. Hypotension associated with HD manifests as a symptomatic decrease in systolic blood pressure of more than 20 mm Hg or a decrease in mean arterial pressure of more than 10 mm Hg during the dialysis session. The primary cause is fluid removal from the bloodstream. Ultrafiltration removes fluid from the plasma, which promotes redistribution of fluids from extracellular spaces into the plasma. However, decreased serum albumin levels and removal of solutes from the bloodstream reduce the osmotic pressure of the plasma relative to the extracellular spaces, slowing redistribution during HD. The decreased plasma volume causes hypotension. Other factors that can contribute to hypotension include antihypertensive medications prior to HD, a target "dry weight" (the target weight after HD session is complete) that is too low, diastolic or autonomic dysfunction, low dialysate calcium or sodium, high dialysate temperature, or ingesting meals prior to or during HD. Elderly age, diabetes, autonomic neuropathy, uremia, and cardiac disease also increase the potential for hypotension.[35] The symptoms associated with hypotension during dialysis include dizziness, nausea, vomiting, abdominal pain, and muscle cramping.

Muscle Cramps Muscle cramps are reported in as many as 35% to 86% of patients receiving HD.[36] The cause is often related to excessive ultrafiltration, which causes hypoperfusion of the muscles. Other contributing factors to the development of muscle cramps include hypotension, hypoosmolality, and electrolyte and acid–base imbalances that occur during HD sessions.[36]

Thrombosis Thrombosis associated with HD most commonly occurs in patients with venous catheter access for dialysis and is a common cause of catheter failure. However, thrombosis can occur in synthetic grafts and less frequently in AVF.

Patient Encounter 4, Part 2

The patient returns to the dialysis center 1 month later for routine hemodialysis. Two hours after starting dialysis, he complains of muscle cramps

PE:

VS: BP 121/68 mm Hg; P 72 bpm; T 98.9° F (37.2° C); wt 155 lb (70.3 kg)

What is the most likely cause of his cramping?

What treatment would you recommend?

Infection Infections are an important cause of morbidity and mortality in patients receiving hHD. The cause of infection is usually related to organisms found on the skin, namely, *Staphylococcus epidermidis* and *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA). Gram-negative bacteria are more commonly associated with bacteremia. The greatest risk to patients receiving HD is the development of bacteremia, which is commonly associated with coagulase negative staphylococci and gram-negative bacteria. The risk of bacteremia is up to 10 times higher with venous catheters compared to AVF.[37]

Blood cultures should be obtained for any patient receiving HD who develops a fever. Nonpharmacologic management of infections involves preventive measures with sterile technique, proper disinfection, and minimizing the use and duration of venous catheters for HD access.

Pharmacologic management of infections should cover the gram-positive organisms that most frequently cause access-related infections. Patients who have positive blood cultures should receive treatment tailored to the organism isolated. Preventive measures for access-related infections include mupirocin at the exit site and povidone-iodine ointment. The recommendations of the National Kidney Foundation (NKF) for treatment of infections associated with HD are listed in Table 27–11.[36]

Vitamin Depletion Water-soluble vitamins removed by HD contribute to malnutrition and vitamin deficiency syndromes. Patients receiving HD often require replacement of water-soluble vitamins to prevent adverse effects. The vitamins that may require replacement are ascorbic acid, thiamine, biotin, folic acid, riboflavin, and pyridoxine. Patients receiving HD should take a multivitamin B complex with vitamin C supplement, but they should not take supplements that include fat-soluble vitamins, such as vitamins A, E, or K, which can accumulate in patients with kidney failure.

Peritoneal Dialysis

PD is initiated in 9.7% of patients with newly diagnosed ESKD each year.[3] In 2016, 51,057 patients were receiving PD.[3] PD is associated with improved survival compared with HD.[3] PD preserves residual renal function, which improves cardiovascular stability and may account for the improved survival. Thus, PD may be the preferred method of dialysis in patients with residual renal function.

▶ *Principles of Peritoneal Dialysis*

PD utilizes similar principles as HD in that blood is exposed to a semipermeable membrane against which a physiologic solution is placed. In the case of PD, however, the semipermeable membrane is the peritoneal membrane, and a sterile dialysate is instilled into the peritoneal cavity. The peritoneal membrane is composed of a continuous single layer of mesothelial cells that covers the abdominal and pelvic walls on one side of the peritoneal cavity, and the visceral organs including the GI tract, liver, spleen, and diaphragm on the other side. The mesothelial cells are covered by microvilli that increase the surface area of the peritoneal membrane to approximate body surface area (1–2 m^2). Blood vessels that supply the abdominal organs, muscle, and mesentery serve as the blood component of the system.

The gaps between the mesothelial cells allow for large solutes to pass through into the bloodstream. Both the interstitium and endothelial cells of the blood vessels provide resistance to limit the solute size that is removed from the blood. Diffusion is the most important component of solute transport in PD, which is enhanced by the large surface area and volume of dialysate, as well as contact time with the peritoneal membrane. Ultrafiltration is achieved in PD by creating an osmotic pressure gradient between the dialysate and the blood. Traditionally, glucose has been used

Table 27–11

Management of Hemodialysis Access Infections[36]

AV Fistula	Treat as subacute bacterial endocarditis for 6 weeks Initial antibiotic choice should always cover gram-positive organisms (eg, vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV three times per week) Gram-negative coverage is indicated for patients with diabetes, HIV infection, prosthetic valves, or those receiving immunosuppressive agents (gentamicin 2 mg/kg IV with serum concentration monitoring)
Synthetic Grafts (AVG)	
Local infection	Empiric antibiotic coverage for Gram-positive, Gram-negative, and *Enterococcus* (eg, gentamicin plus vancomycin, then individualize after culture results become available); continue for 2–4 weeks
Extensive infection	Antibiotics as above plus total resection
Access less than 1-month old	Antibiotics as above plus removal of the graft
Tunneled Cuffed Catheters (Internal Jugular, Subclavian)	
Infection localized to catheter exit site	No drainage: topical antibiotics (eg, mupirocin ointment) Drainage present: Gram-positive coverage (eg, cefazolin 20 mg/kg IV three times a week)
Bacteremia with or without systemic signs or symptoms	Gram-positive coverage as above If stable and asymptomatic, change catheter and provide culture-specific antibiotic coverage for a minimum of 3 weeks

AV, arteriovenous. From Ulu MS, Ahsen A. Muscle cramps during hemodialysis: what can we do? New approaches for treatment and preventing. Eur J Gen Med. 2015;12(3):277–281.

to create the osmotic gradient, but the solutions are not biocompatible with the peritoneal membrane, resulting in cytotoxicity of the cells. Polymeric glucose derivatives such as icodextrin may be used in place of glucose to create a colloid-driven osmosis that results in ultrafiltration and convection of solute removal but are more expensive.

In PD, prewarmed dialysate is instilled into the peritoneal cavity where it "dwells" for a specified length of time (usually one to several hours, depending on the type of PD) to adequately clear metabolic waste products and excess fluids and electrolytes. At the end of the dwell time, the dialysate is drained and replaced with fresh dialysate. The continuous nature of PD provides for a more physiologic removal of waste products from the bloodstream, which mimics endogenous kidney function by limiting the fluctuations seen in serum concentrations of the waste products. Similarly, water is removed at a more constant rate, lessening the fluctuations in intravascular fluid balance and providing for more hemodynamic stability.

Several types of PD are used:

- Continuous ambulatory PD (CAPD) is the most common. The patient exchanges 1 to 3 L of dialysate every 4 to 6 hours throughout the day with a longer dwell time overnight.
- Automated PD (APD) procedures involve the use of a cycler machine that performs sequential exchanges overnight while the patient is sleeping.
- Continuous cycling PD (CCPD) performs three to five exchanges throughout the night. The final exchange remains in the peritoneal cavity to dwell for the duration of the day.
- Nightly intermittent PD (NIPD) performs six to eight exchanges throughout the night. The final exchange of dialysate is drained in the morning, and the peritoneal cavity remains empty throughout the day.
- Nocturnal tidal PD (NTPD) is similar to NIPD, with the exception that only a portion of the dialysate is exchanged throughout the night. The final exchange is drained in the morning, and the peritoneal cavity remains empty throughout the day.

▶ *Peritoneal Access*

Access to the peritoneal cavity requires placement of an indwelling catheter with the distal end of the catheter resting in the peritoneal cavity. The central portion of the catheter is generally tunneled under the abdominal wall and SC tissue where it is held in place by cuffs that provide stability and mechanical support to the catheter. The proximal portion of the catheter exits the abdomen near the umbilicus. Several types of indwelling catheters are available; the most common is the Tenckhoff catheter. Placement and handling of the catheter during PD exchanges requires a sterile environment to minimize the risk of infectious complications.

▶ *Complications of Peritoneal Dialysis*

Complications associated with PD include mechanical problems related to the PD catheter, metabolic problems associated with the components of the dialysate fluid, damage to the peritoneal membrane, and infections (Table 27–12). Strategies to manage infectious complications of PD are discussed below.

Peritonitis Peritonitis is a leading cause of morbidity in PD patients, which often leads to loss of the catheter and subsequent change to HD as the treatment modality. However, advances with connectors used during instillation and drainage of dialysate and delivery systems have dramatically decreased the incidence of peritonitis. Peritonitis can also be caused by chemical irritation or microorganisms.

Table 27–12

Common Complications During Peritoneal Dialysis

Mechanical Complications
Kinking in catheter
Catheter migration
Catheter adherence to peritoneal tissue
Excessive movement of catheter at exit site

Peritoneal Damage
Alterations in permeability of the peritoneal membrane
Sclerosis of the peritoneal membrane

Pain
Impingement of the catheter tip on visceral organs
Instillation pain
- Rapid inflow of dialysate
- Acidic pH of dialysate
- Chemical irritation from dialysate additives (eg, antibiotics)
- Low dialysate temperature

Infections
Peritonitis
Exit-site infections
Tunnel infections

Metabolic Complications
Exacerbation of diabetes mellitus from glucose load
Fluid overload
- Exacerbation of chronic heart failure
- Edema
- Pulmonary congestion

Electrolyte abnormalities
Malnutrition
- Albumin and amino acid loss
- Muscle wasting
- Increased adipose tissue
- Fibrin formation in dialysate

Weight gain

Pathophysiology. Gram-positive organisms, namely, *S. epidermidis*, are the most common cause of peritonitis. Other pathologic organisms include *S. aureus*, streptococcal species, enterococcus species, gram-negative organisms including *Escherichia coli* and *Pseudomonas* species, and fungal organisms. Peritonitis should be presumed if cloudy fluid is drained from the peritoneal cavity and the fluid should be evaluated by cultures. Antibiotic treatment should be initiated immediately, until cell counts and cultures prove otherwise.[38] Patients with peritonitis may also complain of abdominal pain, although pain may be absent in some cases.

Treatment. The International Society of Peritoneal Dialysis (ISPD) revised the recommendations for the treatment of PD-related infections in 2016.[38] Drug selection for empirical treatment of peritonitis should cover both gram-positive and gram-negative organisms specific to the dialysis center and be based on the protocols and sensitivity patterns of organisms known to cause peritonitis, as well as the history of infections in the patient. First-generation cephalosporins, such as cefazolin, or vancomycin are recommended for empirical coverage of Gram-positive organisms. Appropriate coverage for Gram-negative organisms includes third- or fourth-generation cephalosporins, such as ceftazidime or cefepime, or aminoglycosides. Alternatives for gram-negative coverage include oral fluoroquinolones and aztreonam. An example of an appropriate empiric treatment for peritonitis includes cefazolin in combination with ceftazidime, cefepime, or an aminoglycoside. If the patient has a β-lactam allergy, vancomycin in combination with an aminoglycoside or aztreonam is an alternative empirical treatment.[38] It should be noted that aminoglycosides can decrease residual renal function in patients receiving PD.

The preferred route of administration is intraperitoneal (IP) rather than IV to achieve maximum concentrations at the site of infection. Antibiotics can be administered IP intermittently as a single large dose in one exchange per day or continuously as multiple smaller doses with each exchange. Intermittent administration requires at least 6 hours of dwell time in the peritoneal cavity to allow for adequate systemic absorption and provides adequate levels to cover the 24-hour period. However, continuous administration is better suited for PD modalities that require more frequent exchanges (less than 6-hour dwell time). See the ISPD guidelines for dosing recommendations for IP antibiotics in CAPD and APD patients.[38] The dose of the antibiotics should be increased by 25% for patients with residual kidney function who are able to produce more than 100 mL urine output per day.

Once the organism has been identified and sensitivities are known, drug selection should be adjusted to reflect the susceptibilities of the organism. Streptococcal, staphylococcal, and enterococcal species sensitive to β-lactam antibiotics should be treated with continuous IP dosing to increase efficacy and minimize resistance.[38] Peritonitis caused by *S. aureus* or *P. aeruginosa* are often associated with catheter-related infections, which are difficult to treat and often require removal of the catheter. Two antibiotics are required for treatment of *P. aeruginosa* peritonitis.[38] If multiple organisms are cultured, treatment should cover all the organisms, including anaerobic organisms, and the patient should be evaluated for other intra-abdominal pathologies.[38]

Peritonitis caused by fungal organisms is associated with mortality in 25% of patients,[38] which can be reduced by removing the catheter after fungal organisms are identified. If a fungal organism is identified, empirical treatment should include IP amphotericin B and flucytosine,[38] but alternative agents can be used based on susceptibilities. Although IP amphotericin administration is associated with chemical irritation and pain, penetration of amphotericin into the peritoneal cavity is poor with IV administration. Fluconazole, voriconazole, or caspofungin may be suitable alternatives, depending on culture results.

Catheter-Related Infections Catheter-related infections generally occur at the exit site or the portion of the catheter that is tunneled in the SC tissue. Previous infections increase the risk and incidence of catheter-related infections.

Pathophysiology. The major pathologic organisms responsible for causing catheter-related infections are *S. aureus* and *P. aeruginosa*. These organisms also cause the most serious catheter-related infections. *S. epidermidis* is found in less than 20% of catheter-related infections.[39]

Exit-site infections present with purulent drainage at the site. Erythema may or may not be present with an exit-site infection. Tunnel infections are generally extensions of exit-site infections and rarely occur alone. Symptoms of a tunnel infection may include tenderness, edema, and erythema over the tunnel pathway but are often asymptomatic. Ultrasound can be used to detect tunnel infections in asymptomatic patients. Exit-site infections caused by *S. aureus* and *P. aeruginosa* often spread to tunnel infections and are the most common causes of catheter-infection–related peritonitis.

JCPP Patient Care Process: Chronic Kidney Disease

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements.
- Review the medical history, laboratory tests, and physical assessment.
- Speak with the patient and review records to identify socioeconomic factors that affect medication access and other aspects of care.

Assess the Information:

- Identify risk factors that increase the risk for CKD (Table 27–3).
- Determine whether the patient has any concomitant diseases that may hasten the progression of CKD or increase the risk of CVD.
- Identify medications the patient is taking that may cause nephrotoxicity or require adjustment for renal dysfunction.
- Review relevant laboratory tests to determine if patient is experiencing complications of CKD.
- Calculate GFR to determine the staging of CKD (Tables 27–1 and 27–2).
- Determine if the patient is experiencing signs and symptoms associated with CKD, or complications CKD (Figures 27–3 and 27–4).

Develop a Care Plan:

- Determine if pharmacotherapy is indicated for proteinuria or other concomitant disease states.
- Select appropriate medical treatments to control complications of CKD, including anemia (Figure 27–2, Tables 27–5 and 27–6); mineral and bone diseases (Figure 27–3, Tables 27–6 and 27–7); and electrolyte imbalances.
- Select medications and doses that are appropriately adjusted for the level of kidney function.

Implement the Care Plan:

- Educate the patient about changes in drug therapy.
- Address patient's concerns about CKD and its management.
- Educate the patient on dietary and lifestyle changes to treat complications of CKD.
- Stress the importance of adherence with the treatments for CKD and associated complications including lifestyle modifications and medications.
- Recommend a therapeutic regimen that is easy for the patient to accomplish.

Follow-up: Monitor and Evaluate:

- Follow-up at regular intervals to assess effectiveness and safety of therapy.
- Review physical exam and lab tests to assess changes in clinical status.

Treatment. Exit-site infections may be treated immediately with empiric coverage, or treatment may be delayed until cultures return. Empiric treatment of catheter-related infections should cover *S. aureus* with a first-generation cephalosporin or penicillinase-resistant penicillin. Coverage for MRSA or *P. aeruginosa* should also be included if the patient has a history of infections with either organism. Vancomycin or clindamycin are used for empiric coverage of MRSA, while oral fluoroquinolones are used as first-line agents to treat *P. aeruginosa*.[39]

Cultures and sensitivity testing are particularly important in tailoring antibiotic therapy for catheter-related infections to ensure eradication of the organism and prevent recurrence or related peritonitis. Treatment of catheter-related infections should be continued until the exit site appears normal with no erythema or drainage. Generally, at least 2 weeks of therapy or longer are required to ensure complete eradication of the organism and prevent future recurrence, which is common with *S. aureus* and *P. aeruginosa*. Infections that do not resolve may require replacement of the PD catheter. Catheter-related infections that present in conjunction with or progress to peritonitis with the same organism require removal of the PD catheter until the peritonitis is resolved.[39]

Prophylaxis of Peritonitis and Catheter-Related Infections. Prevention of peritonitis and catheter-related infections starts when the catheter is placed. The exit site should be properly cared for until it is well healed before it can be used for PD. Patients should receive proper instructions for care of the catheter during this time period, which can last up to 2 weeks. Patients should also be instructed on the proper techniques to use for dialysate exchanges to minimize the risk of infections during exchanges, which is the most common cause of peritonitis.

Topical antibiotics, including mupirocin, gentamicin, or ciprofloxacin cream or ointment should be applied daily around the exit site to prevent catheter-related infections.[39] Intranasal *S. aureus* increases the risk of *S. aureus* exit-site infections, tunnel infections, peritonitis, and subsequent catheter loss.[39]

Outcome Evaluation. Clinical improvement should be seen within 48 hours of initiating treatment for peritonitis or catheter-related infections. Perform daily inspections of peritoneal fluid or the exit site to determine clinical improvement. Peritoneal fluid should become clear with improvement of peritonitis and erythema, and discharge should remit with improvement of catheter-related infections. If no improvement is seen within 48 hours, obtain additional cultures and cell counts to determine the appropriate alterations in therapy.

Abbreviations Introduced in This Chapter

ACEI	Angiotensin-converting enzyme inhibitor
AGE	Advanced glycation end-product
AKI	Acute kidney injury
APD	Automated peritoneal dialysis
ARB	Angiotensin receptor blocker
AVF	Arteriovenous fistula
AVG	Arteriovenous graft
BUN	Blood urea nitrogen
CAPD	Continuous ambulatory peritoneal dialysis
CCPB	Calcium-containing phosphate binder
CCPD	Continuous cycling peritoneal dialysis
CKD	Chronic kidney disease
CKD-EPI	Chronic Kidney Disease Epidemiology Collaboration equation
CKD-MBD	Chronic kidney disease mineral and bone disease
CVD	Cardiovascular disease
DKD	Diabetic kidney disease
DM	Diabetes mellitus
ECG	Electrocardiogram
EPO	Erythropoietin
ESA	Erythropoiesis-stimulating agent
GFR	Glomerular filtration rate
HbA1c	Hemoglobin$_{\text{a1c}}$
Hct	Hematocrit
HD	Hemodialysis
HDL-C	High-density lipoprotein cholesterol
Hgb	Hemoglobin
IP	Intraperitoneal
iPTH	Intact parathyroid hormone
ISPD	International Society of Peritoneal Dialysis
KDIGO	Kidney Disease: Improving Global Outcomes
LDL-C	Low-density lipoprotein cholesterol
LVH	Left ventricular hypertrophy
MCHC	Mean corpuscular hemoglobin concentration
MCV	Mean corpuscular volume
MDRD	Modification of Diet in Renal Disease (study)
MRSA	Methicillin-resistant *Staphylococcus aureus*
NIPD	Nightly intermittent peritoneal dialysis
NKF	National Kidney Foundation
NTPD	Nocturnal tidal peritoneal dialysis
PD	Peritoneal dialysis
PTH	Parathyroid hormone
RBC	Red blood cell
ROD	Renal osteodystrophy
RRT	Renal replacement therapy
SC	Subcutaneous
SCr	Serum creatinine
sHPT	Secondary hyperparathyroidism
SPS	Sodium polystyrene sulfonate
TIBC	Total iron binding capacity
TSat	Transferrin saturation
USRDS	United States Renal Data Service

28 Fluids and Electrolytes

Mark A. Malesker and Lee E. Morrow

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Estimate the volumes of various body fluid compartments.
2. Calculate the daily maintenance fluid requirement for patients given their weight, and gender.
3. Differentiate among currently available fluids for volume resuscitation.
4. Identify the electrolytes primarily found in the extracellular and intracellular fluid compartments.
5. Describe the unique relationship between serum sodium concentration and total body water (TBW).
6. Review the etiology, clinical presentation, and management for disorders of sodium, potassium, calcium, phosphorus, and magnesium.

BODY FLUID COMPARTMENTS

A thorough understanding of the fundamentals of fluid and electrolyte homeostasis is essential, given the frequency with which clinical disturbances are seen and the profound effects these disturbances can have on various aspects of patient care. However, the interplay of body fluids, serum electrolytes, and clinical monitoring is complex, and a thorough command of these issues is a challenging task even for advanced practitioners.[1] Clinicians must be familiar with the key concepts of body compartment volumes, calculation of daily fluid requirements, and the various types of fluid available for replacement. The management of disorders of sodium, potassium, calcium, phosphorus, and magnesium integrates these concepts with issues of dose recognition and patient safety.

The most fundamental concept to grasp is an assessment of total body water (TBW), which is directly related to body weight. KEY CONCEPT TBW constitutes approximately 50% of lean body weight in healthy females and 60% of lean body weight in males. For clinical purposes, most clinicians generalize that TBW accounts for 60% of lean body weight in adults, regardless of gender. The percentage of TBW decreases as body fat increases and/or with age (75%–85% of body weight is water for newborns). Unless the patient is obese (body weight > 120% of ideal body weight [IBW]), clinicians typically use a patient's actual body weight when calculating TBW.[2] In obese patients, it is customary to estimate TBW using lean body weight or IBW as calculated by the Devine–Devine method: males' lean body weight = 50 kg + (2.3 kg/in. × [height in inches − 60]) and females' lean body weight = 45.5 kg + (2.3 kg/in. × [height in inches − 60]).[3–5] Note that 1 kg is equivalent to 2.2 lb, 1 in. is equivalent to 2.54 cm, and 1 L of water weighs 1 kg (2.2 lb).

The intracellular fluid (ICF) represents the water contained within cells and is rich in electrolytes such as potassium, magnesium, phosphates, and proteins. KEY CONCEPT The ICF is approximately two-thirds of TBW regardless of gender. For a 70-kg person, this would mean that the TBW is 42 L and the ICF is approximately 28 L. Note that ICF represents approximately 40% of total body weight.

The extracellular fluid (ECF) is the fluid outside the cell and is rich in sodium, chloride, and bicarbonate. KEY CONCEPT The ECF is approximately one-third of TBW (14 L in a 70-kg person) and is subdivided into two compartments: the interstitial fluid and the intravascular fluid. The interstitial fluid represents the fluid occupying the spaces between cells and is about 25% of TBW (10.5 L in a 70-kg person). The intravascular fluid (also known as plasma) represents the fluid within the blood vessels and is about 8% of TBW (3.4 L in a 70-kg person). Because the exact percentages are cumbersome to recall, many clinicians accept that the ECF represents roughly 20% of body weight (regardless of gender) with 15% in the interstitial space and 5% in the intravascular space.[6] Note that serum electrolytes are routinely measured from the ECF.

The transcellular fluid includes the viscous components of the peritoneum, pleural space, and pericardium, as well as the cerebrospinal fluid, joint space fluid, and the GI digestive juices. Although the transcellular fluid normally accounts for about 1% of TBW, this amount can increase significantly during various illnesses favoring fluid collection in one of these spaces (eg, pleural effusions or ascites in the peritoneum). The accumulation of fluid in the transcellular space is often referred to as "third spacing." To review the calculations of the body fluid compartments in a representative patient, see Patient Encounter 1.

Fluid balance is assessed by several means each of which has its limitations. Blood pressure (BP) measurements estimate fluid status relative to the amount of blood volume pumped by the heart but are affected by cardiac function and vascular pliability. Patients with significant volume deficiency may appear hypotensive, but this is a late finding that may require greater than

Patient Encounter 1: Body Fluid Compartments

Calculate the TBW, ICF, and ECF in a 78-kg male.

20% of TBW to be lost. Patients with significant volume excess may appear edematous; however, third spacing may hide this finding until late in the course as well. The physical examination can indicate the presence of fluid deficits (dry mucous membranes) and fluid excess (peripheral edema, coarse breath sounds). Data suggest that dynamic assessments of volume status (pulse pressure variability, ultrasound-derived vena cava diameter variations, passive leg raising) are more accurate than either the bedside clinical exam or passive measurements of volume status (arterial catheter, central venous catheter, pulmonary artery catheter).

To maintain fluid balance, the total amount of fluid gained throughout the day (input, or "ins") must equal the total amount of fluid lost (output, or "outs"). Although most forms of the body's input and output can be measured, several cannot. For a normal adult on an average diet, ingested fluids are easily measured and average 1400 mL/day. Other fluid inputs, such as those from ingested foods and the water by-product of oxidation, are not directly measurable. Fluid outputs such as urinary and stool losses are also easily measured and referred to as sensible losses. Other sources of fluid loss, such as evaporation of fluid through the skin and/or lungs, are not readily measured and are called insensible losses. Table 28–1 shows the estimated ins and outs (I&Os) for a healthy 68-kg (150-lb) man.[6] The measurable I&Os are routinely measured in hospitalized patients and are used to estimate total fluid balance for each 24-hour period. It is important to realize that in hospitalized patients, multiple other forms of fluid loss must be considered. These include losses from enteric suctioning (most commonly, nasogastric [NG] tubes), from surgical drains (eg, chest tubes, nephrostomy tubes, and pancreatic drains), via fistulous tracts, and enhanced evaporative losses (burns and fever).

TBW depletion (often referred to as "dehydration") is typically a gradual, chronic problem. Because TBW depletion represents a loss of hypotonic fluid (proportionally more water is lost than sodium) from all body compartments, a primary disturbance of **osmolality** is usually seen. The signs and symptoms of TBW depletion include CNS disturbances (mental status changes, seizures, and coma), excessive thirst, dry mucous membranes, decreased skin turgor, elevated serum sodium, increased plasma osmolality, concentrated urine, and acute weight loss. Common causes of TBW depletion include insufficient oral intake, excessive insensible losses, diabetes insipidus, excessive osmotic diuresis, and impaired renal concentrating mechanisms. Elderly long-term care residents are frequently admitted to the acute care hospital with TBW depletion secondary to lack of adequate oral intake, often with concurrent excessive insensible losses.

Table 28–1

Approximate I&Os for a Healthy 68-kg (150-lb) Man

Input	mL/day	Output	mL/day
Ingested fluid[a]	1400	Urine[a]	1500
Fluid in food	850	Skin losses	500
Water of oxidation	350	Respiratory tract losses	400
		Stool	200
Total	2600	Total	2600

[a]Readily quantifiable.

Table 28–2

Useful Calculations for the Estimation of Patient Maintenance Fluid Requirements

Neonate (1–10 kg) = 100 mL/kg
Child (10–20 kg) = 1000 mL + 50 mL for each kilogram greater than 10
Adult (> 20 kg) = 1500 mL + 20 mL for each kilogram greater than 20

The volume of fluid required to correct TBW depletion equals the basal fluid requirement plus ongoing exceptional losses plus the fluid deficit. Basal daily fluid requirements are calculated using the formulas in Table 28–2. For an adult, this represents 1500 mL/day for the first 20 kg of body weight plus 20 mL/day for each additional kilogram. The volume of replacement fluids required for a given patient (the fluid deficit) can be estimated by the acute weight change in the patient (1 kg = 1 L of fluid). Because the precise weight change is not typically known, it is often calculated as follows: fluid deficit = normal TBW − present TBW. Normal TBW is estimated based on the patient's weight using the formulas in Table 28–2, and the present TBW is estimated based on the patient's current body weight. The choice of fluids used for replacement is guided by the presence of concurrent electrolyte abnormalities and acid-base status. The adequacy of replacement is guided by each patient's objective response to fluid replacement (improved skin turgor, adequate urine output, normalization of heart rate, BP, etc.).

Once TBW has been restored, the volume of "maintenance" fluid equals the basal fluid requirement plus ongoing exceptional losses. If the pathophysiologic process leading to TBW depletion has not been identified and corrected (or accounted for in the calculation of maintenance fluid requirements), TBW depletion will quickly recur. To review the concepts involved in the calculation of replacement fluids for a representative patient, see Patient Encounter 2.

Compared with TBW depletion, ECF depletion tends to occur acutely. In this setting, rapid and aggressive fluid replacement is required to maintain adequate organ perfusion. Because ECF depletion is generally due to the loss of isotonic fluid (proportional losses of sodium and water), major disturbances of plasma osmolality are not common. ECF depletion manifests clinically as signs and symptoms associated with decreased tissue perfusion: dizziness, orthostasis, tachycardia, decreased urine output, increased hematocrit, decreased central venous pressure, and/or hypovolemic shock. Common causes of ECF depletion include external fluid losses (burns, hemorrhage, diuresis, GI losses, and adrenal insufficiency) and third spacing of fluids (septic shock, anaphylactic shock, or abdominal ascites).

In clinical practice, the most encountered problem is depletion of TBW and ECF. Accordingly, the fluid resuscitation strategy should address both compartments. As these compartments are repleted, serum electrolytes must be monitored closely as discussed in subsequent sections of this chapter.

Patient Encounter 2: Fluid Requirements

Calculate the daily fluid requirement for a 73-kg adult female.

THERAPEUTIC FLUIDS

Crystalloids

KEY CONCEPT Therapeutic IV fluids include crystalloid solutions and colloidal solutions. Crystalloids are composed of water and electrolytes, all of which pass freely through semipermeable membranes and remain in the intravascular space for shorter periods of time. As such, these solutions are very useful for correcting electrolyte imbalances but result in smaller hemodynamic changes for a given unit of volume.

Crystalloids can be classified further according to their tonicity. Isotonic solutions (ie, normal saline or 0.9% sodium chloride [NaCl]) have a tonicity equal to that of the ICF (approximately 310 mEq/L [mmol/L]) and do not shift the distribution of water between the ECF and the ICF. Because hypertonic solutions (ie, hypertonic saline or 3% NaCl) have greater tonicity than the ICF (> 376 mEq/L [mmol/L]), they draw water from the ICF into the ECF. In contrast, hypotonic solutions (ie, 0.45% NaCl) have less tonicity than the ICF (< 250 mEq/L [mmol/L]) leading to osmotic pressure gradient that favors shifts of water from the ECF into the ICF. The tonicity, electrolyte content, and glucose content of selected fluids are shown in Table 28–3.

The tonicity of crystalloid solutions is directly related to their sodium concentration. The most used crystalloids include normal saline, dextrose/half-normal saline, hypertonic saline, and lactated Ringer's solution. Excessive administration of any fluid replacement therapy, regardless of tonicity, can lead to fluid overload and/or electrolyte changes, particularly in patients with cardiac or renal insufficiency. Glucose is often added to hypotonic crystalloids in amounts that result in isotonic fluids (D_5W, D5½NS, and D5¼NS). These solutions are often used as maintenance fluids to provide basal amounts of calories and water.

▶ *Normal Saline (0.9% NaCl or NS)*

Normal saline is an isotonic fluid composed of water, sodium, and chloride. It provides primarily ECF replacement and can be used for virtually any cause of TBW depletion. Common uses of normal saline include perioperative fluid administration; volume resuscitation of shock, sepsis, hemorrhage, or burn patients; fluid challenges in hypotensive or oliguric patients; and hyponatremia. Normal saline can also be used to treat metabolic alkalosis (also known as contraction alkalosis). Large volumes of normal saline can cause a hyperchloremic metabolic acidosis.

▶ *Half-Normal Saline (0.45% NaCl or ½ NS)*

Half-normal saline is a hypotonic fluid that provides free water in relative excess when compared with the sodium concentration. This crystalloid is typically used to treat patients who are hypertonic due to primary depletion of the ECF. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

▶ *5% Dextrose/Half-Normal Saline (D5 ½ NS)*

D5 ½ NS is a hypotonic fluid that is commonly used as a maintenance fluid. This crystalloid is typically used once fluids deficits have been corrected with normal saline or lactated Ringer's solution. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

▶ *Hypertonic Saline (3% NaCl)*

Hypertonic saline is obviously hypertonic and provides a significant sodium load to the intravascular space. This solution is used very infrequently given the potential to cause significant shifts in the water balance between the ECF and the ICF. It is typically used to treat patients with severe hyponatremia who have symptoms attributable to low serum sodium. Hypertonic saline

Table 28–3

Electrolyte and Dextrose Content of Selected Crystalloid Fluids

IV Solution	Osmolarity (mOsm or mmol)	Dextrose (g/L) mmol/L	Sodium (mEq/L) mmol/L	Potassium (mEq/L) mmol/L	Calcium (mEq/L) mmol/L	Chloride (mEq/L) mmol/L	Lactate (mEq/L) mmol/L
D5%	250	50 2.78					
D10%	505	100 5.55					
0.9% NaCl	308		154			154	
0.45% NaCl	154		77			77	
3% NaCl	1025		512			512	
D5% and 0.45% NaCl	405	50 2.78	77			77	
Ringer's injection	310		147	4	5 2.5	156	
Lactated Ringer's solution	274		130	4	3 1.5	109	28
Lactated Ringer's solution and D5%	525	50 2.78	130	4	3 1.5	109	28

D, dextrose; NaCl, sodium chloride.

in concentrations of 3% to 23.4% has been used to acutely lower intracranial pressure in the setting of traumatic brain injury and stroke. The literature is inconsistent for the optimal hypertonic concentration, dosing, timing of replacement, and goals for use in this population. This fluid is used for short periods in the intensive care setting where frequent serum sodium and neurologic checks can be very closely monitored.

▶ *Ringer's Lactate*

This isotonic volume expander contains sodium, potassium, chloride, and lactate in concentrations that approximate the fluid and electrolyte composition of the blood. Ringer's lactate (also known as "Lactated Ringers" or LR) provides ECF replacement and is most often used in the perioperative setting and for patients with lower GI fluid losses, burns, or dehydration. The lactate component of LR is metabolized into bicarbonate in the liver and works as a buffer to increase the pH. Accordingly, large volumes of LR may cause iatrogenic metabolic alkalosis. Because patients with significant liver disease are unable to metabolize lactate sufficiently, LR administration in this population may lead to accumulation of lactate with iatrogenic lactic acidosis.

▶ *5% Dextrose in Water (D_5W)*

D_5W solution is a combination of free water and dextrose that provides a modest amount of calories but no electrolytes. Although it is technically isotonic, it acts as a hypotonic solution in the body. It is commonly used to treat severe hypernatremia. D5W is also used in small volumes (100 mL) to dilute many IV medications or at a low infusion rate (10 to 15 mL/h) to "keep the vein open" (KVO) for IV medications.

Colloids

In contrast to crystalloids, colloids do not dissolve into a true solution and therefore do not pass readily across semipermeable membranes. As such, colloids effectively remain in the intravascular space and increase the oncotic pressure of the plasma. This effectively shifts fluid from the interstitial compartment to the intravascular compartment. In clinical practice, these theoretical benefits are generally short lived (given metabolism of colloidal proteins/sugars), and for most patients, there is little therapeutic advantage of colloids over crystalloids or vice versa. Examples of colloids include 5% albumin, 25% albumin, the dextrans, hetastarch, and fresh-frozen plasma (FFP). Because each of these agents contains a substance (proteins or complex sugars) that will ultimately be metabolized, the oncotic agent will be ultimately lost and only the remaining hypotonic fluid delivery agent will remain. As such, use of large volumes of colloidal agents is more likely to induce fluid overload compared with crystalloids. Although smaller volumes of colloids have equal efficacy as larger volumes of crystalloids, they generally must be infused more slowly. Often the net result is that the time to clinical benefit is the same regardless of which class of fluid is utilized. For example, 500 mL of normal saline is required to increase the systolic BP to the same degree as seen with approximately 250 mL of 5% albumin; however, the normal saline can be administered twice as fast.

▶ *Albumin*

Albumin is a protein derived from fractionating human plasma. Because albumin infusion is expensive and may be associated with adverse events, it should be used for acute volume expansion and *not* as a supplemental source of protein calories. Historically, albumin was used indiscriminately in the intensive care unit until anecdotal publications suggested that albumin might cause immunosuppression. However, the Saline Versus Albumin Fluid Evaluation (SAFE) trial found that the mortality for those who received albumin was the same as for those who received normal saline.[7] In 1818 patients with severe sepsis, albumin replacement with crystalloids as compared to crystalloids alone did not improve the rate of survival at 28 and 90 days.[8]

Based on limited availability, health systems and hospitals have had to define the appropriate albumin indications for their patients and ration albumin accordingly. Evidence-based indications for albumin include plasmapheresis/apheresis, large-volume paracentesis (> 4 L removed), hypotension in hemodialysis, and spontaneous bacterial peritonitis. Inappropriate uses of albumin include nutritional supplementation, pancreatitis, alteration of drug pharmacokinetics, or acute normovolemic hemodilution in surgery.

▶ *Hydroxyethyl Starch Solutions and Dextran*

While albumin is the most used colloid, the other available products are not without their own risks and benefits. Hydroxyethyl starch solutions (HES) include Hetastarch and Hextend. Hetastarch (various manufacturers) contains 6% starch and 0.9% NaCl. Hextend, Hospira, is a comparable plasma expander that contains 6% hetastarch in a lactated electrolyte solution. HES products have no oxygen-carrying capacity and are administered intravenously as plasma expanders. Limitations of these products include acquisition cost, hypersensitivity reactions, and bleeding. Dosing should be reduced in the presence of renal dysfunction. Clinical data linking HES solutions with an increased risk of mortality and renal injury requiring renal replacement therapy in critically ill patients prompted the FDA to issue a MedWatch safety communication in November 2013. FDA concluded these solutions should not be used in critically ill patients, including sepsis and those admitted to the intensive care unit, and a boxed warning to highlight the risk of mortality and severe renal injury is warranted. A list of recommendations for patients and health-care providers to consider before use of HES solutions can be found on the FDA website. (http://www.fda.gov/Safety/MedWatch/)

Low molecular weight dextran 40 (various manufacturers) is a polysaccharide plasma expander. Anaphylactic reactions and prolonged bleeding times have limited its use. Potential mechanisms of colloid solution-induced bleeding include platelet inhibition or possible dilution of clotting factors via infusion of a large-volume colloid solution.

Fluid Management Strategies

Classic indications for IV fluid include maintenance of BP, restoring the ICF volume, replacing ongoing renal or insensible losses when oral intake is inadequate, for medication delivery, and the need for glucose as a fuel for the brain.[9]

When determining the appropriate fluid to be utilized, it is important to first determine the type of fluid problem (TBW versus ECF depletion) and start therapy accordingly. For patients demonstrating signs of impaired tissue perfusion, the immediate therapeutic goal is to increase the intravascular volume and restore tissue perfusion. The historical standard therapy is normal saline given at 150 to 500 mL/hour (for adult patients) until perfusion is optimized. Although LR is a therapeutic alternative, lactic acidosis may arise with massive or prolonged infusions. LR has less chloride content versus normal saline (109 mEq/L [mmol/L] versus 154 mEq/L [mmol/L]) and has the advantage of use when large volumes of normal saline produce acidosis during fluid resuscitation. In severe cases, a colloid or blood transfusion may be indicated to increase oncotic pressure within the vascular space. Once euvolemia is achieved, patients may be switched to a more hypotonic maintenance solution (D5 ½ NS or 0.45% NaCl) at a rate that delivers estimated daily needs.

In two linked studies (SMART, SALT-ED) collectively studying over 29,000 patients, NS administration was associated with a significantly higher risk of metabolic acidosis and major adverse kidney events when compared to balanced crystalloid solutions. As a result, many clinicians have transitioned their practice to prioritize LR and Plasma-Lyte as first-line agents over NS for volume resuscitation and fluid maintenance.[10,11]

The clinical scenario and the severity of the volume abnormality dictate monitoring parameters during fluid replacement therapy. These may include the subjective sense of thirst, mental status, skin turgor, orthostatic vital signs, pulse rate, weight changes, blood chemistries, fluid input and output, central venous pressure, pulmonary capillary wedge pressure, and cardiac output. Fluid replacement requires particular caution in patient populations at risk of fluid overload, such as those with renal failure, cardiac failure, hepatic failure, or the elderly. Other complications of parenteral fluid therapy include IV site infiltration, infection, phlebitis, thrombophlebitis, and extravasation.

In summary, common settings for fluid resuscitation include hypovolemic patients (eg, sepsis or pneumonia), hypervolemic patients (eg, congestive heart failure [CHF], cirrhosis, or renal failure), euvolemic patients who are unable to take oral fluids in proportion to insensible losses (eg, the perioperative period), and patients with electrolyte abnormalities (see below).

ELECTROLYTES

Normally, the number of anions (negatively charged ions) and cations (positively charged ions) in each fluid compartment are equal. Cell membranes play the critical role of maintaining distinct ICF and ECF spaces, which are biochemically distinct. Serum electrolyte measurements reflect the stores of ECF electrolytes rather than that of ICF electrolytes. Table 28–4 lists the chief cations and anions along with their normal concentrations in the ECF and ICF. The principal cations are sodium, potassium, calcium, and magnesium; the key anions are chloride, bicarbonate, and phosphate. In the ECF, sodium is the most common cation and chloride is the most abundant anion; in the ICF, potassium is the primary cation and phosphate is the main anion. Normal serum electrolyte values are listed in Table 28–5.

Table 28–4

Normal Cation and Anion Concentrations in the ECF and ICF

	ECF		ICF	
Ion Species	**Plasma (mEq/L [mmol/L])**	**Interstitial Fluid (mEq/L [mmol/L])**	**Ion Species**	**mEq/L [mmol/L]**
Cations			Cations

ECF, extracellular fluid; ICF, intracellular fluid.

Table 28–5

Normal Ranges for Serum Electrolyte Concentrations

Sodium	135–145 mEq/L (mmol/L)
Potassium	3.5–5.0 mEq/L (mmol/L)
Chloride	98–106 mEq/L (mmol/L)
Bicarbonate	21–30 mEq/L (mmol/L)
Magnesium	1.4–2.2 mEq/L or 0.7–1.1 mmol/L
Calcium:	
Total	4.4–5.2 mEq/L (9–10.5 mg/dL) or 2.2–2.6 mmol/L
Ionized	2.2–2.8 mEq/L (4.5–5.6 mg/dL) or 1.1–1.4 mmol/L
Phosphorus	3–4.5 mg/dL (1.0–1.5 mmol/L)

Osmolality is a measure of the number of osmotically active particles per unit of solution, independent of the weight or nature of the particle. Equimolar concentrations of all substances in the undissociated state exert the same osmotic pressure. Although the normal serum osmolality is 280 to 300 mOsm/kg (mmol/kg), multiple scenarios exist where this value becomes markedly abnormal. **KEY CONCEPT** The calculated serum osmolality helps determine deviations in TBW content. As such, it is often useful to calculate the serum osmolality as follows:

Serum **osmolality** (mOsm/kg)
= 2 (Na mEq/L) + (glucose [mg/dL])/18
+ (BUN [mg/dL])/2.8.

Serum osmolality using SI units (mmol/kg)
= 2 (Na mmol/L) + (glucose mmol/L)
+ (BUN mmol/L)

Because the body regulates water to maintain osmolality, deviations in serum osmolality are used to estimate TBW stores. Water moves freely across all cell membranes, making serum osmolality an accurate reflection of the osmolality within all body compartments. An increase in osmolality is equated with a loss of water greater than the loss of solute (TBW depletion). A decrease in serum osmolality is seen when water is retained in excess of solute (CHF or hepatic cirrhosis). The difference between the measured serum osmolality and the calculated serum osmolality, using the equation just stated, is referred to as the osmolar gap. Under normal circumstances the osmolar gap should be 10 mOsm/kg (mmol/kg) or less. An increased osmolar gap suggests the presence of a small osmotically active agent and is most commonly seen with the ingestion of alcohols (ethanol, methanol, ethylene glycol, or isopropyl alcohol) or medications such as mannitol or lorazepam. Patient Encounter 3 illustrates the utility of serum osmolality in a clinical setting.

Many of the electrolyte disturbances discussed in the remainder of this chapter represent medical emergencies that call for aggressive interventions including the use of concentrated electrolytes. It is very difficult to promptly reverse the effects of concentrated electrolytes when they are administered improperly, and these solutions are a frequent source of medical errors with significant potential for patient harm. **KEY CONCEPT** As such, The Joint Commission recommends that concentrated electrolyte

Patient Encounter 3: Calculate the Plasma Osmolality

A 42-year-old man reports drinking 750 ml of whiskey each day before lunch. He presents to the emergency department with complaints of dizziness, unsteadiness, and inability to walk by himself without assistance. Symptoms started two days ago and have been progressively worse. Patient endorses no food intake for five days. He was admitted with multiple electrolyte disorders. BP of 131/66 mm Hg was noted. The sodium is 126 mEq/L (mmol/L), potassium 2.1 mEq/L (mmol/L), chloride 64 mEq/L (mmol/L), bicarbonate 38 mEq/L (mmol/L), glucose 247 mg/dL (13.7 mmol/L), and BUN 7 mg/dL (2.5 mmol/L). The measured osmolality was 250 mOsm/kg (mmol/kg).

Calculate the osmolality.

Calculate the osmolar gap.

What is the likely cause of an increased gap in this patient?

solutions (KCl, potassium phosphate, NaCl > 0.9%, sodium bicarbonate 8.4%, and magnesium 50%) be removed from patient care areas. Hospitals should keep concentrated electrolytes in patient care areas only when patient safety necessitates their immediate use and precautions are used to prevent inadvertent administration. Examples include crash carts in intensive care units, emergency departments, and procedural areas. Collaborative cooperation among pharmacists, nurses, and physicians is essential.[12]

Sodium

The body's normal daily sodium requirement is 1.0 to 1.5 mEq/kg (mmol/kg) (80–130 mEq [mmol]) to maintain a normal serum sodium concentration of 135 to 145 mEq/L (mmol/L). Sodium is the predominant cation of the ECF and largely determines ECF volume. Sodium is also the primary factor in establishing the osmotic pressure relationship between the ICF and ECF. All body fluids are in osmotic equilibrium, and changes in serum sodium concentration are associated with shifts of water into and out of body fluid compartments. When sodium is added to the intravascular fluid compartment, fluid is pulled intravascularly from the interstitial fluid and the ICF until osmotic balance is restored. As such, a patient's measured sodium concentration should *not* be viewed as an index of sodium need because this parameter reflects the balance between total body sodium content and TBW. Disturbances in the sodium concentration most often represent disturbances of TBW. Sodium imbalances cannot be properly assessed without first assessing body fluid status.

KEY CONCEPT Hyponatremia is the most common electrolyte disorder in hospitalized patients and is defined as a serum sodium concentration below 135 mEq/L (mmol/L). Clinical signs and symptoms appear at concentrations below 120 mEq/L (mmol/L) and typically consist of irritability, mental slowing, unstable gait/falls fatigue, headache, and nausea. With profound hyponatremia (< 110 mEq/L [mmol/L]), confusion, seizures, stupor/coma, and respiratory arrest may be seen. Clinical practice guidelines regarding the diagnosis and treatment of hyponatremia have recently been published. Hyponatremia can be classified based upon serum sodium concentration, rate of development, symptom severity, serum osmolality, and volume status.[13] Because therapy is also influenced by volume status, hyponatremia is further defined as (a) hypertonic hyponatremia, (b) hypotonic hyponatremia with an increased ECF volume, (c) hypotonic hyponatremia with a normal ECF volume, and (d) hypotonic hyponatremia with a decreased ECF volume.[14]

Hypertonic hyponatremia is usually associated with significant hyperglycemia. Glucose is an osmotically active agent that leads to an increase in TBW with little change in total body sodium. For every 60 mg/dL (3.3 mmol/L) increase in serum glucose above 200 mg/dL (11.1 mmol/L), the sodium concentration is expected to decrease by approximately 1 mEq/L (mmol/L). Appropriate treatment of the hyperglycemia will return the serum sodium concentration to normal.[13]

Hypotonic hyponatremia with an increase in ECF (hypervolemic hyponatremia) is also known as dilutional hyponatremia. In this scenario, patients have an excess of total body sodium and TBW; however, the excess in TBW is greater than the excess in total body sodium. Common causes include CHF, hepatic cirrhosis, and nephrotic syndrome. Treatment includes sodium and fluid restriction in conjunction with treatment of the underlying disorder—for example, salt and water restrictions are used in the setting of CHF along with loop diuretics, angiotensin-converting enzyme inhibitors, and spironolactone.

In hypotonic hyponatremia with a normal ECF volume (euvolemic hyponatremia), patients have an excess of TBW with relatively normal sodium content. In essence, there is a presence of excess free water. This is most frequently seen in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Common causes of SIADH include carcinomas (eg, lung or pancreas), pulmonary disorders (eg, pneumonias or tuberculosis), CNS disorders (eg, meningitis, stroke, tumor, or trauma), and medications (eg, sulfonylureas, antineoplastic agents, barbiturates, morphine, antipsychotics, tricyclic antidepressants, nonsteroidal anti-inflammatory agents, selective serotonin reuptake inhibitors, dopamine agonists, and general anesthetics). These medications stimulate the release of antidiuretic hormone (ADH) from the pituitary gland resulting in water retention and dilution of the body's sodium stores.

Short-term treatment of euvolemic hyponatremia includes fluid restriction, isotonic normal saline, hypertonic saline, or a vaptan (eg, conivaptan, tolvaptan). Initial treatment generally consists of fluid restriction alone. Hypertonic saline is used only when the sodium concentration is less than 110 mEq/L (mmol/L) and/or severe symptoms (eg, seizures) are present. Given the limitations associated with these treatment strategies (unpredictable therapeutic effects and side effects), the arginine vasopressin antagonist conivaptan (Vaprisol, Astellas Pharma) was developed for short-term treatment of euvolemic hyponatremia. While conivaptan can also be used to manage hypervolemic hyponatremia in hospitalized patients, it should not be used for hypovolemic hyponatremia. Conivaptan is dosed 20 mg IV over 30 minutes, followed by a 20-mg continuous infusion over 24 hours for up to 4 days.

Long-term treatment options for euvolemic hyponatremia include fluid restriction, demeclocycline, loop diuretics, saline, lithium, urea, and tolvaptan. Demeclocycline (available as generic) is dosed at 600 to 1200 mg/day, takes days before clinical effect is realized, and can cause nephrotoxicity. Lithium (various generics) also has a slow onset of action and is limited by CNS side effects, GI disturbances, and cardiotoxicity. Furosemide (various generics) or other loop diuretics allow relaxation of fluid restriction but can cause significant volume depletion and electrolyte disturbances, and it has the potential for ototoxicity. Ure-Na is a USP urea, marketed as a medical food to treat euvolemic and hypervolemic hyponatremia, including SIADH. Urea increases water loss in the urine, thus normalizing sodium levels. Ure-Na is available in 15 g pouches, and some patient may experience a mild GI upset. This product should be used only under medical supervision and close laboratory monitoring (www.ure-na.com). Tolvaptan (Samsca, Otsuka) is an oral alternative to IV conivaptan. This product is indicated for treatment of clinically significant hypervolemic and euvolemic hyponatremia (sodium < 125 mEq/L [mmol/L]) or less marked hyponatremia that is symptomatic and has resisted correction with fluid restriction. Patients with CHF, cirrhosis, and SIADH would be candidates for long-term use. Tolvaptan has a boxed warning for initiation of treatment in a hospital setting because of the need for close sodium monitoring. The initial dose is 15 mg orally daily and may be titrated up to a max of 60 mg. Concurrent use with potent CYP 3A4 inhibitors should be avoided: ketoconazole (available as generic), clarithromycin (available as generic), ritonavir (Norvir, Abbott), diltiazem (available as generic), verapamil (available as generic), fluconazole (available as generic), and grapefruit juice.

In hypotonic hyponatremia with a decreased ECF volume (hypovolemic hyponatremia), patients usually have a deficit of both total body sodium and TBW, but the sodium deficit exceeds the TBW deficit. Common causes include diuretic use, profuse sweating, wound drainage, burns, GI losses (vomiting or diarrhea), hypoadrenalism (low cortisol and low aldosterone), and renal tubular acidosis. Treatment includes the administration of sodium to correct the sodium deficit and water to correct the TBW deficit. The sodium deficit can be calculated with the following equation[2]:

$$\text{Sodium deficit (mEq or mmol)} = (\text{TBW [in liters]})(\text{desired Na}^+ \text{ concentration [mEq/L or mmol/L]} - \text{current Na}^+ \text{ concentration}).$$

Although both water and sodium are required in this instance, sodium needs to be provided in excess of water to fully correct this abnormality. As such, hypertonic saline (3% NaCl) is often used. One can estimate the change in serum sodium concentration after 1 L of 3% NaCl infusion using the following equation[14]:

$$\text{Change in serum Na}^+ \text{ (mEq/L or mmol/L)} = (\text{infusate Na}^+ - \text{serum Na}^+)/(\text{TBW} + 1).$$

In this formula, TBW is increased by 1 to account for the addition of the liter of 3% NaCl. Patient Encounters 4 and 5 illustrate the concepts of calculating and correcting the sodium deficit.

Depending on the severity of the hyponatremia and acuity of onset, 0.9%, 3%, or 5% NaCl can be utilized. Most patients can be adequately managed with normal saline rehydration, which is generally the safest agent. Hypertonic saline (3% or 5% NaCl) is generally reserved for patients with severe hyponatremia (< 120 mEq/L [mmol/L]) accompanied by coma, seizures, or high urinary sodium losses. In general, a sodium replacement strategy should target a correction of 6 to 8 mEq/L (mmol/L) in serum per day. To prevent overcorrection of severe hyponatremia, the administration of desmopressin 2 to 4 mcg IV or SC q 8 to 12 hours until the sodium is greater than 128 mEq/L (mmol/L) can prevent excessive urinary water losses.[15] Overly aggressive correction of symptomatic hyponatremia (> 12 mEq/L [mmol/L] per day) can result in central pontine myelinolysis.[16] Given the potential for irreversible neurologic damage if untreated or if improperly treated, acute hyponatremia is an urgent condition that should be promptly treated with careful attention to monitoring serial sodium values and adjusting therapeutic infusions accordingly.[17]

Hypernatremia is a serum sodium concentration greater than 145 mEq/L (mmol/L) and can occur in the absence of a sodium deficit (pure water loss) or in its presence (hypotonic fluid loss).[18] The signs and symptoms of hypernatremia manifest with a serum sodium concentration greater than 160 mEq/L (mmol/L) and are usually the same as those found in TBW depletion: thirst, mental slowing, and dry mucous membranes. Signs and symptoms become more profound as hypernatremia worsens, with the patient eventually demonstrating confusion, hallucinations, acute weight loss, decreased skin turgor, intracranial bleeding, and/or coma. Many coexisting disorders and medications may complicate the diagnosis.

The classic causes of hypernatremia are associated with TBW depletion. These include dehydration from loss of hypotonic fluid from the respiratory tract or skin, decreased water intake, osmotic diuresis (eg, mannitol, available as generic), and diabetes insipidus (eg, decreased ADH; phenytoin, available as generic; lithium, available as generic). Hypernatremia in hospitalized patients occurs secondary to inappropriate fluid management in patients at risk for increased free water losses and impaired thirst or restricted water intake.[19] Iatrogenic hypernatremia is occasionally caused by the administration of excessive hypertonic saline. Treatment of hypernatremia includes calculation of the TBW deficit followed by the administration of hypotonic fluids as previously described. The fluid volume should be replaced over 48 to 72 hours depending on the severity of symptoms and the degree of hypertonicity.[20] For asymptomatic patients, the rate of correction should not exceed 0.5 mEq/L/h (mmol/L/h). One rule of thumb is to reduce serum sodium by a maximum of 6 to 8 mEq (mmol) every 24 hours.[18] Excessively rapid correction of hypernatremia may lead to cerebral edema and death. Patient Encounters 6 and 7 reinforce the concepts of calculating TBW deficit and expected changes in serum sodium concentration with therapy.

Potassium

The body's normal daily potassium requirement is 0.5 to 1 mEq/kg (mmol/kg) or 40 to 80 mEq (mmol) to maintain a serum

Patient Encounter 5: Estimate the Anticipated Change in Serum Sodium

Estimate the anticipated change in serum sodium concentration after the infusion of 1 L of 3% NaCl in a 78-kg male with a serum sodium of 122 mEq/L (mmol/L).

Patient Encounter 4: Calculation of Serum Sodium Deficit

Calculate the sodium deficit for a 78-kg male with a serum sodium of 122 mEq/L (mmol/L).

Patient Encounter 6: Calculate Water Deficit

Calculate the water deficit in an 84-kg female with a serum sodium of 160 mEq/L (mmol/L). The daily goal is to correct the sodium 6 mEq/L (mmol/L).

Patient Encounter 7: Calculate the Anticipated Change in Serum Sodium

Calculate the anticipated change in serum sodium concentration after IV infusion of 1 L of 5% dextrose in a 82 kg male with a serum sodium of 156 mEq/L (mmol/L).

potassium concentration of 3.5 to 5 mEq/L (mmol/L). Potassium is the most abundant cation in the ICF, balancing the sodium contained in the ECF and maintaining electroneutrality of bodily fluids. Because most potassium is intracellular, serum potassium concentration is not a good measure of total body potassium; however, clinical manifestations of potassium disorders correlate well with serum potassium. The acid–base balance of the body affects serum potassium concentrations: hyperkalemia is routinely seen in patients with decreased pH (acidosis). Potassium regulation is primarily under the control of the kidneys with excess dietary potassium being excreted in the urine. Although mild abnormalities of serum potassium are considered a nuisance, severe hyperkalemia or hypokalemia can be life threatening.[21-23]

Hypokalemia (serum potassium < 3.5 mEq/L [mmol/L]) is a common clinical problem. While generally asymptomatic, signs and symptoms of hypokalemia include cramps, muscle weakness, polyuria, electrocardiogram (ECG) changes (flattened T waves and presence of U waves), and cardiac arrhythmias (bradycardia, heart block, atrial flutter, premature ventricular contractions, and ventricular fibrillation). Causes of hypokalemia include GI losses (vomiting, diarrhea, or NG tube suction), renal losses (high aldosterone and low magnesium), inadequate potassium intake (in IV fluids or oral), or alkalosis. Many medications can precipitate hypokalemia. β_2-agonists (eg, albuterol, available as generic) and insulin (multiple product formulations) lower potassium via cellular redistribution. The use of loop diuretics (furosemide, Lasix, also available as generic), thiazide diuretics (hydrochlorothiazide, available as generic), high-dose antibiotics (penicillin, available as generic), and corticosteroids (prednisone, available as generic) cause renal potassium wasting. In addition, amphotericin B (available as generic), cisplatin (available as generic), and foscarnet (available as generic) can also produce hypokalemia secondary to depletion of magnesium. Hypomagnesemia diminishes intracellular potassium concentration and produces potassium wasting. Given the potential for significant morbidity and mortality, serum potassium concentrations should be monitored closely for patients with known (or suspected) hypokalemia.[2,23,24] Hypokalemia is a risk factor for digitalis toxicity.

Potassium repletion should be guided by close monitoring of serial serum concentrations instead of using empirically chosen amounts. Of the five potassium salts available, potassium acetate (10.2 mEq/K$^+$/g [mmol/K$^+$/g]) and KCl (13.4 mEq/K$^+$/g [mmol/K$^+$/g]) are the most used forms. When hypokalemia occurs in the setting of alkalosis, KCl is the preferred agent; in acidosis, potassium should be provided in the form of acetate, citrate, bicarbonate, or gluconate salt. Table 28–6 outlines the potassium content of each potassium salt preparation, and Table 28–7 lists each of the oral potassium replacement products. Potassium acetate and chloride are available for IV infusions as premixed solutions. The usual dose of these agents is 10 to 20 mEq (mmol) diluted in 100 mL of normal saline.[2,24,25]

Table 28–6

Potassium Content in Various Potassium Salt Preparations

Potassium Salt	mEq/g (mmol/g)
Potassium gluconate[a]	4.3
Potassium citrate[a]	9.8
Potassium bicarbonate[a]	10.0
Potassium acetate[a]	10.2
Potassium chloride[b]	13.4

[a] Favored for hypokalemia and concurrent acidosis.

[b] Favored for hypokalemia and concurrent alkalosis.

Moderate hypokalemia is defined as a serum potassium of 2.5 to 3.5 mEq/L (mmol/L) without ECG changes. In this setting, potassium replacement can usually be given orally at a dose of 40 to 120 mEq/day (mmol/day). Anecdotally, oral potassium supplementation (see Table 28–7) is often more effective in repleting moderate hypokalemia. Oral potassium supplements should be administered with or after meals to minimize potential gastrointestinal irritation. For patients with an ongoing source of potassium loss, chronic replacement therapy should be considered. The potassium deficit is a rough approximation of the amount of potassium needed to be replaced and can be estimated as follows:

$$\begin{aligned}&\text{Potassium deficit (mEq/L or mmol/L)}\\&\quad = (4.0 - \text{current serum potassium}) \times 100\end{aligned}$$

Severe hypokalemia is defined as a serum potassium less than 2.5 mEq/L (mmol/L) or hypokalemia of any magnitude that is associated with ECG changes (eg, flattening of T wave or elevation of U wave) and cardiac arrhythmias. In these situations, IV replacement should be initiated urgently. **KEY CONCEPT** Potassium infusion at rates exceeding 10 mEq/h (mmol/h) requires cardiac monitoring given the potential for cardiac arrhythmias. Although the maximally concentrated solution for potassium replacement is 80 mEq/L (mmol/L), the maximum infusion rate is 40 mEq/h (mmol/h) and must be administered via a central line. For safety, most hospitals define 20 mEq/h (mmol/h) as the maximum infusion rate. Table 28–8 outlines current IV potassium replacement guidelines.

Caution must be exercised when repleting potassium with IV agents given possible vein irritation and/or thrombophlebitis.

Table 28–7

Oral Potassium Replacement Products

Product	Salt	Strength[a]
Extended/controlled-release tablets	Chloride	10 mEq (750 mg) 20 mEq (1500 mg)
Effervescent tablets	Chloride and bicarbonate	10 mEq 20 mEq 25 mEq
Liquid	Chloride	20 mEq/15 mL (10%) 40 mEq/15 mL (20%)
Powder packets	Chloride	20 mEq 25 mEq

[a] For potassium, 1 mEq = 1 mmol.

Table 28–8

Recommended Potassium Dosage/Infusion Rate

Clinical Scenario	Maximum Infusion Rate[a]	Maximum Concentration[a]
K^+ greater than 2.5 mEq/L *and* No ECG changes of hypokalemia	10 mEq/h	40 mEq/L
K^+ less than 2.5 mEq/L *or* ECG changes of hypokalemia	40 mEq/h	80 mEq/L

[a]For potassium, 1 mEq = 1 mmol.

The risk of these complications is minimized by using less concentrated solutions and by giving infusions via central access if possible. Administration of potassium in vehicles containing glucose is discouraged because glucose facilitates the intracellular movement of potassium. Posttherapy improvements in serum potassium may be transient, and continuous monitoring is required. Patients with low serum magnesium will have exaggerated potassium losses from the kidneys and GI tract leading to refractory hypokalemia. In this situation, the magnesium deficit must be corrected to successfully treat the concurrent potassium deficiency. In the hypokalemic patient with concurrent acidosis, potassium is often given as the acetate salt, given that acetate is metabolized to bicarbonate. In the patient with depleted phosphorus and potassium, therapy with potassium phosphate is the natural choice.[21,26,27]

Hyperkalemia is defined as a serum potassium concentration greater than 5 mEq/L (mmol/L). Manifestations of hyperkalemia include muscle weakness, paresthesias, hypotension, ECG changes (eg, peaked T waves, shortened QT intervals, and wide QRS complexes), cardiac arrhythmias, and a decreased pH. Causes of hyperkalemia fall into three broad categories: (a) increased potassium intake, (b) decreased potassium excretion, and (c) potassium release from the intracellular space.

Increased potassium intake results from excessive dietary potassium (salt substitutes), excess potassium in IV fluids, and other select medications (potassium-sparing diuretics, cyclosporine [available as generic], angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory agents, pentamidine [available as generic], unfractionated heparin, and low molecular weight heparins). Decreased potassium excretion results from acute renal failure, chronic renal failure, or Addison's disease. Excess potassium release from cells results from tissue breakdown (surgery, trauma, hemolysis, or rhabdomyolysis), blood transfusions, and metabolic acidosis.

In addition to discontinuing all potassium supplements, potassium-sparing medications, and potassium-rich salt substitutes, management of hyperkalemia addresses three concurrent strategies: (a) agents to antagonize the proarrhythmic effects of hyperkalemia, (b) agents to drive potassium into the intracellular space and acutely lower the serum potassium, and (c) agents that will definitively (but more gradually) lower the total body potassium content.[28] If the serum potassium concentration is greater than 7 mEq/L (mmol/L) and/or ECG changes are present, IV calcium is administered to stabilize the myocardium. Depending on the acuity of the situation, 1 g of calcium chloride (13.5 mEq or 6.75 mmol) is administered by direct injection or diluted in 50 mL of D_5W and delivered IV over 15 minutes. Clinical effects are seen within 1 to 2 minutes of infusion and persist for 10 to 30 minutes. Repeat doses may be administered, as necessary. Because most patients with clinically significant hyperkalemia receive multiple boluses of calcium directed by ECG findings, iatrogenic hypercalcemia is a potential complication of hyperkalemia treatment. As such, total calcium concentration is commonly checked with each potassium concentration measurement. Ionized calcium measurements should be obtained in patients who have comorbid conditions that would lead to inconsistency between total serum calcium and free calcium (abnormal albumin, protein, or immunoglobulin concentrations).

Dextrose and insulin (with or without sodium bicarbonate) are typically given at the time of calcium therapy to redistribute potassium into the intracellular space. Dextrose 50% (25 g in 50 mL) can be given by slow IV push over 5 minutes or dextrose 10% with 20 units of regular insulin can be given by continuous IV infusion over 1 to 2 hours. The onset of action for this combination is 30 minutes; the duration of clinical effects is 2 to 6 hours. High-dose inhaled β_2-agonists (eg, albuterol, available as generic) may also be used to acutely drive potassium into the intracellular space.

It is critically important to recognize that the treatments of hyperkalemia discussed thus far are transient, temporizing measures. They are intended to provide time to institute definitive therapy aimed at removing excess potassium from the body. Agents that increase potassium excretion from the body include sodium polystyrene sulfonate (Kayexalate, available as generic), sodium zirconium cyclosilicate (Lokelma, AstraZeneca), loop diuretics, and hemodialysis or hemofiltration (used only in patients with renal failure). Sodium polystyrene sulfonate can be given orally, via NG tube, or as a rectal retention enema and is dosed at 15 to 60 g in four divided doses per day. MedWatch issued a safety alert that cases of colonic necrosis and other serious GI-adverse events (bleeding, ischemic colitis, perforation) had been reported in association with sodium polystyrene sulfonate (Kayexalate) suspension. Most of these cases reported the concurrent use of sorbitol, yet intestinal necrosis is also reported among patients not taking concurrent sorbitol. Clinicians are advised not to use sodium polystyrene sulfonate to reduce potassium levels. Medication safety alerts are available at www.fda.gov/MedWatch. Patiromer(Veltassa, Relypsa), a nonabsorbed cation exchange polymer increases fecal potassium excretion and is utilized to manage hyperkalemia in nonemergent situations, primarily in outpatients. Sodium zirconium cyclosilicate (Lokelma) exchanges potassium for hydrogen in the intestine. A delayed onset of action has limited the acute use of this product for emergency situations.

Calcium

More than 99% of total body calcium is found in bone; the remaining less than 1% is in the ECF and ICF. Calcium plays a critical role in the transmission of nerve impulses, skeletal muscle contraction, myocardial contractions, maintenance of normal cellular permeability, and the formation of bones and teeth. There is a reciprocal relationship between the serum calcium concentration (normally 8.6 to 10.2 mg/dL [2.15 to 2.55 mmol/L]) and the serum phosphate concentration that is regulated by a complex interaction between parathyroid hormone, vitamin D, and calcitonin. About one-half of the serum calcium is bound to plasma proteins; the other half is free ionized calcium. Given that the serum calcium has significant protein binding, the serum calcium measurement must be corrected in patients who have low albumin concentrations (the major serum protein). The most used formula adds 0.8 mg/dL (0.2 mmol/L) of calcium for each gram of albumin deficiency as follows:

$$\text{Corrected [Ca mg/dL]} = \text{Measured [Ca mg/dL]} + [0.8 \times (4 - \text{measured albumin g/dL})]$$[29–31]

$$\text{Corrected [Ca mmol/L]} = \text{Measured [Ca mmol/L]} + [0.02 \times (40 - \text{measured albumin g/L})]$$

Clinical manifestations of hypocalcemia are seen with total serum concentrations less than 6.5 mg/dL (1.63 mmol/L) or an ionized calcium less than 1.12 mmol/L and include tetany, circumoral tingling, muscle spasms, hypoactive reflexes, anxiety, hallucinations, hypotension, myocardial infarction, seizures, lethargy, stupor, and **Trousseau's sign** or **Chvostek's sign**.[23,32] Ionized calcium concentrations are typically used to assess calcium status in the critically ill as these patients often have concurrent hypoalbuminemia.

Causes of hypocalcemia include hypoparathyroidism, hypomagnesemia, alcoholism, hyperphosphatemia, blood product infusion (due to chelation by the citrate buffers), chronic renal failure, vitamin D deficiency, acute pancreatitis, alkalosis, and hypoalbuminemia. In the setting of hypocalcemia, magnesium concentration should be checked and corrected if low. Given that hypocalcemia may be caused by hypomagnesemia, clinicians should be aware that the serum calcium concentrations may not normalize until serum magnesium is replaced. Medications that cause hypocalcemia include phosphate replacement products, loop diuretics, phenytoin (Dilantin, available as generic), phenobarbital (available as generic), corticosteroids, aminoglycoside antibiotics, and acetazolamide (available as generic).[30–32]

Oral calcium replacement products include calcium carbonate (Os-Cal, Glaxo Consumer, and various generics; Tums, Glaxo Consumer and various generics) and calcium citrate (Citracal, Mission Bayer and various generics). IV calcium replacement products include calcium gluconate and calcium chloride (both products available as generic). **KEY CONCEPT** Calcium gluconate is preferred for peripheral use because it is less irritating to the veins; it may also be given intramuscularly. Each 10 mL of a 10% calcium gluconate solution provides 90 mg (4.5 mEq or 2.25 mmol) of elemental calcium. **KEY CONCEPT** Calcium chloride is associated venous irritation and extravasation and is generally reserved for administration via central line. Each 10 mL of a 10% calcium chloride solution contains 270 mg (13.5 mEq or 6.75 mmol) of elemental calcium. IV calcium products are given as a slow push or added to 100 mL of 0.9% normal saline for slow infusion.[31,32] In addition to hypocalcemia, IV calcium may also be used for massive blood transfusions, calcium channel blocker overdose, and emergent hyperkalemia and hypermagnesemia.

For acute symptomatic hypocalcemia, 200 to 300 mg of elemental calcium is administered IV and repeated until symptoms are fully controlled. This is achieved by infusing 1 g of calcium chloride or 2 to 3 g of calcium gluconate at a rate no faster than 30 to 60 mg of elemental calcium per minute. More rapid administration is associated with hypotension, bradycardia, or cardiac asystole. Total calcium concentration is commonly monitored in critically ill patients. Under normal circumstances, about half of calcium is loosely bound to serum proteins while the other half is free. Total calcium concentration measures bound and free calcium. Ionized calcium measures free calcium only. Under usual circumstances, a normal calcium concentration implies a normal free ionized calcium concentration. Ionized calcium should be obtained in patients with comorbid conditions that would lead to inconsistency between total calcium and free serum calcium (abnormal albumin, protein, or immunoglobulin concentrations). For chronic asymptomatic hypocalcemia, oral calcium supplements are given at doses of 2 to 4 g/day of elemental calcium. Many patients with calcium deficiency have concurrent vitamin D deficiency that must also be corrected to restore calcium homeostasis.[2,32,33]

Hypercalcemia is defined as a calcium concentration greater than 10.2 mg/dL (2.55 mmol/L). It may be categorized as mild if total serum calcium is 10.3 to 12 mg/dL (2.58 to 3.00 mmol/L), moderate if total serum calcium is 12.1 to 13 mg/dL (3.03–3.25 mmol/L), or severe when serum concentration is greater than 13 mg/dL (3.25 mmol/L). Causes of hypercalcemia include hyperparathyroidism, malignancy, Paget's disease, Addison's disease, granulomatous diseases (eg, tuberculosis, sarcoidosis, or histoplasmosis), hyperthyroidism, immobilization, multiple bony fractures, acidosis, and milk-alkali syndrome. Multiple medications cause hypercalcemia and include thiazide diuretics, estrogens, lithium, tamoxifen, vitamin A, vitamin D, and calcium supplements.[2,32,34,35]

Because the severity of symptoms and the absolute serum concentration are poorly correlated in some patients, institution of therapy should be dictated by the clinical scenario. All patients with hypercalcemia should be treated with aggressive rehydration: normal saline at 200 to 300 mL/h is a routine initial fluid prescription. For patients with mild hypercalcemia, hydration alone may provide adequate therapy. The moderate and severe forms of hypercalcemia are more likely to have significant manifestations and require prompt initiation of additional therapy. These patients may present with anorexia, confusion, and/or cardiac manifestations (bradycardia and arrhythmias with ECG changes). Total calcium concentrations greater than 13 mg/dL (3.25 mmol/L) are particularly worrisome because these concentrations can unexpectedly precipitate acute renal failure, ventricular arrhythmias, and sudden death.

Once fluid administration has repleted the ECF, forced diuresis (with associated calcium loss) can be initiated with a loop diuretic. For this approach to be successful, normal kidney function is required. In renal failure patients, the alternative therapy is emergent hemodialysis. Other treatment options include bisphosphonates (zoledronic acid, pamidronate), hydrocortisone, calcitonin, and gallium. Given their efficacy and favorable side-effect profile, bisphosphonates are typically the agents of choice. **Table 28–9** outlines the treatment options for hypercalcemia including time to onset of effect, duration of effect, and efficacy.[2,32,33,34]

Phosphorus

Phosphorus is primarily found in the bone (80%–85%) and ICF (15%–20%): the remaining less than 1% is found in the ECF. Note that phosphorus is the major anion within the cells. Given this distribution, serum phosphate concentration does not accurately reflect total body phosphorus stores. Phosphorus is expressed in milligrams (mg) or millimoles (mmol), not as milliequivalents (mEq). Because phosphorus is the source of phosphate for adenosine triphosphate (ATP) and phospholipid synthesis, manifestations of phosphorus imbalance are variable.

Dietary intake, parathyroid hormone levels, and renal function are the major determinants of the serum phosphorus concentration, which is normally 2.7 to 4.5 mg/dL (0.87–1.45 mmol/L).[2,32,36,37,38] Hypophosphatemia is defined by a serum phosphorus concentration less than 2.5 mg/dL (0.81 mmol/L); severe

Table 28–9

Selected Treatment Options for the Management of Hypercalcemia

Therapy	Dose	Onset	Duration	Efficacy[a]
Normal saline	3–6 L/day	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Furosemide (Lasix, available as generic)	80–160 mg/day	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Hydrocortisone (available as generic)	200 mg/day	Hours	Days	Mild/unpredictable
Calcitonin (Miacalcin, Novartis)	4–8 units/kg	Hours	Hours	1–2 mg/dL (0.25–0.50 mmol/L)
Pamidronate (available as generic)	30–90 mg/week	Days	1–4 weeks	1–5 mg/dL(0.25–1.25 mmol/L)
Zoledronic acid (available as generic)	4–8 mg	Days	Weeks	1–5 mg/dL (0.25–1.25 mmol/L

[a] Expected decrease in serum Ca^{2+}.

hypophosphatemia occurs when the phosphorus concentration is less than 1 mg/dL (0.32 mmol/L). Hypophosphatemia can be caused by increased distribution to the ICF (hyperglycemia, insulin therapy, or malnourishment), decreased absorption (starvation, excessive use of phosphorus-binding antacids, vitamin D deficiency, diarrhea, or laxative abuse) or increased renal loss (diuretic use, diabetic ketoacidosis, alcohol abuse, hyperparathyroidism, or burns).[33,36] **KEY CONCEPT** Severe hypophosphatemia can result in impaired diaphragmatic contractility and acute respiratory failure. Medications that can cause hypophosphatemia include diuretics (acetazolamide [Diamox, available as generic], furosemide [Lasix, available as generic], hydrochlorothiazide [HydroDIURIL, available as generic]), sucralfate (Carafate, available as generic), corticosteroids, cisplatin (available as generic), antacids (aluminum carbonate, calcium carbonate, and magnesium oxide [antacids all available as generic]), foscarnet (available as generic), phenytoin (Dilantin, available as generic), phenobarbital (available as generic), and phosphate binders (sevelamer [Renvela, Genzyme Corp.], and calcium acetate [PhosLo, available as generic]).

Signs and symptoms of hypophosphatemia include paresthesias, muscle weakness, myalgias, bone pain, anorexia, nausea, vomiting, red blood cell breakdown (hemolysis), acute respiratory failure, seizures, and coma.[33,39] For mild hypophosphatemia, patients should be encouraged to eat a high-phosphorus diet including eggs, nuts, whole grains, meat, fish, poultry, and milk products. For moderate hypophosphatemia (1–2.5 mg/dL, 0.32–0.81 mmol/L), oral supplementation of 1.5 to 2 g/day (30–60 mmol/day) is usually adequate. Diarrhea may be a dose-limiting side effect with oral phosphate replacement products.

Injectable phosphate products are reserved for patients with severe hypophosphatemia or those in the intensive care unit.[40] The available agents are provided as sodium or potassium salts; however, unless concurrent hypokalemia is present, sodium phosphate is usually used. Empirically, for a mild serum phosphorus deficiency (2.3–3.0 mg/dL, 0.74–0.97 mmol/L), the corresponding IV phosphorus dose is 0.32 mmol/kg; for a moderate deficiency of serum phosphorus 1.6 to 2.2 mg/dL (0.52–0.71 mmol/L), the replacement dose is 0.64 mmol/kg; and the dose is 1 mmol/kg when the serum phosphorus is less than 1.5 mg/dL (0.48 mmol/L).[41] IV phosphorus preparations are usually infused over 4 to 12 hours. Table 28–10 compares the available phosphate replacement products.

Hyperphosphatemia is defined by a serum phosphorus concentration greater than 4.5 mg/dL (1.45 mmol/L). The manifestations of hyperphosphatemia are similar to findings of hypocalcemia (see earlier), and include paresthesias, ECG changes (prolonged QT interval and prolonged ST segment), and metastatic calcifications. Causes of hyperphosphatemia include impaired phosphorus excretion (hypoparathyroidism or renal failure), redistribution of phosphorus to the ECF (acid–base imbalance, rhabdomyolysis, muscle necrosis, or tumor lysis during chemotherapy), and increased phosphorus intake (various medications).[33] Medications that can cause hyperphosphatemia include enemas containing phosphorus (eg, Fleet, Fleet), laxatives containing phosphate or phosphorus, parenteral or oral supplements (eg, K-Phos Neutral, Beach), vitamin D supplements, and the bisphosphonates (eg, pamidronate, various manufacturers).[42]

Hyperphosphatemia is generally benign and rarely needs aggressive therapy. Dietary restriction of phosphate and protein is effective for most minor elevations. Phosphate binders such as aluminum-based antacids, calcium carbonate, calcium acetate (PhosLo, available as generic), sevelamer hydrochloride (Renagel, Genzyme), sevelamer carbonate (Renvela, Genzyme, Global), and lanthanum carbonate (Fosrenol, Shire) may be necessary for some patients (typically those with chronic renal failure).[43] Sucroferric oxyhydroxide (Velphoro, Fresenius Medical Care) is a

Table 28–10

Phosphate Replacement Products

Product	Route	mgPO$_4^-$	mmolPO$_4^-$	mEq (mmol) Na$^+$	mEq (mmmol) K$^+$
Potassium phosphate (KPO$_4$/mL), available as generic	IV	94	3	0	4.4
Sodium phosphate (NaPO$_4$/mL), available as generic	IV	94	3	4	0
Phos-NaK packets, Cypress	Oral	250	8	7.2	7
K-Phos Neutral tablets, Beach	Oral	250	8	13.1	1.4
K-Phos Original tablets, Beach	Oral	114	3.7	-	3.7

noncalcium based chewable phosphate binder administered with each meal. If patients exhibit findings of hypocalcemia (tetany), IV calcium should be administered empirically. Phosphate binders can reduce serum phosphate concentration by 1 to 2 mg/dL (0.32-0.65 mmol/L) in patients requiring dialysis. Interestingly, the clinical benefit of phosphate binders in end stage renal disease has not been demonstrated by randomized clinical trial data to date versus no treatment.[44]

Magnesium

The body's normal daily magnesium requirement is 300 to 350 mg/day to maintain a serum magnesium concentration of 1.5 to 2.4 mEq/L (0.75–1.20 mmol/L). Less than 1% of magnesium is found in the ECF. Magnesium is the second most abundant ICF cation and ECF serum concentrations are a relatively poor measure of total body stores. Magnesium catalyzes and/or activates more than 300 enzymes, provides neuromuscular stability, and is involved in myocardial contraction. Magnesium is generally not part of standard chemistry panels and therefore must be ordered separately.[2,32,42,45,46]

Hypomagnesemia is defined as a serum magnesium less than 1.5 mEq/L (0.75 mmol/L) and is most frequently seen in the intensive care and postoperative settings. Hypomagnesemia results from inadequate intake (alcoholism, dietary restriction, or inadequate magnesium in total parenteral nutrition [TPN]), inadequate absorption (steatorrhea, cancer, malabsorption syndromes, or excess calcium or phosphorus in the GI tract), excessive GI loss of magnesium (diarrhea, laxative abuse, NG tube suctioning, or acute pancreatitis), or excessive urinary loss of magnesium (primary hyperaldosteronism, certain medications, diabetic ketoacidosis, and renal disorders). Hypomagnesemia often occurs in the setting of hypokalemia and hypocalcemia. Clinicians should evaluate the serum magnesium concentration in these patients and correct if low. To evaluate magnesium status, both laboratory tests and clinical assessment is required. For calcium and potassium concentrations to normalize, magnesium supplementation is often required. Medications that potentially can cause hypomagnesemia include aminoglycoside antibiotics, amphotericin B (available as generic), cisplatin (available as generic), insulin, cyclosporine (available as generic), loop diuretics, and thiazide diuretics There is also a strong correlation between hypokalemia and hypomagnesemia.[33,35,42,47] Clinicians should be alerted that the long-term use of proton pump inhibitors may be associated with unexplained hypomagnesemia, with subsequent hypokalemia or hypocalcemia.

The findings of hypomagnesemia include muscle weakness, cramps, agitation, confusion, tremor, seizures, ECG changes (increased PR interval, prolonged QRS complex, peaked T waves, and increased QT interval), findings of hypocalcemia (see earlier), refractory hypokalemia (see earlier), metabolic alkalosis, and digoxin toxicity.[42,48,49]

Asymptomatic mild magnesium deficiencies (1.0–1.5 mEq/L) (0.50–0.75 mmol/L) can be managed with increased oral intake of magnesium-containing foods or with oral supplementation. Magnesium oxide (Mag-Ox various manufacturers) 400-mg tablets contain 241 mg (20 mEq or 10 mmol) of magnesium, and magnesium chloride hexahydrate tablets (Slow-Mag, various generics) contains 64 mg of elemental magnesium. Diarrhea is often a dose-limiting side effect of oral supplementation. Severely deficient patients (< 1.0 mEq/L [0.50 mmol/L]) and all deficient critically ill patients should be managed with IV magnesium sulfate. Ten milliliters of a 10% magnesium sulfate solution contains 1 g of magnesium, which is equivalent to 98 mg (8.12 mEq or 4.06 mmol) of elemental magnesium. IV magnesium supplementation may also be used in the setting of status asthmaticus, premature labor, and torsade de pointes. In May 2013, the FDA released a drug safety communication recommending against the prolonged use of magnesium sulfate to stop preterm labor due to bone changes in exposed babies. Administration of magnesium sulfate injection to pregnant women longer than 5 to 7 days may lead to low calcium levels and bone fractures in the developing baby or fetus. (http://www.fda.gov/Safety/MedWatch/) Magnesium concentrations need to be monitored closely in these patients. **KEY CONCEPT** Because magnesium concentration does not correlate well with total body magnesium stores, magnesium is often administered empirically to critically ill patients.[2,32]

The most common causes of hypermagnesemia are renal failure, often in conjunction with magnesium-containing medications (cathartics, antacids, or magnesium supplements), and lithium therapy (available as generic). Hypermagnesemia is defined as a serum magnesium concentration greater than 2.4 mEq/L (1.20 mmol/L). Mild hypermagnesemia is present if

Patient Encounter 8: Putting It All Together

MH, a 69-year-old man who resides in an independent living center is admitted to the hospital with a 3-day history of altered mental status. The patient was unable to give a history or review of systems. On physical examination, the vital signs revealed a BP of 100/60 mm Hg, pulse 113 beats per minute, respirations 16 per minute, and a temperature of 38.3°C (101°F). Rales and dullness to percussion were noted at the posterior right base. The cardiac examination was significant for tachycardia. No edema was present. Laboratory studies included sodium 159 mEq/L (mmol/L), potassium 4.6 mEq/L (mmol/L), chloride 119 mEq/L (mmol/L), bicarbonate 30 mEq/L (mmol/L), glucose 104 mg/dL (5.8 mmol/L), BUN 34 mg/dL (12.1 mmol/L), and creatinine 2.2 mg/dL (194 μmol/L). The CBC was within normal limits. Procalcitonin is pending. Chest x-ray indicated right lower lobe pneumonia. The patient is 5 ft 10 in. (178 cm) tall and currently weighs 72 kg (158 lb). His normal weight is 77 kg (170 lb).

What are the likely causes for the increased sodium concentration in this patient?

Calculate the TBW, ICF, and ECF for this patient.

Calculate DM's fluid deficit if one is present.

In the next 24 hours, the medical team wants to replace 50% of the fluid deficit plus an extra 240 mL to account for increased insensible losses in addition to the patient's maintenance needs. Using the equation (1500 mL + 20 mL for each kilogram > 20 kg), calculate the rate of fluid administration for the total fluids needed in this 24-hour period and over the next 48 hours.

Calculate MH's daily maintenance fluids.

Calculate MH's fluid administration rate for the first 24 hours (hospital day 1).

Calculate MH's fluids for the subsequent 48 hours (hospital days 2 and 3) if the goal is to replete the remaining fluid deficit during that time.

What type of fluid should be used to treat MH's fluid disorder?

Patient Care and Monitoring

Collect Information

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements.
- Review the medical history, laboratory data, and physical assessment findings.
- Identify lifestyle habits, preferences, health goals, and socioeconomic factors that cause risk of fluid imbalance and/or acute and chronic electrolyte disorders.

Assess the Information

- Determine if the patient is taking any substance that could alter fluid status or electrolyte balance.
- Based upon physical exam, review of systems, and laboratory data, determine whether the patient is experiencing signs or symptoms of fluid imbalance or an electrolyte disorder.
- Identify any significant adverse drug effects or interactions.

Develop a Care Plan

- Determine if fluid replacement and/or electrolyte supplementation is indicated.
- Choose replacement fluid and/or electrolyte doses that are optimal for the patient.

Implement the Care Plan

- Educate the patient about changes in drug therapy, medication administration, potential new effects, and how to manage and report adverse events that occur.
- Discuss importance of medication adherence and lifestyle changes to maintain fluid status and electrolyte balance.
- Determine if the patient has insurance coverage on whether recommended agents are included on the institution's formulary.

Follow-up: Monitor and Evaluate

- Follow up at appropriate intervals to assess effectiveness and safety of electrolyte replacement therapy.
- Review medication adherence.
- Review physical exam, laboratory tests, and results of other diagnostic tests to assess changes in clinical status.

the serum magnesium concentration is between 2.5 and 4 mEq/L (1.25–2.00 mmol/L) and manifests as nausea, vomiting, cutaneous vasodilation, and bradycardia. Moderate hypermagnesemia is present if the serum magnesium concentration is between 4 and 12 mEq/L (2 to 6 mmol/L) and may manifest with hyporeflexia, weakness, somnolence, hypotension, and ECG changes (increased QRS interval). Severe hypermagnesemia is present if the serum magnesium concentration is greater than 13 mEq/L (6.5 mmol/L) and can manifest as muscle paralysis, complete heart block, asystole, respiratory failure, refractory hypotension, and death.[2,50]

All patients with hypermagnesemia should have all magnesium supplements or magnesium-containing medications discontinued.[2,32] Iatrogenic hypermagnesemia has been observed after IV magnesium therapy for refractory asthma or preeclampsia. Mild hypermagnesemia and moderate hypermagnesemia without cardiac findings can be treated with normal saline infusion and furosemide therapy (assuming the patient has normal renal function). Moderate hypermagnesemia with cardiac irritability and severe hypermagnesemia require concurrent IV calcium gluconate to reverse the neuromuscular and cardiovascular effects. Calcium gluconate given at typical doses of 1 to 2 g IV will have transient effects and can be repeated as clinically indicated. Hemodialysis may be necessary for those with severely compromised renal function.

CONCLUSION

Because disturbances in fluid balance are routinely encountered in clinical medicine, it is essential to have a thorough understanding of body fluid compartments and the therapeutic use of fluids. Similarly, disturbances in serum sodium, potassium, calcium, phosphorus, and magnesium are ubiquitous and must be mastered by all clinicians. Dysregulation of fluid and/or electrolyte status has serious implications regarding the concepts of drug absorption, volumes of distribution, and toxicity. Similarly, many medications can disrupt fluid and/or electrolyte balance as an unintended consequence.

Abbreviations Introduced In This Chapter

ADH	Antidiuretic hormone
ASHP	American Society of Health-System Pharmacists
ATP	Adenosine triphosphate
BP	Blood pressure
BUN	Blood urea nitrogen
Ca^+	Calcium
CHF	Congestive heart failure
Cl	Chloride
D5W	Dextrose 5% water
ECF	Extracellular fluid
ECG	Electrocardiogram
FFP	Fresh-frozen plasma
IBW	Ideal body weight
ICF	Intracellular fluid
I&Os	Ins and outs
JCAHO	Joint Commission on Accreditation of Healthcare Organizations
K^+	Potassium
KPO^4	Potassium phosphate
KVO	Keep the vein open
LR	Lactated Ringer's (solution)
Mg^{++}	Magnesium
Na^+	Sodium
NaCl	Sodium chloride
NaPO4	Sodium phosphate
NG	Nasogastric
NS	Normal saline
SI	Standardized international units
SIADH	Syndrome of inappropriate antidiuretic hormone secretion
TBW	Total body water
TPN	Total parenteral nutrition

Acid–Base Disturbances

Lee E. Morrow and Mark A Malesker

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Compare and contrast the six primary acid–base disturbances within the human body.
2. Apply simple formulas in a systematic manner to determine the etiology of simple acid–base disturbances and the adequacy of compensation.
3. Integrate the supplemental concepts of the anion gap and the excess gap to further assess for complex acid–base disturbances.
4. Discuss the most common clinical causes for each primary acid–base abnormality.
5. Describe the potential clinical complications of altered acid–base homeostasis.
6. Propose an appropriate treatment plan for patients with deranged acid–base physiology.

INTRODUCTION

Given its reputation for complexity and the need to memorize innumerable formulas, acid–base analysis intimidates many health-care providers. In reality, acid–base disorders always obey well-defined biochemical and physiological principles. The pH determines a patient's acid–base status and an assessment of the serum bicarbonate (HCO_3^-) and arterial blood carbon dioxide ($PaCO_2$) values identifies the underlying process. Rigorous use of a systematic approach to arterial blood gases increases the likelihood that derangements in acid–base physiology are recognized and correctly interpreted. This chapter outlines a clinically useful approach to acid–base abnormalities and applies it in a series of increasingly complex clinical scenarios.

Disturbances of acid–base equilibrium occur in a wide variety of illnesses and are among the most frequently encountered disorders in critical care medicine. The importance of a thorough command of this content cannot be overstated given that acid–base disorders are remarkably common and may result in significant morbidity and mortality. Although severe derangements may affect virtually any organ system, the most serious clinical effects are cardiovascular (arrhythmias, impaired contractility), neurologic (coma, seizures), pulmonary (dyspnea, impaired oxygen delivery, respiratory fatigue, respiratory failure), and/or renal (hypokalemia). Changes in acid–base status also affect multiple aspects of drug disposition (clearance, protein binding) and pharmacodynamics.

PHYSIOLOGY OF ACID–BASE HOMEOSTASIS

Acid–base homeostasis is responsible for maintaining blood hydrogen ion concentration [H^+] near normal despite the daily acidic and/or alkaline loads derived from the intake and metabolism of foods. Acid–base status is traditionally represented in terms of pH, the negative logarithm of [H^+]. Because [H^+] is equal to 24 times the ratio of $PaCO_2$ to HCO_3^- (for $PaCO_2$ expressed in units of mm Hg), the pH can be altered by a change in either the bicarbonate concentration or the dissolved carbon dioxide. A critically important concept is that [H^+] depends only on the *ratio* of $PaCO_2$ to HCO_3^- and not the absolute amount of either. As such, a normal $PaCO_2$ or HCO_3^- alone does not guarantee that the pH will be normal. Conversely, a normal pH does not imply that either the $PaCO_2$ or HCO_3^- will be normal.[1]

KEY CONCEPT Acid–base homeostasis is tightly regulated by the complex, but predictable, interactions of the kidneys, the lungs, and various buffer systems. The kidneys control serum HCO_3^- concentration through the excretion or reabsorption of filtered HCO_3^-, the excretion of metabolic acids, and synthesis of new HCO_3^-. The lungs control arterial carbon dioxide (CO_2) concentrations through changes in the depth and/or rate of respiration. The net result is tight regulation of the blood pH by these three distinct mechanisms working in harmony: extracellular HCO_3^- and intracellular protein buffering systems; pulmonary regulation of $PaCO_2$, effectively allowing carbonic acid to be eliminated by the lungs as CO_2; and renal reclamation or excretion of HCO_3^- and excretion of acids such as ammonium.

Because kidneys excrete less than 1% of the estimated 13,000 mEq (mmol) of H^+ ions generated in an average day, renal failure can be present for prolonged periods before life-threatening imbalances occur. Conversely, cessation of breathing for minutes results in profound acid–base disturbances.[1]

The best way to assess a patient's acid–base status is to review the results of an arterial blood gas (ABG) specimen. ABG analyzers directly measure the pH and $PaCO_2$, while the HCO_3^- value is calculated using the Henderson-Hasselbalch equation. A more direct measure of serum HCO_3^- is obtained by measuring the total venous carbon dioxide (tCO_2). Because dissolved CO_2 is almost exclusively in the form of HCO_3^-, tCO_2 is essentially equivalent to the measured serum HCO_3^- concentration. This value (HCO_3^-) is routinely reported on basic chemistry panels. In the remainder of this chapter, the pH and $PaCO_2$ values should be assumed to come from an ABG while HCO_3^- values should be considered to be the measured serum concentration.

BASIC PATHOPHYSIOLOGY

Under normal circumstances, the arterial pH is tightly regulated between 7.35 and 7.45. **Acidemia** is an abnormally low arterial blood pH (< 7.35) while **acidosis** is a pathologic process that acidifies body fluids. Similarly, **alkalemia** is an abnormally high arterial blood pH (> 7.45) while **alkalosis** is a pathologic process that alkalinizes body fluids. As such, although a patient can simultaneously have acidosis *and* alkalosis, the end result will be acidemia *or* alkalemia.

Changes in the arterial pH are driven by changes in the $PaCO_2$ and/or the serum HCO_3^-. CO_2 is a volatile acid regulated by the depth and rate of respiration. Because CO_2 can be either "blown off" or "retained" by the respiratory system, it is referred to as being under respiratory control. KEY CONCEPT **Respiratory acidosis** and **alkalosis** result from primary disturbances in the arterial CO_2 concentration. Metabolic compensation for respiratory disturbances is a slow process, often requiring days for the serum HCO_3^- to reach steady state. KEY CONCEPT **Respiratory acidosis** is caused by respiratory insufficiency resulting in an increased arterial CO_2 concentration. The compensation for respiratory acidosis (if present for prolonged periods) is an increase in serum HCO_3^-. KEY CONCEPT **Respiratory alkalosis** is caused by hyperventilation resulting in a decreased arterial CO_2 concentration. The compensation for respiratory alkalosis (if present for prolonged periods) is a decrease in serum HCO_3^-.

A respiratory acid–base disorder is a pH disturbance caused by pathologic alterations of the respiratory system or its CNS control. Such an alteration may result in the accumulation of $PaCO_2$ beyond normal limits (> 45 mm Hg [6.0 kPa]), a situation termed *respiratory acidosis*, or it may result in the loss of $PaCO_2$ beyond normal limits (< 35 mm Hg or 4.7 kPa), a condition termed *respiratory alkalosis*. Variations in respiratory rate and/or depth allow the lungs to achieve changes in the $PaCO_2$ very quickly (within minutes).

HCO_3^- is a base regulated by renal metabolism via the enzyme carbonic anhydrase. As such, HCO_3^- is often referred to as being under metabolic control. KEY CONCEPT **Metabolic acidosis** and alkalosis result from primary disturbances in the serum HCO_3^- concentration. Respiratory compensation of metabolic disturbances begins within minutes and is complete within 12 hours. KEY CONCEPT **Metabolic acidosis** is characterized by a decrease in serum HCO_3^-. The anion gap is used to narrow the differential diagnosis because metabolic acidosis may be caused by addition of acids (increased anion gap) or loss of HCO_3^- (normal anion gap). The compensation for metabolic acidosis is an increase in ventilation with a decrease in arterial CO_2. KEY CONCEPT **Metabolic alkalosis** is characterized by an increase in serum HCO_3^-. This disorder requires loss of fluid that is low in HCO_3^- from the body or addition of HCO_3^- to the body. The compensation for metabolic alkalosis is a decrease in ventilation with an increase in arterial CO_2.

A metabolic acid–base disorder is a pH disturbance caused by derangement of the pathways responsible for maintaining a normal HCO_3^- concentration. This may result in a pathologic accumulation of HCO_3^- (> 26 mEq/L [mmol/L]), a condition termed *metabolic alkalosis*, or it may result in the loss of HCO_3^- beyond normal (< 22 mEq/L [mmol/L]), a condition termed *metabolic acidosis*. In contrast to the lungs' rapid effects on CO_2, the kidneys change the HCO_3^- very slowly (hours to days).

Respiratory and metabolic derangements can occur in isolation or in combination. If a patient has an isolated primary acid–base disorder that is not accompanied by another primary acid–base disorder, a simple (uncomplicated) disorder is present. The most common clinical disturbances are simple acid–base disorders. If two or three primary acid–base disorders are simultaneously present, the patient has a mixed (complicated) disorder. More complex clinical situations lead to mixed acid–base disturbances. Because CO_2 is a volatile acid, it can rapidly be changed by the respiratory system. If a respiratory acid–base disturbance is present for minutes to hours, it is considered an acute disorder, while if it is present for days or longer it is considered a chronic disorder. By definition, the metabolic machinery that regulates HCO_3^- results in slow changes, and all metabolic disorders are chronic.

Physiologic changes that follow the primary disorder and attempt to restore the blood pH to normal are referred to as compensatory changes. It should be stressed that compensation never normalizes the pH. Because all metabolic acid–base disorders are chronic and the normal respiratory system can quickly alter the $PaCO_2$, essentially all metabolic disorders are accompanied by some degree of respiratory compensation.[2,3] Similarly, chronic respiratory acid–base disorders are typically accompanied by attempts at metabolic compensation.[4,5] However, with acute respiratory acid–base disorders, there is insufficient time for the metabolic pathways to compensate significantly.[6] As such, acute respiratory derangements are essentially uncompensated.

The amount of compensation (metabolic or respiratory) can be reliably predicted based on the degree of derangement in the primary disorder. Table 29–1 outlines the simple acid–base disorders and provides formulas for calculating the expected compensatory responses.[7] Although it is not mandatory to memorize these formulas to interpret acid–base problems, they can be helpful tools. If the measured values differ markedly from the calculated values (the measured serum HCO_3^- is > 2 mEq/L [mmol/L] from the calculated value or the measured $PaCO_2$ is more than 4 mm Hg [0.5 kPa] from the calculated value), a second acid–base disorder is present as outlined in Table 29–2.

Table 29–1

The Six Simple Acid–Base Disorders

Type of Disorder	pH	$PaCO_2$[a]	HCO_3^-
1. Metabolic acidosis	↓	Decreased[b] $PaCO_2 = (1.5 \times HCO_3^-) + 8$	Decreased[c]
2. Metabolic alkalosis	↑	Increased[b] $PaCO_2 = (0.9 \times HCO_3^-) + 15$	Increased[c]
3. Acute respiratory acidosis	↓	Increased[c]	Approximately normal $\Delta HCO_3^- = 0.1 \times \Delta PaCO_2$[a]
4. Chronic respiratory acidosis	↓	Increased[c]	Increased[d] $\Delta HCO_3^- = 0.35 \times \Delta PaCO_2$[a]
5. Acute respiratory alkalosis	↑	Decreased[c]	Approximately normal $\Delta HCO_3^- = 0.2 \times \Delta PaCO_2$[a]
6. Chronic respiratory alkalosis	↑	Decreased[c]	Decreased[d] $\Delta HCO_3 = 0.4 \times \Delta PaCO_2$[a]

[a] $PaCO_2$ in mm Hg and is calculated from kPa by dividing by 0.133.

[b] Respiratory compensation: If inappropriate, see Table 29–2.

[c] Primary disorder.

[d] Metabolic compensation: If inappropriate, see Table 29–2.

Table 29–2

Diagnosis of Concurrent Acid–Base Disturbances When Compensation Is Inappropriate

Primary Acid–Base Disturbance	Assessment of Compensation	Concurrent Acid–Base Disturbance
Metabolic acidosis	PaCO$_2$ too low[a]	Respiratory alkalosis
	PaCO$_2$ too high[a]	Respiratory acidosis
Metabolic alkalosis	PaCO$_2$ too low[a]	Respiratory alkalosis
	PaCO$_2$ too high[a]	Respiratory acidosis
Respiratory acidosis	Hco$_3^-$ too low[b]	Metabolic acidosis
	Hco$_3^-$ too high[b]	Metabolic alkalosis
Respiratory alkalosis	HCO$_3^-$ too low[b]	Metabolic acidosis
	HCO$_3^-$ too high[b]	Metabolic alkalosis

[a] Measured PaCO$_2$ more than 4 mm Hg (0.5 kPa) from the calculated value.

[b] Measured HCO$^-_3$ more than 2 mEq/L (mmol/L) from the calculated value.

DIAGNOSIS

When given an ABG for interpretation, it is essential to use an approach that is focused and comprehensive.[8] An algorithm illustrating this concept is shown in Figure 29–1. Using this algorithm, Step 1 is to identify all abnormalities in the pH, PaCO$_2$, and/or HCO$_3^-$ and then decide which abnormal values are primary and which are compensatory. This is best done by initially looking at the pH. Whichever side of 7.40 the pH is on, the process that caused it to shift to that side is the primary abnormality. If the arterial pH is lower than 7.40 (acidemia), an elevated PaCO$_2$ (> 45 mm Hg [6.0 kPa], **respiratory acidosis**) or a lowered HCO$_3^-$ (< 22 mEq/L [mmol/L], **metabolic acidosis**) would be the primary abnormality. If the arterial pH is higher than 7.40 (alkalemia), a decreased PaCO$_2$ (< 35 or 4.7 kPa, **respiratory alkalosis**) or an increased HCO$_3^-$ (> 25 mEq/L [mmol/L], **metabolic alkalosis**) would be the primary abnormality. Once the primary disorder is established, step 2 is to apply the formulas from Table 29–1 to assess whether the observed compensation is appropriate for the primary disorder and to look for concurrent processes.[7]

An alternative to a diagnostic algorithm is use of a graphic nomogram.[9] These nomograms are plots of the pH, PaCO$_2$, and HCO$_3^-$ that allow the user to rapidly determine whether arterial blood gas values are consistent with one of the six simple primary acid–base disturbances. Although nomograms are commonly used to identify acid–base disturbances in clinical practice, only individuals who fully comprehend the fundamental concepts of acid–base assessment should use these tools. Also, appreciate that

Patient Encounter 1

A 23-year-old heroin addict is brought to the emergency department after friends found her unconscious with a needle in her arm. Her initial ABG has a pH of 7.12 with a PaCO$_2$ of 75 mm Hg (10.0 kPa), and the serum HCO$_3$ is 27 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 2

A 79-year-old man with advanced emphysema presents to the emergency department with superficial facial burns after the cigarette he was smoking ignited the supplemental oxygen he was using. His admission ABG shows a pH of 7.33, a PaCO$_2$ of 75 mm Hg (10.0 kPa), and an HCO$_3^-$ of 36 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 3

A 61-year-old woman presented to the ER with chest pain, palpitations, and a sense of impending doom. After an extensive workup is negative, her symptoms are attributed to a panic attack. Her ABG shows a pH of 7.55, a PaCO$_2$ of 19 mm Hg (2.5 kPa), and an HCO$_3^-$ of 20 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 4

An 18-year-old man presents to his university's student health clinic for evaluation of dyspnea and peripheral edema. He has a reduced left ventricular ejection fraction due to congenital cardiomyopathy and is prescribed daily furosemide therapy to maintain euvolemia. However, he has been intermittently noncompliant since moving into his dormitory. An ABG shows the following: pH of 7.49, a PaCO$_2$ of 43 mm Hg (5.7 kPa), and an HCO$_3^-$ of 31 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

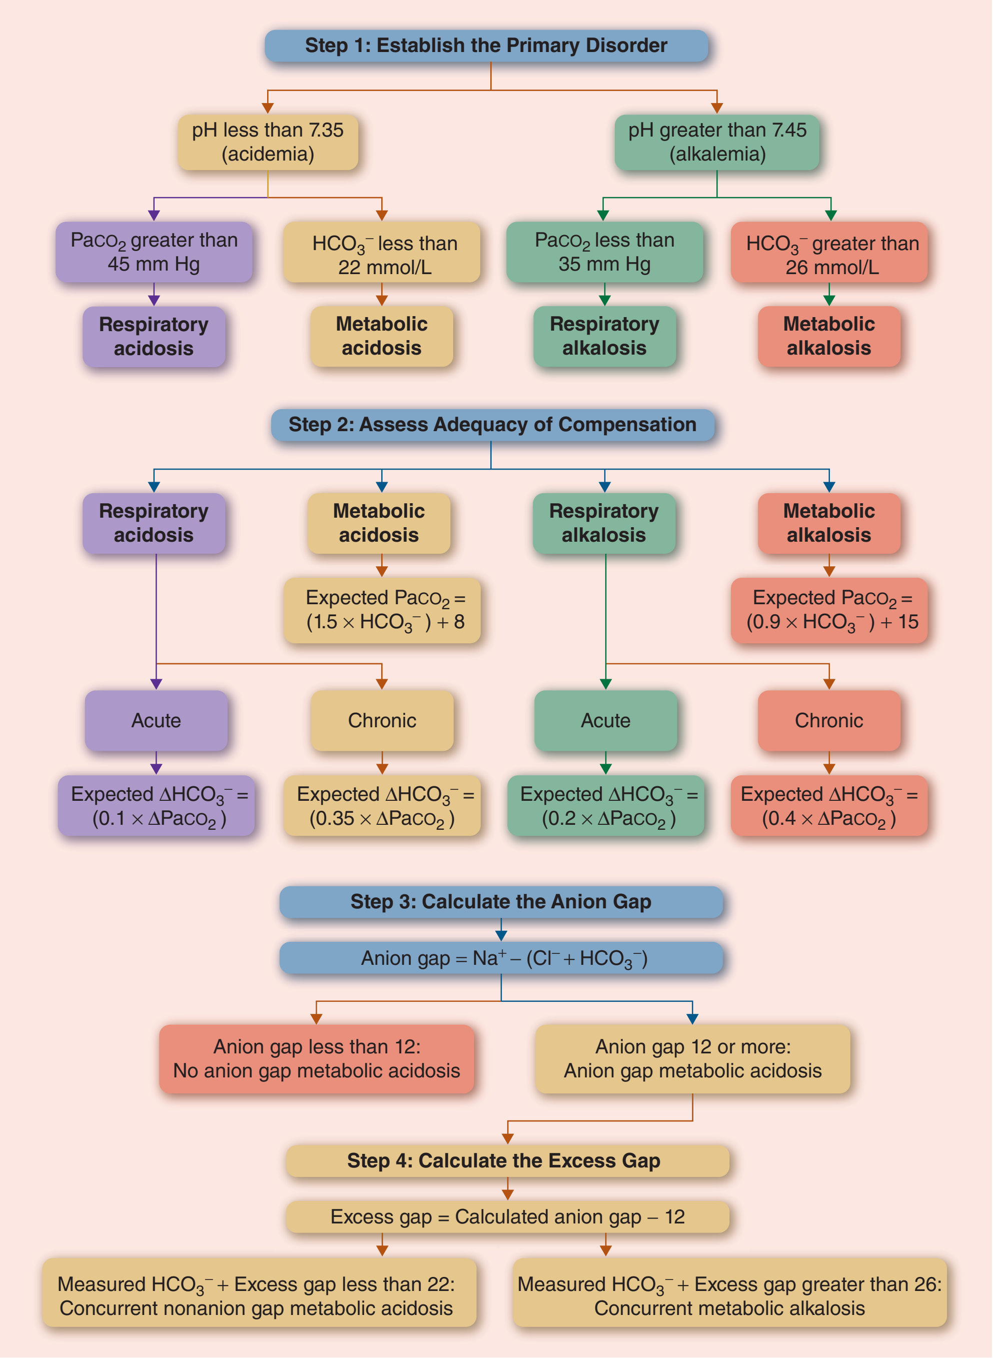
Patient Encounter 5

A 50-year-old woman who is being admitted to the hospital for orthopedic surgery after suffering fractures to her left femur, pelvis, and ribs in a skiing accident. Although she has no comorbid illnesses and does not take any medications chronically, she has been taking acetazolamide for altitude sickness prophylaxis for the past 5 days. Her ABG in the ER shows a pH of 7.26, a PaCO$_2$ of 26 mm Hg (3.5 kPa), and an HCO$_3^-$ of 12 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?



Step 1: Establish the Primary Disorder
pH less than 7.35 (acidemia)
pH greater than 7.45 (alkalemia)
Paco$_2$ greater than 45 mm Hg
HCO_3^- less than 22 mmol/L
Paco$_2$ less than 35 mm Hg
HCO_3^- greater than 26 mmol/L
Respiratory acidosis
Metabolic acidosis
Respiratory alkalosis
Metabolic alkalosis
Step 2: Assess Adequacy of Compensation
Respiratory acidosis
Metabolic acidosis
Respiratory alkalosis
Metabolic alkalosis
Expected Paco$_2$ = (1.5 × HCO_3^-) + 8
Expected Paco$_2$ = (0.9 × HCO_3^-) + 15
Acute
Chronic
Acute
Chronic
Expected ΔHCO_3^- = (0.1 × ΔPaco$_2$)
Expected ΔHCO_3^- = (0.35 × ΔPaco$_2$)
Expected ΔHCO_3^- = (0.2 × ΔPaco$_2$)
Expected ΔHCO_3^- = (0.4 × ΔPaco$_2$)
Step 3: Calculate the Anion Gap
Anion gap = $Na^+ - (Cl^- + HCO_3^-)$
Anion gap less than 12: No anion gap metabolic acidosis
Anion gap 12 or more: Anion gap metabolic acidosis
Step 4: Calculate the Excess Gap
Excess gap = Calculated anion gap – 12
Measured HCO_3^- + Excess gap less than 22: Concurrent nonanion gap metabolic acidosis
Measured HCO_3^- + Excess gap greater than 26: Concurrent metabolic alkalosis

FIGURE 29–1. An algorithmic approach to acid–base disorders. Normal values: pH 7.35 to 7.45, $PaCO_2$ 35 to 45 mm Hg (4.7 to 6.0 kPa), HCO_3^- 22 to 26 mEq/L (mmol/L), anion gap less than 12 mEq/L (mmol/L). Note that $PaCO_2$ should be in units of mm Hg to use the equations in the figure. To convert $PaCO_2$ in units of kPa to mm Hg, divide by 0.133. (Cl^-, chloride ion; HCO_3^-, bicarbonate; Na^+, sodium ion; $PaCO_2$, partial pressure of arterial carbon dioxide.)

nomograms have limited utility when dealing with complex acid–base derangements.

Acid–base disturbances are always manifestations of underlying disorders. It is useful to specifically define the primary acid–base abnormality because each disorder is caused by a limited number of disease processes. Establishing the specific disease process responsible for the observed acid–base disorder is clinically important because treatment of a given disorder will only be accomplished by correcting the underlying disease process.

ADVANCED PATHOPHYSIOLOGY

The concepts in this section are used to further expand on steps 3 and 4 of the diagnostic algorithm shown in Figure 29–1. Under normal circumstances, the serum is in the isoelectric state. This means that the positively charged entities reported in a standard chemistry panel (cations: sodium [Na+] and potassium [K+]) should be exactly balanced by the negatively charged entities (anions: chloride [Cl^-] and bicarbonate [HCO_3^-]). However, this relationship is consistently incorrect because the measured cations are higher than the measured anions by 10 to 12 mEq/L (mmol/L). This discrepancy results from the presence of unmeasured anions (eg, circulating proteins, phosphates, and sulfates). This apparent difference in charges, the serum **anion gap**, is calculated as follows:

$$\text{Anion gap} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-).$$

Because the serum K+ content is relatively small and is very tightly regulated, it is generally omitted from the calculation.[10]

It is important to realize that the serum HCO_3^- concentration may be affected by the presence of unmeasured endogenous acids (lactic acid or ketoacids). HCO_3^- will attempt to buffer these acids, resulting in a 1 mEq (mmol) loss of serum HCO_3^- for each 1 mEq (mmol) of acid titrated. Because the cation side of the equation is not affected by this transaction, the loss of serum HCO_3^- results in an increase in the calculated anion gap. Identification of an increased anion gap is very important because a limited number of clinical scenarios lead to this unique acid–base disorder. A mnemonic to recall the differential diagnosis for an anion gap acidosis is shown in Table 29–3. The concept of the increased anion gap is applied later in Patient Encounters 6 through 10.

Step 3 in Figure 29–1 suggests that any time an ABG is analyzed, it is wise to concurrently inspect the serum chemistry values and calculate the anion gap. The body does not generate an anion gap to compensate for a primary disorder. As such, if the calculated anion gap exceeds 12 mEq/L (mmol/L), there is a primary metabolic acidosis regardless of the pH or the serum HCO_3^- concentration. The anion gap may be artificially lowered by decreased serum albumin, multiple myeloma, lithium intoxication, or a profound increase in the serum potassium, calcium, or magnesium.[11] Of these etiologies, hypoalbuminemia is the most clinically relevant as albumin accounts for approximately 75% of the unmeasured anions in the normal anion gap.[12] The anion gap is reduced by 2.5 mEq/L (mmol/L) for each 1 g/dL (10 g/L) the albumin is reduced below normal (4.0 g/dL [40 g/L]).

Step 4 in Figure 29–1 shows how calculation of the anion gap also facilitates determination of the **excess gap** or the degree to which the calculated anion gap exceeds the normal anion gap. The excess gap is calculated as follows:

$$\begin{aligned}\text{Excess gap} &= \text{calculated anion gap} - \text{normal anion gap}\\ &= [\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)] - 12.\end{aligned}$$

The excess gap represents the amount of HCO_3^- that has been lost due to buffering unmeasured cations. The excess gap can be added back to the measured HCO_3^- to determine what the patient's HCO_3^- would be if these endogenous acids were not present. This is a very valuable tool that can be used in narrowing the differential diagnosis of certain acid–base disorders as well as in uncovering occult or mixed acid–base disorders.

Table 29–3

Mnemonics for the Differential Diagnoses of Metabolic Acidosis

Elevated Anion Gap[a]	Normal Anion Gap[a]
M—Methanol, metformin	**U**—Ureteral diversion
U—Uremia	**S**—Saline infusion
D—Diabetic (or alcoholic) ketoacidosis	**E**—Exogenous acid
P—Paraldehyde, phenformin	**D**—Diarrhea
I—Isoniazid, iron	**C**—Carbonic anhydrase inhibitors
L—Lactic acidosis	**A**—Adrenal insufficiency
E—Ethylene glycol, ethanol	**R**—Renal tubular acidosis
S—Salicylates	

[a] Anion gap = serum sodium concentration − (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances, the anion gap should be 10 mEq/L (mmol/L) or less.

In summary, the approach to assessment of acid–base status involves four key steps as outlined in Figure 29–1: step 1 = initial inspection of the pH, PaCO_2, and HCO_3^-; step 2 = assessment of the adequacy of compensation; step 3 = calculation of the anion gap; and step 4 = calculation of the excess gap.

ETIOLOGY AND TREATMENT

KEY CONCEPT Arterial blood gases, serum electrolytes, physical examination findings, the clinical history, and the patient's recent medications must be reviewed to establish the etiology of a given acid–base disturbance. Tables 29–3 to 29–7 outline the most commonly encountered causes for each of the primary acid–base disorders. The therapeutic approach to each of these acid–base derangements should emphasize a search for the cause, as opposed to immediate attempts to normalize the pH.

KEY CONCEPT It is critical to treat the underlying causative process to effectively resolve most observed acid–base disorders. However, supportive treatment of the pH and electrolytes is often needed until the underlying disease state is improved.[13,14]

All patients with significant disturbances in their acid–base status require continuous cardiovascular and hemodynamic monitoring. Because frequent assessment of the patient's response to treatment is critical, an arterial line is often placed to minimize patient discomfort with serial ABG collections. If the anion gap was initially abnormal, serial blood chemistries should be followed to ensure that the anion gap resolves with treatment. Specific treatment decisions depend on the underlying pathophysiologic state (eg, dialysis for renal failure, insulin for diabetic ketoacidosis, or improving tissue perfusion and oxygenation for lactic acidosis).

Metabolic Acidosis

Metabolic acidosis is characterized by a reduced arterial pH, a primary decrease in the HCO_3^- concentration, and a compensatory reduction in the PaCO_2. The etiologies of metabolic acidosis are divided into those that lead to an increase in the anion gap and those associated with a normal anion gap and are listed in Table 29–4. Although there are numerous mnemonics to recall the differential diagnosis of the metabolic acidosis, two simple ones are shown in Table 29–3. High anion gap metabolic acidosis is most frequently caused by lactic acidosis, ketoacidosis, and/or renal failure. Although there is considerable variation, the largest anion gaps are caused by ketoacidosis, lactic acidosis, and methanol or ethylene glycol ingestion.[15]

Symptoms of metabolic acidosis are attributable to changes in cardiovascular, musculoskeletal, neurologic, or pulmonary functioning. Respiratory compensation requires marked increases in minute ventilation and may lead to dyspnea, respiratory fatigue, and respiratory failure. Acidemia predisposes to ventricular arrhythmias and reduces cardiac contractility, each of which can result in pulmonary edema and/or systemic hypotension.[16] Neurologic symptoms range from lethargy to coma and are usually proportional to the severity of the pH derangement. Chronic metabolic acidosis leads to a variety of musculoskeletal problems including impaired growth, rickets, osteomalacia, or osteopenia. These changes are believed to be caused by the release of calcium and phosphate during bone buffering of excess H^+ ions.

Table 29–4

Common Causes of Metabolic Acidosis

Elevated Anion Gap[a]	Normal Anion Gap[a]
Intoxications	Bowel fistula
Methanol	Diarrhea
Ethylene glycol	Dilutional acidosis
Salicylates	Drugs
Paraldehyde	Acetazolamide[b]
Isoniazid	Ammonium chloride[b]
Ketoacidosis	Amphotericin B[b]
Diabetic	Arginine hydrochloride[c]
Ethanol	Cholestyramine[b]
Starvation	Hydrochloric acid[b]
Lactic acidosis	Lithium[b]
Carbon monoxide poisoning	Parenteral nutrition[b]
Drugs	Topiramate[b]
IV lorazepam (due to vehicle)[c]	Zonisamide[b]
Metformin[b]	Lead poisoning
Nitroprusside (due to cyanide accumulation)[b]	Renal tubular acidosis
Nucleoside reverse transcriptase inhibitors[b]	Surgical drains
Propofol[c]	Ureteral diversion
Seizures	Villous adenomas (some)
Severe hypoxemia	
Shock	
Renal failure	

[a] Anion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances, the anion gap should be 10 mEq/L (mmol/L) or less.

[b] May be observed with therapeutic doses or overdoses.

[c] Typically observed with overdoses or prolonged, high-dose infusions (the so-called propofol infusion syndrome).

As previously discussed, in anion gap metabolic acidosis, the isoelectric state is maintained because unmeasured anions are present. With a *normal* anion gap metabolic acidosis, the isoelectric state is maintained by an increase in the measured chloride. Because of this, normal anion gap metabolic acidosis is often referred to as hyperchloremic acidosis.

In patients with a normal anion gap metabolic acidosis, it is often helpful to calculate the urine anion gap (UAG).[17] The UAG is calculated from a spot urine collection as follows:

$$\text{UAG} = (\text{Urine Na}^+ + \text{Urine K}^+) - \text{Urine Cl}^-.$$

Patient Encounter 6

A 31-year-old man is admitted to the intensive care unit after ingesting an unknown quantity of aspirin tablets in a suicide attempt. His admission labs are as follows: pH of 7.50, $PaCO_2$ of 20 mm Hg (2.7 kPa), HCO_3^- of 16 mEq/L (mmol/L), sodium concentration of 140 mEq/L (mmol/L), and chloride level of 103 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 7

A 68-year-old woman is brought to the emergency room by her family for increasing confusion. They report that she has had the stomach flu with frequent bouts of emesis over the past 5 days. Given her poor oral intake, frequent vomiting, and weakness, she skipped her last three hemodialysis sessions. Her labs show: pH of 7.40, $PaCO_2$ of 40 mm Hg (5.3 kPa), HCO_3^- of 24 mEq/L (mmol/L), sodium concentration of 145 mEq/L (mmol/L), and chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 8

A frail, 74-year-old man with metastatic colon cancer is brought to the ER from the Hospice House. His family says his condition has worsened dramatically since transfer there from the hospital, and they would like him to be readmitted to resume full cares. They are upset that he has had multiple bouts of feculent emesis from a bowel obstruction since Hospice was started. They are also frustrated that his mental status has steadily worsened. He is an insulin-dependent diabetic, but glucose checks and insulin administration were stopped upon transfer to Hospice. They insisted on transfer to the hospital when they noticed his breathing was very slow and shallow this morning. The blood work drawn in the ER shows a pH of 7.10, a $PaCO_2$ of 50 mm Hg (6.7 kPa), an HCO_3^- of 15 mEq/L (mmol/L), a sodium concentration of 145 mEq/L (mmol/L), and a chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

Patient Encounter 9

A belligerent, intoxicated 18-year-old man is brought to the ER by police after he was found urinating on a police car as part of a fraternity pledging ritual. Shortly after admission he vomits a large volume of emesis that reeks of beer. He immediately develops coughing, some stridorous upper airway sounds, and complains of shortness of breath. Auscultation of his lungs demonstrates coarse rhonchi throughout. He is urgently transferred to the ICU where he is intubated and started on mechanical ventilation for rapidly progressive hypoxemia. His ABG immediately postintubation shows: pH of 7.50, $PaCO_2$ of 20 mm Hg (2.7 kPa), HCO_3^- of 15 mEq/L (mmol/L), sodium concentration of 145 mEq/L (mmol/L), and chloride level of 100 mEq/L (mmol/L).

What is the primary acid–base disorder?

Is there a mixed disorder?

Given the clinical history, what is the most likely explanation for the ABG findings?

The normal UAG ranges from 0 to 5 mEq/L (mmol/L) and represents the presence of unmeasured urinary anions. In metabolic acidosis, the excretion of NH_4^+ and concurrent Cl^- should increase markedly if renal acidification capacity is intact. This results in UAG values from −20 to −50 mEq/L (mmol/L). This occurs because the urinary Cl^- concentration now markedly exceeds the urinary Na^+ and K^+ concentrations. Diagnoses consistent with an excessively negative UAG include proximal (type 2) renal tubular acidosis, diarrhea, or administration of acetazolamide or hydrochloric acid (HCl). Excessively positive values of the UAG suggest a distal (type 1) renal tubular acidosis.

To effectively treat metabolic acidosis, the *causative process* must be identified and treated.[18] The precise role of adjunctive therapy with sodium bicarbonate ($NaHCO_3$) is not universally agreed upon. However, most practitioners accept that $NaHCO_3$ is indicated when renal dysfunction precludes adequate regeneration of HCO_3^- or when severe acidemia (pH < 7.15) is present.[19] The metabolic acidosis seen with lactic acidosis and ketoacidosis generally resolves with therapy targeted at the underlying cause, and $NaHCO_3$ may be unnecessary regardless of the pH. The metabolic acidosis of renal failure, renal tubular acidosis, or intoxication with ethylene glycol, methanol, or salicylates is much more likely to require $NaHCO_3$ therapy.

If $NaHCO_3$ is used, the plasma HCO_3^- should not be corrected entirely. Instead, aim at increasing HCO_3^- above an absolute value of 10 mEq/L (mmol/L). The total HCO_3^- deficit can be calculated from the current bicarbonate concentration ($HCO_3^-{}_{\text{curr}}$), the desired bicarbonate concentration ($HCO_3^-{}_{\text{post}}$), and the body weight (in kilograms) as follows:

$$\begin{aligned} HCO_3^- \text{ deficit} &= [(2.4/HCO_3^-{}_{\text{curr}}) + 0.4] \times \text{weight} \\ &\quad \times (HCO_3^-{}_{\text{curr}} - HCO_3^-{}_{\text{post}}). \end{aligned}$$

No more than half of the calculated HCO_3^- deficit should be given initially to avoid volume overload, hypernatremia, hyperosmolarity, overshoot alkalemia, hypocalcemia, and/or hypokalemia. The calculated HCO_3^- deficit reflects only the present situation and does not account for ongoing H+ production and HCO_3^- loss. When giving HCO_3^- therapy, serial blood gases are needed to monitor therapy.

Historically, another option for patients with severe acidemia has been tromethamine (tris-hydroxymethyl aminomethane or THAM).[20] This inert amino alcohol buffers acids and CO_2 through its amine ($-NH_2$) moiety:

$$\text{THAM} - NH_2 + H^+ = \text{THAM} - NH_3^+$$
$$\text{THAM} - NH_2 + H_2O + CO_2 = \text{THAM} - NH_3^+ + HCO_3^-$$

Protonated THAM (with Cl^- or HCO_3^-) is excreted in the urine at a rate that is slightly higher than creatinine clearance. As such, THAM augments the buffering capacity of the blood without generating excess CO_2. THAM is less effective in patients with renal failure, and toxicities may include hyperkalemia, hypoglycemia, and possible respiratory depression. THAM is particularly useful in patients with volume overload because it does not contain sodium.

THAM is often administered as an empiric dose of 18 g (150 mEq [mmol]) in 500 mL water via slow IV infusion. Additional infusions are given as dictated by the severity and progression of acidosis. Unfortunately, the only US manufacturer of THAM discontinued its production in 2016, and no future production is anticipated.

Chronic metabolic acidosis can successfully be managed using potassium citrate/citric acid (Polycitra-K, Cytra-K) or sodium citrate/citric acid (Bicitra, Oracit).

Table 29–5

Common Causes of Metabolic Alkalosis

Urine Cl^- < 10 mEq/L (mmol/L)	Urine Cl^- > 10 mEq/L (mmol/L)
Alkali administration	Drugs[a]
IV bicarbonate therapy	Corticosteroid therapy
Oral alkali therapy	Diuretics
Parenteral nutrition with acetate	Hypokalemia
“Contraction alkalosis” postdiuretic use	Mineralocorticoid excess
Decreased chloride intake	Hyperaldosteronism
Loss of gastric acid	Bartter’s syndrome
Vomiting	Cushing’s syndrome
Nasogastric suction	
Posthypercapnia	
Villous adenomas (some)	

[a] May be observed with therapeutic doses or overdoses.

Metabolic Alkalosis

Metabolic alkalosis is characterized by an increased arterial pH, a primary increase in the HCO_3^- concentration, and a compensatory increase in the $PaCO_2$. Patients will always hypoventilate to compensate for metabolic alkalosis—even if it results in profound hypoxemia. For a metabolic alkalosis to persist, there must concurrently be a process that elevates serum HCO_3^- concentration (gastric or renal loss of acids) and another that impairs renal HCO_3^- excretion (hypovolemia, hypokalemia, or mineralocorticoid excess). The etiologies of metabolic alkalosis are listed in Table 29–5.

Patients with metabolic alkalosis rarely have symptoms attributable to alkalemia. Rather, complaints are usually related to volume depletion (muscle cramps, positional dizziness, weakness) or to hypokalemia (muscle weakness, polyuria, polydipsia).

To effectively treat metabolic alkalosis, the *causative process* must be identified and treated. The major causes of metabolic alkalosis are often readily apparent after carefully reviewing the patient’s history and medication list. In hospitalized patients, always look for administration of compounds such as citrate in blood products and acetate in parenteral nutrition that can raise the HCO_3^- concentration. If the etiology of the metabolic alkalosis is still unclear, measurement of the urinary chloride may be useful. Some processes leading to metabolic alkalosis (eg, vomiting, nasogastric suction losses, factitious diarrhea) will have low urinary Cl^- concentrations (< 25 mEq/L [mmol/L]) and are likely to respond to administration of saline. Other causes (eg, diuretics, hypokalemia, and mineralocorticoid excess) will have higher urinary Cl^- concentrations (> 40 mEq/L [mmol/L]) and are less likely to correct with saline infusion.

In general, contributing factors such as diuretics, naso-gastric suction, and corticosteroids should be discontinued if possible. Any fluid deficits should be treated with IV normal saline. Again, patients with metabolic alkalosis and high urine Cl^- (while relatively uncommon) are generally resistant to saline loading. Potassium supplementation should always be given if it is also deficient.

In patients with mild or moderate alkalosis who require ongoing diuresis but have rising HCO_3^- concentrations, the carbonic anhydrase inhibitor acetazolamide can be used to reduce the HCO_3^- concentration. Acetazolamide is typically dosed at 250 mg every 6 to 12 hours as needed to maintain the pH in a clinically acceptable range. This agent results in gradual changes in the serum HCO_3^- and is not used to acutely correct a patient’s acid–base status. If alkalosis is profound and potentially life threatening (due to seizures or ventricular tachyarrhythmias), hemodialysis or transient HCl infusion can be considered. The hydrogen ion deficit (in mEq or mmol) can be estimated from the current serum bicarbonate concentration ($HCO_3^-{}_{curr}$), the desired bicarbonate concentration ($HCO_3^-{}_{post}$), and the body weight (in kg) as follows:

$$H^+ \text{ deficit} = 0.4 \times \text{weight} \times (HCO_3^-{}_{curr} - HCO_3^-{}_{post}).$$

After estimating the H^+ deficit, 0.1 to 0.2 N hydrochloric acid (HCl) is infused at 20 to 50 mEq/h (mmol/h) into a central vein. Arterial pH must be monitored at least hourly and the infusion stopped as soon as clinically feasible. Ammonium chloride and arginine hydrochloride, agents that result in the formation of HCl, are not commonly prescribed because they may lead to significant toxicity. Ammonium chloride may cause accumulation of ammonia leading to encephalopathy while arginine hydrochloride can induce life-threatening hyperkalemia through unclear mechanisms.

Respiratory Acidosis

Respiratory acidosis is characterized by a reduced arterial pH, a primary increase in the arterial $PaCO_2$ and, when present for sufficient time, a compensatory rise in the HCO_3^- concentration. Because increased CO_2 is a potent respiratory stimulus, respiratory acidosis represents ventilatory failure or impaired central control of ventilation as opposed to an increase in CO_2 production. As such, most patients will have hypoxemia in addition to hypercapnia. The most common etiologies of respiratory acidosis are listed in Table 29–6.

Table 29–6

Common Causes of Respiratory Acidosis

- CNS disease
  - Brainstem lesions
  - Central sleep apnea
  - Infection
  - Intracranial hypertension
  - Trauma
  - Tumor
  - Vascular
- Drugs[a]
  - Aminoglycosides
  - Anesthetics
  - β-Blockers
  - Botulism toxin
  - Hypnotics
  - Narcotics
  - Neuromuscular blocking agents
  - Organophosphates
  - Sedatives
- Neuromuscular disease
  - Guillain-Barré syndrome
  - Muscular dystrophy
  - Myasthenia gravis
  - Polymyositis
- Pulmonary disease
  - Lower airway obstruction
  - Foreign body
  - Status asthmaticus
  - Chronic obstructive pulmonary disease
- Pneumonia
- Pneumonitis
- Pulmonary edema
- Restrictive lung disease
  - Ascites
  - Chest wall disorder
  - Fibrothorax
  - Kyphoscoliosis
  - Obesity
  - Pleural effusion
  - Pneumoconiosis
  - Pneumothorax
  - Progressive systemic sclerosis
  - Pulmonary fibrosis
  - Spinal arthritis
- Smoke inhalation
- Upper airway obstruction
  - Foreign body
  - Laryngospasm
  - Obstructive sleep apnea
- Others
  - Abdominal distention
  - Altered metabolic rate
  - Congestive heart failure
  - Hypokalemia
  - Hypothyroidism
  - Inadequate mechanical ventilation

[a] May be observed with therapeutic doses or overdoses.

Severe, acute respiratory acidosis produces a variety of neurologic abnormalities. Initially these include headache, blurred vision, restlessness, and anxiety. These may progress to tremors, asterixis, somnolence, and/or delirium. If untreated, terminal manifestations include peripheral vasodilation leading to hypotension and cardiac arrhythmias. Chronic respiratory acidosis is typically associated with cor pulmonale and peripheral edema.

To effectively treat respiratory acidosis, the *causative process* must be identified and treated. If a cause is identified, specific therapy should be started. This may include naloxone for opiate-induced hypoventilation or bronchodilator therapy for acute bronchospasm. Because respiratory acidosis represents ventilatory failure, an increase in alveolar ventilation is required. This can often be achieved by controlling the underlying disease (eg, bronchodilators and corticosteroids in asthma) and/or physically augmenting ventilation.

Although their precise role and mechanisms of action are unclear, agents such as medroxyprogesterone, theophylline, and doxapram stimulate respiration and have been used to treat mild-to-moderate respiratory acidosis. Of these, only doxapram is approved by the FDA for this indication. Doxapram is administered IV, typically 0.5 to 1 mg/kg repeated every five minutes to a maximum dose of 3 g per 24 hours. Patients given doxapram require monitoring of their blood pressure, pulse, and deep tendon reflexes as this drug can cause cardiac excitation and spasticity. Moderate or severe respiratory acidosis requires assisted ventilation. This can be provided to spontaneously breathing patients via bilevel positive airway pressure (BiPAP) delivered via a tight-fitting mask or by intubation followed by mechanical ventilation. In mechanically ventilated patients, respiratory acidosis is treated by increasing the minute ventilation. This is achieved by increasing the respiratory rate and/or tidal volume.

As with the treatment of metabolic acidosis, the role of $NaHCO_3$ therapy is not well defined for respiratory acidosis. Realize that administration of $NaHCO_3$ can paradoxically result in increased CO_2 generation ($HCO_3^- + H^+ \rightarrow H_2O + CO_2$) and worsened acidemia. Careful monitoring of the pH is required if $NaHCO_3$ therapy is started for this indication. The use of tromethamine in respiratory acidosis (see Metabolic Acidosis section earlier) has unproven safety and benefit.

The goals of therapy in patients with chronic respiratory acidosis are to maintain oxygenation and improve alveolar ventilation if possible. Because of the presence of metabolic compensation, it is usually not necessary to treat the pH, even in patients with severe hypercapnia. Although the specific treatment varies with the underlying disease, excessive oxygen and sedatives should be avoided because they can worsen CO_2 retention.

Respiratory Alkalosis

Respiratory alkalosis is characterized by an increased arterial pH, a primary decrease in the arterial $PaCO_2$ and, when present for sufficient time, a compensatory fall in the HCO_3^- concentration. Respiratory alkalosis represents hyperventilation and is remarkably common. The most common etiologies of respiratory alkalosis are listed in Table 29–7 and range from benign (anxiety) to life threatening (pulmonary embolism). Some causes of hyperventilation and respiratory acidosis are remarkably common (hypoxemia or anemia).

The symptoms produced by respiratory alkalosis result from increased irritability of the central and peripheral nervous systems. These include light-headedness, altered consciousness,

  - Early restrictive lung disease
  - Infection
  - Pneumothorax
  - Pulmonary edema
  - Pulmonary embolism
- Tissue hypoxia
  - Burn injury
  - Excessive mechanical ventilation
  - Fever
  - Hepatic failure
  - Hypoxemia
  - Pain
  - Postmetabolic acidosis
  - Pregnancy
  - Severe anemia
  - Thyrotoxicosis

[a] May be observed with therapeutic doses or overdoses.

distal extremity paresthesias, circumoral paresthesia, cramps, carpopedal spasms, and syncope. Various supraventricular and ventricular cardiac arrhythmias may occur in extreme cases, particularly in critically ill patients. An additional finding in many patients with severe respiratory alkalosis is hypophosphatemia, reflecting a shift of phosphate from the extracellular space into the cells. Chronic respiratory alkalosis is generally asymptomatic.

It is imperative to identify serious causes of respiratory alkalosis and institute effective treatment. In spontaneously breathing patients, respiratory alkalosis is typically only mild or moderate in severity and no specific therapy is indicated. Severe alkalosis generally represents respiratory alkalosis imposed on metabolic alkalosis and may improve with sedation or rebreathing maneuvers (rebreathing mask, paper bag). Patients receiving mechanical ventilation are treated with reduced minute ventilation achieved by decreasing the respiratory rate and/or tidal volume. If the alkalosis persists in the ventilated patient, high-level sedation or paralysis is effective.

SUMMARY

Acid–base disturbances are common clinical problems that are not difficult to analyze if approached in a consistent manner. The pH, $PaCO_2$, and HCO_3^- should be inspected to identify all abnormal values. This should lead to an assessment of which deviations represent the primary abnormality and which represent compensatory changes. The serum electrolytes should always be used to calculate the anion gap. In cases in which the anion gap is increased, the excess anion gap should be added back to the measured HCO_3^-. The anion gap and the excess gap are useful tools that can identify hidden disorders. This rigorous assessment of the patient's acid–base status, incorporated with the available clinical data, increases the likelihood that the clinician will successfully determine the cause of each identified disorder. Although supportive therapy is often required for profound acid–base disturbances, definitive therapy must target the underlying process that has led to the observed derangements.

Patient Care Process

Collect Information

- Every patient with a suspected acid–base disturbance should have an arterial blood gas and a serum chemistry panel drawn concurrently.
- Review each patient's history, physical examination, and current medication list for clues regarding potential causes of the observed acid–base disorder.

Assess the Information

- The results of the arterial blood gas and serum chemistry should be reviewed using a systematic approach to ensure proper interpretation.
- What is/are the primary disorder(s)?
- Has compensation occurred?
- Is the anion gap excessively large?
- If the anion gap is abnormal, does calculation of the excess gap identify another acid–base disorder?

Develop a Care Plan

- Because all acid–base abnormalities result from underlying disease processes, an explanation for each acid-base disorder is necessary.
- Definitive therapy for acid-base disturbances requires treatment of the underlying illness that has disrupted the pH equilibrium.

Implement the Care Plan

- The severity of the acid-base disorder(s) dictates the proper site of care.
- Medications causing and/or contributing to the observed acid-base disorder should be withheld.

Follow-up: Monitor and Evaluate

- Continuous cardiovascular and hemodynamic monitoring should be used for significant pH disturbances because the most serious sequelae of acid–base disorders include electrolyte abnormalities, cardiac dysrhythmias, and hypotension.
- Serial arterial blood gases and serum chemistries should be compared because every patient's acid–base status is continuously changing based on the underlying disease state and any therapy initiated.

LIST OF ABBREVIATIONS

ABG	Arterial blood gas
BiPAP	Bilevel positive airway pressure
Cl^-	Chloride ion
CO2	Carbon dioxide
Δ(delta)	Change
ER	Emergency room
H^+	Hydrogen ion
HCl	Hydrochloric acid
HCO_3^-	Bicarbonate
$HCO_{3\ curr}^-$	Current bicarbonate
$HCO_{3\ post}^-$	Posttherapy bicarbonate
Hg	Mercury
K^+	Potassium ion

Na^+	Sodium ion
$NaHCO_3$	Sodium bicarbonate
NH_2	Terminal amine group
NH_4^+	Ammonium
pH	Logarithm of the hydrogen ion concentration
$PaCO_2$	Partial pressure of arterial carbon dioxide
tCO_2	Total venous carbon dioxide
THAM	Tromethamine
UAG	Urine anion gap

Alzheimer Disease

Megan J. Ehret and Kevin W. Chamberlin

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology of Alzheimer disease (AD) and its effects on society.
2. Describe the pathophysiology, including genetic and environmental factors that may be associated with AD.
3. Detail the clinical presentation of the typical patient with AD.
4. Describe the clinical course of the disease and typical patient outcomes.
5. Explain how nonpharmacologic therapy is combined with pharmacologic therapy for patients with AD.
6. Recognize and recommend treatment options for disease-specific symptoms as well as behavioral/noncognitive symptoms associated with AD.
7. Educate patients and/or caregivers about the expected outcomes for patients with AD and provide contact information for support/advocacy agencies.

INTRODUCTION

KEY CONCEPT Alzheimer disease (AD) is characterized by progressive cognitive decline, including memory loss, disorientation, and impaired judgment and learning. There is no single symptom unique to AD; therefore, diagnosis typically relies on a thorough patient history. The exact pathophysiologic mechanism underlying AD is not entirely known, although certain genetic and environmental factors may be associated with the disease. There is no cure for AD; however, drug treatment can slow symptom progression.

Family members of AD patients can be profoundly affected by the increased dependence of their loved ones as the disease progresses. Advocacy organizations, such as the Alzheimer's Association, can provide early education and social support for both the patient and family. The Alzheimer's Association has developed a list of common warning signs, which include memory loss, difficulty completing familiar tasks, disorientation, problems with word finding, misplacing things, impaired judgment, social withdrawal, and changes in mood.[1]

EPIDEMIOLOGY AND ETIOLOGY

AD is the most common type of dementia, affecting an estimated 5.8 million Americans in 2020.[2] Eighty percent are of age 75 or older. Additional classifications of dementia include dementia of the Alzheimer type, vascular dementia, and dementia due to human immunodeficiency virus (HIV) disease, head trauma, Parkinson disease, Huntington disease, Pick disease, or Creutzfeldt–Jakob disease.[3] This chapter addresses only Alzheimer-type dementia.

The prevalence of AD increases with age. Three percent of people aged 65 to 74, 17% of people aged 75 to 84, and 32% of people aged 85 and older have AD.[2] It is projected that by 2050, the number of people aged 65 and older with AD is projected to reach 13.8 million.[2] The severity of AD also correlates with increasing age and is classified as mild, moderate, or severe. Other risk factors for AD include family history, female gender, and vascular risk factors such as diabetes, hypertension, heart disease, and current smoking.[4] It is unknown how factors such as the environment contribute and interact with the genetic predisposition for AD.

The mean survival time of persons with AD is approximately 4 to 8 years from symptom onset. However, age at diagnosis, severity of AD, and other medical conditions affect survival time.[5] Although AD does not directly cause death, it is associated with an increase in risk factors that often contribute to death, such as senility, sepsis, stroke, pneumonia, dehydration, and decubitus ulcers.[5]

The etiology of AD is unknown; however, genetic factors may contribute to errors in protein synthesis resulting in the formation of abnormal proteins, which contribute to pathogenesis.[6] Early onset (AD prior to age 60) accounts for approximately 1% of all AD. This type is usually familial and follows an autosomal dominant pattern in approximately 50% of cases. Mutations in three genes, presenilin 1 on chromosome 14, amyloid precursor protein (APP) on chromosome 21, and presenilin 2 on chromosome 1 lead to an increase in the accumulation of amyloid beta (Aβ) in the brain, resulting in oxidative stress, neuronal destruction, and the clinical syndrome of AD.[7,8]

In late-onset AD, genetic susceptibility is more sporadic, and it may be more dependent on environmental factors.[6] The apolipoprotein E (apo E) gene on chromosome 19 has been identified as a strong risk factor for late-onset AD. Of the three variants of apo E, carriers of two or more of the apo E4 allele have an earlier onset of AD (~6 years earlier) compared with noncarriers.[6] Only 50% of AD patients have the apo E4 allele, thus indicating it is only a susceptibility marker.

PATHOPHYSIOLOGY

KEY CONCEPT Pathologic hallmarks of the disease in the brain include neurofibrillary tangles (NFTs) (made up of abnormally phosphorylated tau [τ] protein) and neuritic plaques (primarily composed of insoluble forms of Aβ). Accumulation of these toxic forms results in neurodegeneration. In early stages of the disease, neurodegeneration of areas responsible for cholinergic transmission results in a cholinergic deficit. As the disease progresses, widespread neurodegeneration causes an imbalance in all neurotransmitter systems. These are primarily located in brain regions involved in learning, memory, and emotional behaviors such as the hippocampus within the medial temporal lobe of the cerebral cortex, basal forebrain, and amygdala.[9]

Tangles

NFTs interfere with neuronal function, and their presence has been correlated with the severity of dementia.[10] Unfortunately, NFTs are insoluble even after cell death, and they cannot be removed once established; thus, prevention is the key. The neurons that provide most of the cholinergic innervation to the cortex are prominently affected.[11]

Plaques

The Aβ protein is present in neuritic plaques in a nontoxic, soluble form in human brains. In AD, conformational changes occur that render it insoluble and cause it to deposit into amorphous diffuse plaques associated with dystrophic neuritis.[12] Over time, these deposits become compacted into plaques, and the Aβ protein becomes fibrillary and neurotoxic. Inflammation occurs secondary to clusters of astrocytes and microglia surrounding these plaques.

Acetylcholine

In AD, the plaques and tangles damage acetylcholine (Ach) pathways, leading to a shortage of Ach and learning and memory impairment.[13] The basis of current pharmacologic treatment of AD has been to improve cholinergic neurotransmission in the brain. Blocking acetylcholinesterase, the enzyme that degrades Ach in the synaptic cleft, leads to an increased level of Ach with a goal of stabilizing neurotransmission.[13] This process is flawed as cholinergic cell loss appears to be a secondary consequence of AD pathology and not the disease-producing event. Cholinergic neurons are only one of the many neuronal pathways affected in AD.

Glutamate

Glutamate is the primary excitatory neurotransmitter in the central nervous system; it is involved in memory, learning, and neuronal plasticity. It affects cognition through facilitation of connections with cholinergic neurons in the cerebral cortex and basal forebrain.[14] In AD, one type of glutamate receptor, *N*-methyl-D-aspartate (NMDA), is less prevalent than normal. There also appears to be overactivation of unregulated glutamate signaling. This results in a rise in calcium ions that induce secondary cascades, which lead to neuronal death and an increased production of APP.[13] The increased production of APP is associated with higher rates of plaque development and hyperphosphorylation of τ protein.[14] Current treatment of AD includes selective inhibition of NMDA receptor–mediated excitotoxicity.

Cholesterol

Increased cholesterol concentrations have also been associated with AD. Cholesterol increases β-amyloid protein synthesis, which can lead to plaque formation.[13] Also, the apo E4 allele is thought to be involved in cholesterol metabolism and is associated with higher cholesterol levels.[13]

Clinical Presentation and Diagnosis of Alzheimer Disease

General

The diagnosis of AD is primarily made by medical and psychiatric history, neurological examination, formal memory testing, interview of caregivers and family members, and laboratory and imaging data.

Signs and Symptoms

- Cognitive, which occur gradually: memory loss, problems with language, disorientation to time and place, poor or decreased judgment, problems with learning and abstract thinking, misplacing things
- Noncognitive: Changes in mood, behavior, personality, or loss of initiative
- Functional: Difficulty performing familiar tasks

Tests

- Neuropsychological tests such as the Folstein Mini-Mental State Examination (MMSE) or the Montreal Cognitive Assessment (MoCA)
- MRI, PET scan, or CT to measure changes in brain size and volume in the medial temporal lobe/hippocampus and rule out stroke, brain tumor, or cerebral edema

Laboratory Tests

- Tests to exclude possible causes of dementia: depression screen, vitamin B_{12} and folate levels, thyroid function tests (thyroid-stimulating hormone and free triiodothyronine and thyroxine), complete blood count, and chemistry panel[17]
- Other diagnostic tests to consider for differential diagnosis: erythrocyte sedimentation rate, urinalysis, toxicology, chest X-ray, heavy metal screen, HIV testing, and cerebrospinal fluid (CSF) examination

Cerebrovascular Pathologies

Cerebrovascular pathologies are common pathologies with age-related cognitive decline along with AD pathologies. Although criteria are still being evaluated to understand the levels of cerebrovascular pathologies that contribute to cognitive impairment, epidemiological studies have found that the presence of vascular and metabolic risk factors during midlife is most strongly associated with the risk of cognitive impairment and dementia.[15] Studies have found that antihypertensive treatment can be beneficial in reducing the risk of dementia.[16] Longitudinal studies are needed to study the evolution of cerebrovascular pathologies in those at higher risk of cardiovascular disease starting at midlife.

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT The diagnosis of AD is established following an extensive history and physical examination and by ruling out other potential causes of dementia. Molecular imaging with positron emission tomography (PET) tracers can help identify patients with high levels of amyloid protein (ie, florbetapir, flutemetamol, and florbetaben) and tau neurofibrillary tangles (ie, flortaucipir).[17]

Table 30–1

DSM-5 Diagnostic Criteria for Major Neurocognitive Disorders

- A. Evidence of significant cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual motor, or social cognition) is based on:
  1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a significant decline in cognitive function and
  2. A substantial impairment in cognitive performance, preferably documented by standardized neuropsychological testing or, in its absence, another quantified clinical assessment
- B. Cognitive deficits interfere with independence in everyday activities
- C. Cognitive deficits do not occur exclusively in the context of delirium
- D. Cognitive deficits are not better explained by another mental disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed, Washington, DC: American Psychiatric Association; 2013:602–603, with permission.

Further research is needed to improve brain imaging, CSF, and other AD biomarkers for routine clinical diagnostic use. The clinical presentation and diagnosis of AD are based on history, signs and symptoms, and laboratory and/or imaging tests.

AD is a progressive disease that, over time, affects multiple areas of cognition. The American Psychiatric Association has published criteria for AD in the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*). See Tables 30–1, 30–2, and 30–3 for full criteria.[3]

Clinical Course and Typical Patient Outcomes

AD has a gradual onset and is slowly progressive, with episodic memory, executive function, visuospatial function, and

Table 30–2

DSM-5 Diagnostic Criteria for Mild Neurocognitive Disorder

- A. Evidence of modest cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual motor, or social cognition) is based on:
  1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a mild decline in cognitive function and
  2. A modest impairment in cognitive performance, preferably documented by standardized neuropsychological testing, or in its absence, another quantified clinical assessment
- B. Cognitive deficits do not interfere with the capacity for independence in everyday activities
- C. Cognitive deficits do not occur exclusively in the context of delirium
- D. Cognitive deficits are not better explained by another mental disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed, Washington, DC: American Psychiatric Association; 2013:605; with permission.

Table 30–3

DSM-5 Diagnostic Criteria for Major or Mild Neurocognitive Disorder Due to Alzheimer Disease

- A. Criteria are met for major or mild neurocognitive disorder
- B. Insidious onset and gradual progression of impairment in one or more cognitive domains (for major neurocognitive disorder, at least two domains must be impaired)
- C. Criteria are met for either probable or possible Alzheimer disease as follows:
  For Major Neurocognitive Disorder:
  Probable Alzheimer disease: diagnosed if either of the following is present; otherwise possible Alzheimer disease should be diagnosed.
  1. Evidence of a causative Alzheimer disease genetic mutation from family history or genetic testing
  2. All three of the following are present:
     - a. Clear evidence of decline in memory and learning and at least one other cognitive domain
     - b. Steadily progressive gradual decline in cognition, without extended plateaus
     - c. No evidence of mixed etiology

  For Mild Neurocognitive Disorder:
  Probable Alzheimer disease: diagnosed if there is evidence of a causative Alzheimer disease genetic mutation from either genetic testing or family history
  Possible Alzheimer disease: diagnosed if there is no evidence of a causative Alzheimer disease genetic mutation from either genetic testing or family history, and all three of the following are present:
  1. Clear evidence of decline in memory and learning
  2. Steadily progressive, gradual decline in cognition, without extended plateaus
  3. No evidence of mixed etiology
- D. Disturbance is not better explained by cerebrovascular disease, another neurodegenerative disease, the effects of a substance, or another mental, neurological, or systematic disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed. Washington, DC: American Psychiatric Association; 2013:611; with permission.

Patient Encounter Part 1

A man presents at the clinic with his 75-year-old mother complaining that his mother's memory is worsening. He complains that his mother is continuing to forget things, including paying the bills and emptying the cat's litter box. Three months ago, she was started on donepezil 5 mg, which was titrated to 10 mg. Her son organizes a weekly pillbox and helps administer the medications. The son asks if there is anything else his mother could take to help her memory.

What education points about Alzheimer disease would you provide to the son?

Where would you recommend the son find more information about Alzheimer disease?

How would you address the son's question regarding the pharmacologic management of his mother's Alzheimer disease?

word-finding difficulties being affected early in the disease course. Impairment in motor, behavioral, and sensory functioning occurs later in the illness. During the final stages, patients are not aware of the events occurring around them and are dependent on others.

TREATMENT

Desired Outcomes

KEY CONCEPT Treatment is focused on delaying disease progression and preservation of functioning as long as possible. Secondary goals include treating psychiatric and behavioral symptoms that may occur during the course of the disease.

General Approach to Treatment

KEY CONCEPT The current gold standard of treatment for cognitive symptoms includes pharmacologic management with an acetylcholinesterase (AChE) inhibitor and/or an NMDA antagonist. There are four agents approved for the treatment of AD, but none are curative or known to directly reverse the disease process; donepezil, rivastigmine, galantamine, and memantine.

Treatment of AD includes education, communication, and planning with the patient's family/caregiver. Treatment options, legal and financial decisions, and course of the illness should be discussed with the patient and family members. The clinician's emphasis should be on helping to maintain a therapeutic living environment while minimizing the burden of care resulting from the disease.

Nonpharmacologic Therapy

The life of a patient with AD must become progressively more simple and structured as the disease progresses, and the caregiver must learn to keep requests and demands on the patient simple. Basic principles in the treatment of patients with AD are shown in Table 30–4.

Pharmacologic Therapy

▶ *Conventional Pharmacologic Treatment for Cognitive Symptoms*

AChE Inhibitors (Donepezil, Rivastigmine, and Galantamine)

Guidelines recommend the use of AChE inhibitors as a valuable treatment for AD.[18] The few head-to-head studies comparing the AChE inhibitors conclude that there are no major differences in clinical outcomes. The selection of one AChE inhibitor over another should be based on differences in mechanisms of action, adverse reactions, titration schedules, potential drug interactions, and patient and caregiver preference.[10,18] AChE inhibitors provide only a modest benefit that should be communicated to the patient and caregiver. Doses of AChE should be titrated to limit adverse effects but high enough to achieve maximum potential benefit.

Table 30–4

Basic Principles in the Management of Patients with AD

- Use a gentle, calm approach to the patient
- Provide reassurance when needed
- Empathy with the patient's concerns
- Use distraction and redirection
- Maintain daily routines
- Provide a safe environment
- Provide daytime activities
- Avoid overstimulation
- Use familiar decorative items in the living area
- Bring abrupt declines in function and the appearance of new symptoms to professional attention

Table 30–5

Treatment Algorithm for Cognitive Symptoms of AD

1. Patient diagnosed with AD
2. Assess all comorbid medical disorders and medication therapies that may affect cognition
3. Rule out comorbid depression
4. Evaluate for pharmacotherapy based on illness stage
   a. Mild AD: Acetylcholinesterase inhibitor
   b. Moderate-to-severe AD: Acetylcholinesterase inhibitor, memantine, or combination acetylcholinesterase inhibitor and memantine
5. Deteriorating Mini-Mental State Examination (MMSE) score > 2–4 points after 1 year: Change to a different acetylcholinesterase inhibitor
6. Stable MMSE: Continue regimen
7. Treat behavioral/noncognitive symptoms associated with AD as they arise

AD, Alzheimer disease.

Data From: Rabins PV, Rovner BW, Rummans T, Schneider LS, Tariot PN. American Psychiatric Association Guideline Watch (October 2014): Practice Guideline for the Treatment of Patients with Alzheimer's Disease and Other Dementias. Washington, DC: American Psychiatric Press; 2014.

Treatment should begin as early as possible after diagnosis.[10,18] Table 30–5 provides a recommended treatment algorithm. Patients should be switched to another AChE inhibitor from their initial AChE inhibitor if they show an initial lack of efficacy, initially respond but then lose clinical benefit, or experience safety/tolerability issues. This switch should not be attempted until the patient has been on a maximally tolerated dose for 3 to 6 months. The switch should also be based on realistic expectations of the patient and/or caregiver.[10,18] Mixed recommendations exist regarding AChE inhibitor discontinuation. There is some data to suggest continuation versus stopping treatment in moderate-to-severe dementia, but the long-term adverse effects of AChE inhibitor therapy need to be considered as well (ie, anorexia, weight loss, falls, hip fractures, syncope, bradycardia, increased use of cardiac pacemakers).[19] Beneficial effects of AChE inhibitor therapy can be found if a patient's dementia appears to be progressing slowly and should be continued as long as the patient or caregiver is willing to continue, adherence to the treatment is maintained, there are no comorbidities to offset the medication, adverse effects are monitored, and the patient has not progressed to a severely impaired stage.[20] Abrupt discontinuation should be avoided as this can worsen cognitive impairment.

Donepezil Donepezil is a piperidine AChE inhibitor that reversibly and noncompetitively inhibits centrally active acetylcholinesterase.[21] A dose of 10 mg/day has demonstrated efficacy in patients with either mild-to-moderate or moderate-to-severe forms of AD, while the 23-mg dose is also approved for patients with moderate-to-severe disease. The 23-mg dose showed a small improvement in cognitive symptoms compared to the

Table 30–6

Dosing Strategies for Cognitive Agents

	Donepezil (Aricept)	Rivastigmine (Exelon)	Galantamine (Razadyne)	Memantine (Namenda, Namenda XR)	Memantine +Donepezil (Namzaric)
Starting dose	5 mg daily in the evening	Oral: 1.5 mg twice daily Patch: 4.6 mg/24 hour applied daily	IR: 4 mg twice daily ER: 8 mg daily in the morning	IR: 5 mg daily ER: 7 mg daily	7 mg/10 mg (if patient is stabilized on donepezil and not currently on memantine); 28 mg/10 mg (if patient is stabilized on memantine and donepezil)
Maintenance dose	5–23 mg daily	Oral: 3–6 mg twice daily Patch: 9.5 mg/24 hour applied daily	IR: 8–12 mg twice daily ER: 16–24 mg daily	IR: 10 mg twice daily ER: 28 mg daily	28 mg/10 mg daily
Time between dose adjustments	4–6 weeks between 5 and 10 mg increment; 3 months between 10 and 23 mg increment	Oral: 2 weeks Patch: 4 weeks	4 weeks	1 week	1 week
Dosage adjustments for renal or hepatic impairment	None	Moderate-to-severe renal impairment, mild-to-moderate hepatic impairment, or low body weight (< 50 kg): consider a maximum dose of 4.6 mg/24 hour (not studied in hepatic impairment)	Do not exceed 16 mg for moderately impaired hepatic or renal function; do not administer in severe renal or hepatic impairment	Severe renal impairment: target maintenance dose of 5 mg twice daily or 14 mg daily	Severe renal impairment: 14 mg/10 mg daily

10 mg/day dose; however, there was no improvement in the overall functioning, and there was a higher incidence of adverse effects.[22] Table 30–6 describes dosing strategies for all of the approved agents for AD. The most frequent adverse effects are mild-to-moderate gastrointestinal symptoms.[21,23–27] Others include headache, dizziness, syncope, bradycardia, and muscle weakness. Table 30–7 compares their major side effects and monitoring parameters.[21,23–27]

Only a small number of drug interactions have been reported with donepezil. Monitoring for increased peripheral side effects is advised when adding a cytochrome P450 (CYP) 2D6 or 3A3/4 inhibitor to donepezil treatment. Also, inducers of CYP2D6 and 3A4 could increase the elimination rate of donepezil.[21]

Rivastigmine Rivastigmine, approved for the treatment of mild-to-moderate AD, has a central activity for both acetylcholinesterase and butyrylcholinesterase, which could potentially lead to broader efficacy.[23]

Rivastigmine is available as an oral formulation and a patch. If the patient is taking less than 6 mg/day orally, the 4.6 mg/24-hour patch is recommended if switching from oral form to the patch. If the patient is taking 6 to 12 mg/day orally, the 9.5 mg/24-hour patch is recommended. The first patch should be applied on the day following the last oral dose.[23]

Cholinergic side effects are common, but they are usually well tolerated if the recommended dosing schedule is followed. If side effects cause intolerance, several doses can be held, and then dosing can be restarted at the same or next lower dose. Drugs that induce or inhibit CYP450 metabolism are not expected to alter rivastigmine metabolism.[23]

Galantamine Galantamine, approved for the treatment of mild-to-moderate AD, is an AChE inhibitor, which elevates Ach in the cerebral cortex.[24] It also modulates the nicotinic Ach receptors to increase Ach release from surviving presynaptic nerve terminals. Galantamine may also increase glutamate and serotonin levels, but whether this brings additional benefit is unknown.

CYP3A4 and 2D6 are the major metabolizing enzymes, and pharmacokinetic studies with inhibitors of these enzymes have shown increased galantamine concentrations or reductions in clearance. Similar to donepezil, if inhibitors are given concurrently with galantamine, increased cholinergic side effects should be monitored.[24]

NMDA Receptor Antagonist Memantine is a noncompetitive antagonist of the NMDA type of glutamate receptors that are located throughout the brain. NMDA receptors regulate activity

Table 30–7

Adverse Effects for Currently Approved Medications for Alzheimer Disease[a]

Adverse Event	Donepezil 5–10 mg/day (%) (n = 747)	Donepezil 23 mg/day (%) (n = 963)	Rivastigmine 6–12 mg/day (%) (n = 1189)	Galantamine IR 16–24 mg/day (%) (n = 2932)	Memantine IR 5–20 mg/day (%) (n = 940)	Memantine XR 28 mg/day (%) (n = 341)

throughout the brain by controlling the amount of calcium that enters the nerve cell, a process essential for establishing an environment required for information storage. Overstimulation of the NMDA receptor by excessive glutamate allows too much calcium into the cell, disrupting information processing. Blocking NMDA receptors with memantine may protect neurons from the effects of excessive glutamate without disrupting normal neurotransmission.[25]

Memantine is approved to treat moderate-to-severe AD. It can be given as monotherapy or in combination with AChE inhibitors. Only the modest benefit can be anticipated with the utilization of memantine. Memantine is not indicated for mild AD, and current evidence does not support its use in mild AD.[28] Adverse reactions associated with memantine include constipation, confusion, dizziness, headache, coughing, and hypertension. Closer monitoring should be done if memantine is given concurrently with an AChE inhibitor.

In vitro studies have shown that memantine produces minimal inhibition of CYP450 enzymes 1A2, 2A6, 2C9, 2D6, 2E1, and 3A4, and that no pharmacokinetic interactions with drugs metabolized by these enzymes should be expected.[25,26]

Future Therapies **KEY CONCEPT** Future therapies for AD may include disease-modifying therapies. Current investigations into future therapies for the treatment of AD include the following:

- Targeting of the etiologic pathologies of AD: neurofibrillary tangles and senile plagques.[29,30]
- Fortifying transcortical networks and enhancing interneuronal connections in order to enhance cognitive function.[31]
- Early identification of the at-risk population and subsequent treatment in the preclinical stage.[32]

▶ *Nonconventional Pharmacologic Treatment*

Nonconventional treatments have historically been used as adjunctive treatments of AD. Vitamin E was previously recommended because of its antioxidant properties, but a meta-analysis suggested that greater than 400 IU/day should be avoided due to an increased all-cause mortality.[33] There is insufficient data supporting efficacy for nonsteroidal anti-inflammatory drugs (NSAIDs); gastritis, GI bleeds, and increased cardiovascular events are associated with their use.[34] Statins (3-hydroxy-3-methylglutaryl-CoA reductase inhibitors) should be reserved for those who have other indications for their use.[35] Until Ginkgo biloba has a more standardized manufacturing process and its long-term safety and efficacy are established, it should be recommended with caution.[36]

The medical food caprylidene (AC-1202, Axona) is a medium chain triglyceride approved for the dietary management of metabolic processes associated with mild-to-moderate AD.[37] Reduced neuronal metabolism of glucose has been associated with AD, and ketone bodies can potentially be used as an alternative energy source for AD patients.[37] Caprylidene is converted by the liver into the ketone body β-hydroxybutyrate (BHB). BHB crosses the blood–brain barrier and can be utilized by neurons as a potential energy source to generate adenosine triphosphate (ATP) and increase pools of Ach.[38] Tramiprosate (homotaurine) demonstrated early promise in the treatment of AD, but phase III trials were disappointing. Homotaurine is naturally occurring in seaweed and is thought to interfere with amyloid plaque formation and subsequent degeneration of neuronal cells.[39]

With the growing body of evidence that brain vascular disease plays a role in the progression of dementia, guidelines support monitoring blood pressure, glucose, cholesterol, and homocysteine, and initiating appropriate interventions.[16] Adherence to the Mediterranean Diet or Dietary Approaches to Stop Hypertension diet may reduce the risk of cognitive impairment or decline.[40] Additionally, physical activity is an important component of vascular brain health and has been shown in some short-term studies to be associated with a reduced risk of cognitive impairment as well.[40]

Patient Encounter Part 2

The patient returns to the clinic in 6 months. She has been on donepezil 10 mg daily and memantine 10 mg twice daily. Her memory symptoms have slowed in their decline, but recently she has been agitated at bedtime and talking to her deceased sister. The son is particularly concerned about the symptoms and wants to know what he could do to help. The patient's record is as follows:

PMH: Diabetes mellitus since age 51 (well controlled until last year when she became confused about when to take her medication); hypertension (treated for 23 years, well controlled, has been hypotensive on a few occasions recently during physicals); osteopenia (last bone mineral density test 12 months ago [T-score = −1.2] on therapy); hypercholesterolemia (last cholesterol panel 12 months ago showed well-controlled levels in normal range, on therapy)

FH: Father died of myocardial infarction at age 76; mother died of breast cancer at age 79

SH: Lives with wheelchair-bound husband; son lives across street and checks in daily; denies drinking alcohol or smoking

Meds: Metformin 500 mg orally twice daily; insulin glargine 18 units subcutaneously at bedtime; hydrochlorothiazide 25 mg orally once daily in the morning; lisinopril 20 mg orally once daily in the morning; calcium carbonate and vitamin D 600 mg/200 international units orally twice daily with lunch and dinner; atorvastatin 10 mg orally once daily with dinner; donepezil 10 mg orally daily and memantine 10 mg orally twice daily

ROS: (+) Weight loss of 6.3 kg (14 lb) since last visit; (−) N/V/D, change in appetite, heartburn, chest pain, or shortness of breath

PE:

VS: BP 111/72 mm Hg supine, P 79 beats/min, RR 16 breaths/min, T 37°C (98.6°F)

Gen: Poorly groomed, thin woman looks as stated age

Neuro: Folstein Mini-Mental State Examination score 20/30 (suggestive of moderate dementia) and MoCA score 18/30 (suggestive of moderate dementia); disoriented to month, date, and day of week, clinic name and floor; poor registration with impaired attention and short-term memory; good language skills but problems with commands

CT Scan: Mild-to-moderate generalized cerebral atrophy

What do you recommend with regard to her current donepezil and memantine treatment?

What nonpharmacologic and pharmacologic interventions could be recommended for the agitation and psychosis?

Treatment of Behavioral Symptoms

KEY CONCEPT Treatment of behavioral symptoms should not only begin with nonpharmacologic treatments but may also include antipsychotic agents and/or antidepressants. Nonpharmacologic recommendations for treatment include the following[41]:

- Music
- Videotapes of family members
- Audiotapes of the voices of caregivers
- Walking and light exercise
- Sensory stimulation and relaxation

Clinical trials have reported a modest benefit in managing behavioral symptoms with AChE inhibitors and memantine, although the long-term benefits have not been demonstrated to date. Antipsychotics are also frequently used for neuropsychiatric symptoms associated with AD. A meta-analysis concluded that only 17% to 18% of dementia patients demonstrated treatment response to atypical antipsychotics.[42] A double-blind, placebo-controlled trial of olanzapine, quetiapine, or risperidone for the treatment of psychosis, aggression, or agitation in patients with AD showed that adverse effects outweigh the benefits of atypical antipsychotics.[43]

In April 2005, the US Food and Drug Administration (FDA) issued a statement requiring black box warnings on all antipsychotics stating that elderly people with dementia-related psychosis treated with an antipsychotic are at an increased risk of death compared with those treated with placebo.[44] Fifteen of 17 trials investigating olanzapine, aripiprazole, quetiapine, or risperidone in elderly demented patients with behavioral disorders showed an increase in mortality compared with the placebo-treated groups (1.6–1.7 times increased risk of death). Causes for these deaths were heart-related events (heart failure and sudden death) and infections (mostly pneumonia).[44] Readers are referred to Chapter 38 for additional information on antipsychotics.

Antipsychotics are not approved for the treatment of elderly patients with dementia-related psychosis. Therefore, it is important to individually assess and balance the risk versus benefit of antipsychotic use in this population. Both the American Society of Consultant Pharmacists and the American Psychiatric Association have published statements regarding the use of antipsychotics to treat agitation and psychosis in dementia.[45,46]

Depressive symptoms occur in as many as 50% of patients with AD and can be difficult to differentiate from symptoms of dementia. Symptoms of depression should be documented for several weeks prior to initiating therapy for depression with AD.[7] The selective serotonin reuptake inhibitors are most commonly used based on their side-effect profile and evidence of efficacy.[7] Indications for the use of antidepressants include depression characterized by poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, and agitation.[7] Readers are referred to Chapter 39 for more information on antidepressants.

Other miscellaneous therapies for AD include benzodiazepines for anxiety, agitation, and aggression. However, their routine use is not advised because of the increase in falls.[7] Mood stabilizer anticonvulsants, carbamazepine, valproic acid, or gabapentin may be used as alternatives, but the current evidence is conflicting.[47] Buspirone has shown benefit in treating agitation and aggression in a limited number of patients with minimal adverse effects.[48] In open-label and controlled studies, selegiline decreased anxiety, depression, and agitation, although monoamine oxidase inhibitors are not typically well tolerated.[49] Finally, trazodone has been shown to decrease insomnia, agitation, and dysphoria, and it has been used to treat sundowning in AD patients.

Patient Encounter Part 3

The patient returns to the clinic for follow-up 6 months later. Her son states her memory has progressed significantly. Her current MoCA score is now 14/30. The addition of risperidone 0.5 mg at bedtime helped with her agitation, but she has significant symptoms that appear late in the afternoon on most days, especially if they have visitors to the house. Recently, she went outside and wandered off the property resulting in a brief police search to find and return her home. Her son would like to know if there are any other choices to help treat his mom.

What changes to the patient's current medications would you recommend?

GENOMICS

KEY CONCEPT At this time, there are no specific recommendations regarding the choice of medications or dosing regimens for the current treatments for AD based on genotype or other biomarkers.

OUTCOME EVALUATION

- The success of therapy is measured by the degree to which the care plan decreases the pretreatment rate of cognitive deterioration, preserves the patients' functioning, and treats psychiatric and behavioral symptoms. The primary outcome measure is thus subjective information from the patient and the caregiver, although the MMSE or MoCA can be a helpful tool. There are no physical examinations or laboratory parameters to evaluate the success of therapy.
- Develop a plan to assess the effectiveness of the AChE inhibitor in slowing the deterioration of cognitive functioning after an appropriate interval (every 3–6 months).
- Assess improvement in quality-of-life measures such as ability to function independently and for slowing of memory deterioration (every 3–6 months).
- Evaluate functional performance, mood, and behaviors.
- Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions at appropriate intervals (soon after drug initiation or change and every 3–6 months).

CONCLUSION

AD is a progressive deterioration of cognitive abilities, often accompanied by behavioral disturbances and personality changes in the later stages of the disease. In an effort to help prepare patients and their caregivers for the inevitable, the Alzheimer's Association has developed 10 quick tips on "Living with Alzheimer's disease," and they can also provide many resources for patients and caregivers. Access the association at:

Alzheimer's Association

Contact Center: 1-800-272-3900

Patient Care Process

Collect Information:

- Assess the type, frequency, and duration of cognitive and noncognitive symptoms.
- Review any available diagnostic data from the medical and psychiatric history, including interviews from family, neuropsychologic testing, CT, PET, and MRI, and other labs (ie, vitamin deficiencies, thyroid function tests, complete blood counts, and chemistry panel).
- Obtain a thorough history of prescription, nonprescription, and natural drug product use.
- Identify allergies to medications and other substances.

Assess the Information:

- Determine whether the patient has any other disease state (ie, depression) or is taking any medication that could contribute to cognitive changes in the elderly.
- Document current cognitive and noncognitive symptoms present in the patient.
- Assess the current pharmacotherapy regimen for appropriateness, effectiveness, adverse effects, drug interactions, appropriate dosing, and medication adherence (see Table 30–7).

Develop a Care Plan:

- Select an appropriate AChE inhibitor to avoid drug–drug interactions and adverse effects and in consideration of cost and patient preference (see Tables 30–6 and 30–7).
- Develop a plan to monitor cognitive response to treatment over time.
- Select appropriate medications for behavior symptoms if lifestyle modifications do not achieve goals.

Implement the Care Plan:

- Provide patients and caregivers information about lifestyle modification and refer them to support when needed.
- Be a resource and give continuous support to the patients and caregivers throughout the long course of the disease.
- Educate patients and caregivers on what to expect from pharmacotherapy.

Follow-up: Monitor and Evaluate:

- Follow up at needed intervals to assess effectiveness and safety of therapy. Review medical history and physical examination findings, lab tests, and results of other diagnostic tests.
- Monitor pharmacotherapy initiation (see Table 30–6) and regularly evaluate the patient for the presence of adverse drug reactions, drug allergies, drug–drug and drug–disease interactions, and adherence.
- If symptoms progress, consider stopping/switching the AChE inhibitor. Switch if there is initial lack of efficacy, loss of clinical benefit, or if poor tolerability develops. Discontinue if there is poor adherence, persistent adverse effects, or development to severe stage of the illness.
- Continue to offer support to the patient and caregiver.

Multiple Sclerosis

Sarah Rajkovic and Jacquelyn L. Bainbridge

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for multiple sclerosis (MS).
2. Distinguish between phenotypes of MS based on patient presentation and disease course.
3. Compare and contrast choice of disease-modifying therapies (DMT) for a given patient.
4. Determine appropriate symptomatic treatment options for a given patient.
5. Develop a monitoring plan for a patient initiated on a specific DMT.

INTRODUCTION

Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS) characterized by myelin destruction and axonal damage. *Multiple* describes the numerous CNS lesions that accrue over time, and *sclerosis* refers to the demyelination of lesions, also called plaques.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

MS is the most common progressive neurologic disease, affecting approximately 2.3 million people worldwide.[1] Diagnosis usually occurs between 20 and 50 years of age, impacting at least twice as many women as men.[1] People of northern European ancestry are more likely to develop MS and the geographical risk increases with increasing distance (north or south) from the equator.[2]

Etiology

The cause of MS is unknown, but may be due to a combination of genetic, environmental, immunologic, or infectious factors. Genetic risks may explain up to 35% of cases.[2] Environmental theories involve infectious exposures (eg, Epstein–Barr Virus), decreased patient or maternal vitamin D serum concentrations, tobacco use, residence at high latitude, and childhood obesity.[2,3]

PATHOPHYSIOLOGY

While the causative agent of MS is unclear, the result is the development of an autoimmune disorder with areas of CNS inflammation and degeneration.

Inflammation

An unknown antigen presented by the major histocompatibility complex (MHC) class II molecules causes T cells to become autoreactive (Figure 31–1). Autoreactive T cells enter lymphatic tissues to expand. Upon a signal involving sphingosine-1-phosphate, T cells reenter the circulation.[4] Once activated, T cells cause blood–brain barrier breakdown and enter the CNS. These T cells come into contact with antigen-presenting cells (APCs) and proliferate and differentiate. Th1 cells secrete cytokines that enhance macrophage and microglial cells that attack myelin.[4]

B cells cross damaged sections of the blood–brain barrier where autoreactive T cells trigger B cells to form myelin autoantibodies. These inflammatory processes are the likely cause of relapses.[4]

Degeneration

Axonal injury and transection disrupts normal nerve signaling. Growing evidence suggests cytotoxic T cells cause axonal injury early in disease.[4] Axonal loss is likely responsible for MS progression.[4]

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis

Clinically isolated syndrome (CIS) is a focal demyelinating event in the CNS, often optic neuritis or myelopathy, in a patient not known to have MS.[5] CIS has approximately 60% rate of conversion to clinically definite MS over 4 years.[6] This clinically definite MS (CDMS) diagnosis is made when dissemination in time and space is demonstrated. Diagnosis requires 1 year of disease progression and two of the following: dissemination in space on MRI of the brain, dissemination in space on MRI of the spinal cord, or positive cerebrospinal fluid (CSF).[7] The use of MRI is critical in the diagnosis of MS as they can help identify T2-hyperintensive lesions in four areas of the CNS, which include cortical, juxtacortical, infratentorial, and spinal cord.[8] An example of MRI findings of patients with MS can be seen in Figure 31–2.

KEY CONCEPT The 2017 McDonald criteria is used to evaluate for the presence of dissemination in time by more than one clinical attack and dissemination in space by the presence of lesions at a different or multiple site(s) in the CNS, such as multiple areas in the brain or spinal cord.[7] Evidence from magnetic resonance imaging (MRI) and/or oligoclonal immunoglobulin G bands can help fulfill these time and space criteria and facilitate earlier diagnosis and treatment (Figure 31–3).[7] **KEY CONCEPT** MS is classified into relapsing and progressive disease (Figure 31–4).

FIGURE 31–1. Autoimmune theory of the pathogenesis of multiple sclerosis (MS). In MS, the immunogenic cells tend to be more myelin reactive, and these T cells produce cytokines mimicking a Th1-mediated proinflammatory reaction. T-helper cells (CD4$^+$) appear to be key initiators of myelin destruction in MS. These autoreactive CD4$^+$ cells, especially of the T-helper cell type 1 (Th1) subtype, are activated in the periphery, perhaps following a viral infection. The activation of T and B cells requires two signals. The first signal is the interaction between MHC and APC (macrophage, dendritic cell, and B cell). The second signal consists of the binding between B7 on the APC and CD28 on the T cell for T-cell activation. Similarly, CD40 expressed on APCs and CD40L expressed on T cells interact to signal the proliferation of B cells within the blood–brain barrier following the entry to T cells. The T cells in the periphery express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood–brain barrier. The activated T cells also produce MMP that help to create openings in the blood–brain barrier, allowing entry of the activated T cells past the blood–brain barrier and into the CNS. Once inside the CNS, the T cells produce proinflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor-α (TNF-α), and interferon-γ (INF-γ), which further create openings in the blood–brain barrier, allowing entry of B cells, complement, macrophages, and antibodies. The T cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing the production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and transforming growth factor-β (TGF-β) also has been described. These cytokines are the products of CD4$^+$, CD8$^+$, and Th1-cells. New pathogenic mechanisms involve, but are not limited to, receptor-ligand–mediated T-cell entry via choroid plexus (CCR6-CCL20 axis), coupling of key receptor-ligands for inhibition of myelination/demyelination (LINGO-1/NOGO66/p75 or TROY complex, Jagged-Notch signaling). New York, NY: McGraw-Hill; 2017, with permission.)

Relapsing-remitting MS (RRMS) is the most common type of MS, affecting about 85% of patients, where patients will experience periods of relapse (exacerbation) followed by periods of remission. It is important to note that even during remission, there is still neuronal damage occurring even without symptoms present. Patients with RRMS can eventually move to a more progressive form of MS, called secondary progressive MS (SPMS).

Clinical Presentation of MS[10,11]

MS symptoms depend on the location of lesions within the CNS and thus can be nonspecific. Myelin increases the speed of nerve impulse transmission; demyelination slows the speed. No impulses can be transmitted if the axon is transected. The primary symptoms of MS are caused by this delay or cessation of impulses. The secondary symptoms of MS result as a complication from the primary symptoms.

Primary Symptoms	Frequency of Occurrence (%)	Related Secondary Symptoms
Urinary incontinence or retention	70	Decubitus ulcers Urinary tract infections
Spasticity	70–80	Falls, care difficulties, pain, gait problems
Optic neuritis	70	Falls, care difficulties
Bowel incontinence or constipation	39–73	Decubitus ulcers Pain
Depression	50	Suicide
Anxiety	36	
Cognitive deficits	43–70	Decline in work or social performance, care difficulties
Fatigue	92	Effects on employment and social roles

Sexual dysfunction		
Erectile dysfunction	50–90	
Female sexual dysfunction	40–85	
Tremor	80	Inability to perform activities of daily living
Pain	86	
Trigeminal neuralgia	15	
Lhermitte sign	4–5	
Dysesthetic pain	14–29	
Impaired gait	64	Inability to perform activities of daily living

Progressive forms of MS are more difficult to diagnose because there are often no overt clinical attacks, rather, patients continue to decline in the Expanded Disability Status Scale (EDSS). For patients who present initially with a progressive onset, this is called primary progressive MS (PPMS). Progressive MS can further be categorized as active versus not active and progressing versus not progressing, which assists in guiding therapy decisions. MS is the most common cause of young adult disability (impaired walking, fine motor movements, sight, cognitive dysfunction, mood disorders, pain) and reduces life expectancy by 10 to 12 years. Early diagnosis and treatment (within first 5 years) is an important clinical consideration to prevent disease progression and disability in order to maintain the quality of life across the patient life span.[9]

TREATMENT

Desired Outcomes and General Approach to Treatment

The goal of treatment is preventing permanent neurologic damage and disability progression. There are three approaches to treatment. **KEY CONCEPT** First, treat acute relapses with corticosteroids to reduce inflammation and speed recovery. **KEY CONCEPT** Second, early initiation of disease-modifying therapies (DMT) decreases the number of annual relapses, prevents permanent neurologic damage, and prevents progression of disability. **KEY CONCEPT** Third, symptomatic treatments can be added to treat common primary symptoms such as pain and spasticity, depression, cognitive dysfunction, and urinary symptoms.

FIGURE 31–3. The 2017 McDonald Criteria for the Diagnosis of MS.[9] An attack is defined as a patient-reported or objectively observed event typical of an acute inflammatory demyelinating event in the CNS with a duration of at least 24 hours in the absence of fever or infection. MRI evidence of dissemination over time is a new T2-weighted lesion after the initial clinical event or the simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time.[a] Dissemination in space by MRI evidence of one or more T2-weighted lesions in at least two of the following areas: periventricular, juxtacortical, infratentorial, spinal cord.

Pharmacologic Treatment

▶ *Treatment of Acute Relapses with Corticosteroids*

Pharmacology and Mechanism of Action Corticosteroids prevent inflammatory cytokine activation, inhibit T- and B-cell activation, and prevent immune cells from entering the CNS.[12] Corticosteroids hasten functional recovery.[12] Equivalence of IV and oral dosage forms has been demonstrated.[13]

Adverse Effects The most common adverse effects are taste change, flushing, gastrointestinal upset, insomnia, and mood disturbance.[14] Since patients are only on this regimen for a few days, adverse effects are usually mild and tolerated well.

Dosing and Administration Methylprednisolone is given 1000 mg/day IV or orally as one daily dose for 3 to 5 days.[13] Oral prednisone 1250 mg/day provides an equivalent dose. Recovery

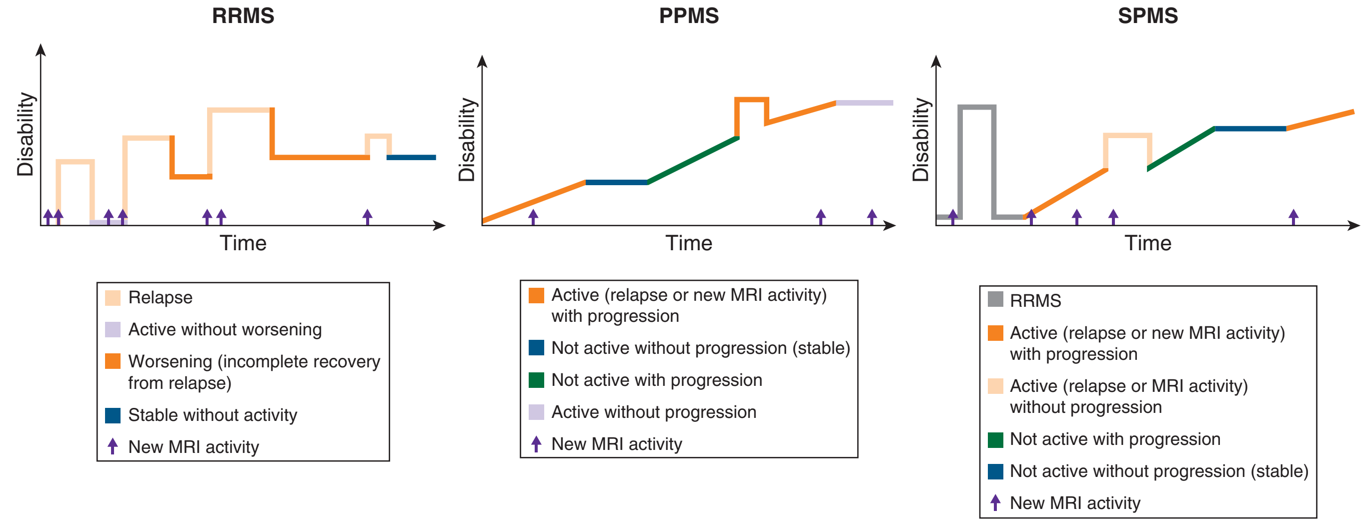

FIGURE 31–4. Clinical phenotypic patterns of MS disease course over time.[7]

Patient Encounter, Part 1

A 26-year-old Caucasian woman with a history of migraines presents to her primary care physician with complaints of decreased sensation and tingling in both of her hands that developed over several hours. She describes the tingling as “pins and needles” that did not resolve with movement. Over the last 2 to 3 years, she has had periodic changes in her visual acuity that resolve spontaneously over weeks and are not related to her typical migraine episodes. She also reports recently quitting her part-time summer job as a dog walker due to frequent loss of balance leading to multiple falls.

What information is suggestive of multiple sclerosis (MS)?

What risk factors does she have for MS?

What additional information or testing would assist in making the diagnosis of MS?

What treatment could be provided to her for the current acute event?

is equivalent with or without a subsequent oral corticosteroid taper.[15]

▶ Outcome Evaluation

- Monitor for symptom improvement
- Educate regarding adverse effects

Disease-Modifying Therapies

Agents indicated for MS are shown in Table 31–1. These DMTs can reduce annualized relapse rates (ARRs) from 30% to 70%.[16–43] Almost all agents are indicated for relapsing forms of MS to include RRMS and active SPMS, and some may be used for the treatment of CIS. **KEY CONCEPT** There is no consensus on the best medication for initial therapy due to the diverse clinical presentation, so treatment must be individualized to each patient. Figure 31–5 suggests a treatment approach.

▶ β-Interferons

Pharmacology and Mechanism of Action β-Interferons decrease T cell activation, thereby decreasing cytokine secretion, which prevents upregulation of adhesion molecules on activated T cells, limits T cells’ access to the CNS, and suppresses matrix metalloproteinases (MMPs), thereby maintaining the integrity of the blood–brain barrier. β-Interferons also decrease microglial proliferation, which helps to preserve myelin, promotes formation of Th2 cells rather than Th1 cells, decreases inflammation, and increases neural growth factor production. All of these mechanisms assist in CNS repair.[16]

Efficacy in Patients with Relapsing-Remitting MS (RRMS) β-Interferons reduce relapses by about one-third versus placebo.[16] CIS treatment with β-interferons resulted in fewer patients converting to CDMS compared with placebo.[16]

Efficacy in Patients with Secondary Progressive MS Who Experience Relapses β-Interferons reduce the risk of relapses but do not slow progression.[17] Treatment is most effective if clinical relapses or MRI inflammatory activity are present.[17]

Adverse Effects Adverse effects are common with β-interferons (Table 31–1). Flu-like symptoms (fever, fatigue, muscle aches, malaise, and chills) begin a few hours postinjection and dissipate within 24 hours.[18] Injection site reactions range from redness to necrosis. There are preventive and treatment measures for these reactions (Table 31–2). Because of conflicting data, it is difficult to determine if β-interferons cause depression; however, providers should monitor and assess for depression because patients with MS do commonly develop depression during the course of the disease (Table 31–3).[18] In a patient who presents with depression, another DMT should be selected to avoid worsening the patient’s condition. Antibodies to beta-interferons can reduce therapeutic effects of these DMT.[16] Neutralizing antibodies develop 6 to 18 months after initiation, can form against any β-interferon, and are cross-reactive.[16,18] There are no standardized recommendations for neutralizing antibody testing.[16]

▶ Glatiramer Acetate

Pharmacology and Mechanism of Action Glatiramer acetate binds to MHC class II, blocking the activation of T cells and activating Th2 cells, preventing inflammation. Activated Th2 cells secrete brain-derived neurotrophic factor, which may be neuroprotective.[20]

Efficacy Glatiramer acetate reduces relapses by 28% compared with placebo but does not prevent sustained progression of RRMS.[21] It is used in CIS to prevent conversion to CDMS.[20]

Adverse Effects Patients report experiencing injection site reactions, including lipoatrophy (see Table 31–2). Icing the injection site pre- and postinjection and/or topical anesthetics mitigate these reactions. A postinjection reaction may yield a systemic effect (flushing, chest tightness, palpitations, anxiety, and shortness of breath). If this occurs, it is self-limited to approximately 15 minutes, close in time to the injection, and recurrence is infrequent. Doses may be reduced by 75% for the week following the reaction, then increased by 25% per week to the full dose.[18]

▶ Teriflunomide

Pharmacology and Mechanism of Action Teriflunomide has a cytostatic effect on rapidly dividing B and T cells by inhibiting *de novo* pyrimidine synthesis and inhibits T-cell activation, entry to the CNS, and secretion of proinflammatory cytokines.[22]

Pharmacokinetics Half-life of oral teriflunomide is 2 weeks, taking about 3 months to achieve steady-state concentrations. An accelerated elimination process with cholestyramine or activated charcoal is available if needed (such as detection of a serious infection or liver injury). Teriflunomide inhibits CYP2C8 and induces CYP1A2 and CYP2C9 enzymes.

Efficacy Teriflunomide reduces relapse rate and progression of disease for relapsing forms of MS.[21] It also prevents CIS from converting to clinically definite MS.[23]

Adverse Effects Teriflunomide is fairly well tolerated, however requires a medication guide due to rare, but serious, adverse effects, including hepatotoxicity, skin reactions, peripheral neuropathy, infections, and teratogenicity.[22]

▶ Fumaric Acid Derivatives

Pharmacology and Mechanism of Action Dimethyl fumarate and diroximel fumarate are prodrugs that undergo metabolism to the same active metabolite, monomethyl fumarate.[24] As of May 2020, monomethyl fumarate is also available and does not require metabolism to the active metabolite. These drugs shift cytokine production from a proinflammatory state to an anti-inflammatory state, prevent macrophage entry into the CNS by an unknown mechanism, and stabilize transcription factor nuclear (erythroid-derived 2)-related factor which may reduce oxidative stress.[25]

Table 31–1

Disease-Modifying Therapies

Drug	Indications	Dose	Route	Frequency	Selected Adverse Effects	Black Box Warnings
Interferons						
Interferon β-1a (Avonex)	CIS RRMS	Initial 7.5 mcg for 1 week, then 15 mcg for 1 week, then 22.5 mg for 1 week, then 30 mcg	IM	Weekly	Flu-like symptoms 61% Anemia 8% Neutralizing antibody formation 2%–18.9%	None
Interferon β-1a (Rebif)	CIS RRMS	22 mcg or 44 mcg Initial 20% increase over 4 weeks to final dose	SQ	Three times/ week	Flu-like symptoms 28% Injection site reactions 66% Leukopenia 22% AST/ALT elevation 17%–27% Neutralizing antibody formation 16.5%–35.4%	None
Interferon β-1b (Betaseron, Extavia)	CIS RRMS	Initial 0.0625 mg, increase over 6 weeks to 0.25 mg	SQ	Every other day	Flu-like symptoms 60%–76% Injection site reactions 50%–85% Asthenia 49% Menstrual disorder 17% Leukopenia 10%–16% AST/ALT elevation 4%–19% Neutralizing antibody formation 27.3%–53.3%	None
Peginterferon β-1a (Plegridy)	RRMS	Initial 63 mcg, 94 mcg day 15, 125 mcg day 29	SQ	Every 2 weeks	Injection site reactions 62% Flu-like symptoms 47% Neutralizing antibody formation < 1%	None
Other Agents						
Glatiramer acetate (Copaxone, Glatopa)	CIS	20 mg	SQ	Daily	Injection site reaction 90% Chest reaction 15% Alopecia 61% Menstrual disorders 61% Urinary tract infection 32% Leukopenia 19% GGT elevation 15% Injection site atrophy 2%	None
	RRMS	40 mg (Copaxone only)	SQ	Three times/ week		
Cladribine (Mavenclad)	Relapsing forms of MS Active SPMS	Course 1: 1.75 mg/kg divided into two cycles given 23–27 days apart Course 2: 1.75 mg/kg divided into two cycles given 23–27 days apart	PO	Course 1: once Course 2: once at least 43 weeks after completing course 1	Upper respiratory tract infection 38% Headache 25% Lymphopenia 24% Nausea 10% Arthralgia/arthritis 7% Insomnia 6%	Malignancies Teratogenicity
Teriflunomide (Aubagio)	Relapsing forms of MS CIS	7 or 14 mg	PO	Daily	AST elevation 12%–14% Alopecia 10%–13% Diarrhea 15%–18% Decreased white blood cell and platelet counts 10%–15%	Hepatotoxicity Teratogenicity
Fumarates						
Dimethyl fumarate (Tecfidera)	Relapsing forms of MS CIS	Initial 120 mg for 1 week, then 240 mg	PO	Twice daily	Flushing 30% Gastrointestinal effects 25% Leucopenia/lymphopenia 4%–10% Influenza viral infections 13% Diarrhea 12% Cough 10% Bradycardia 4%	None

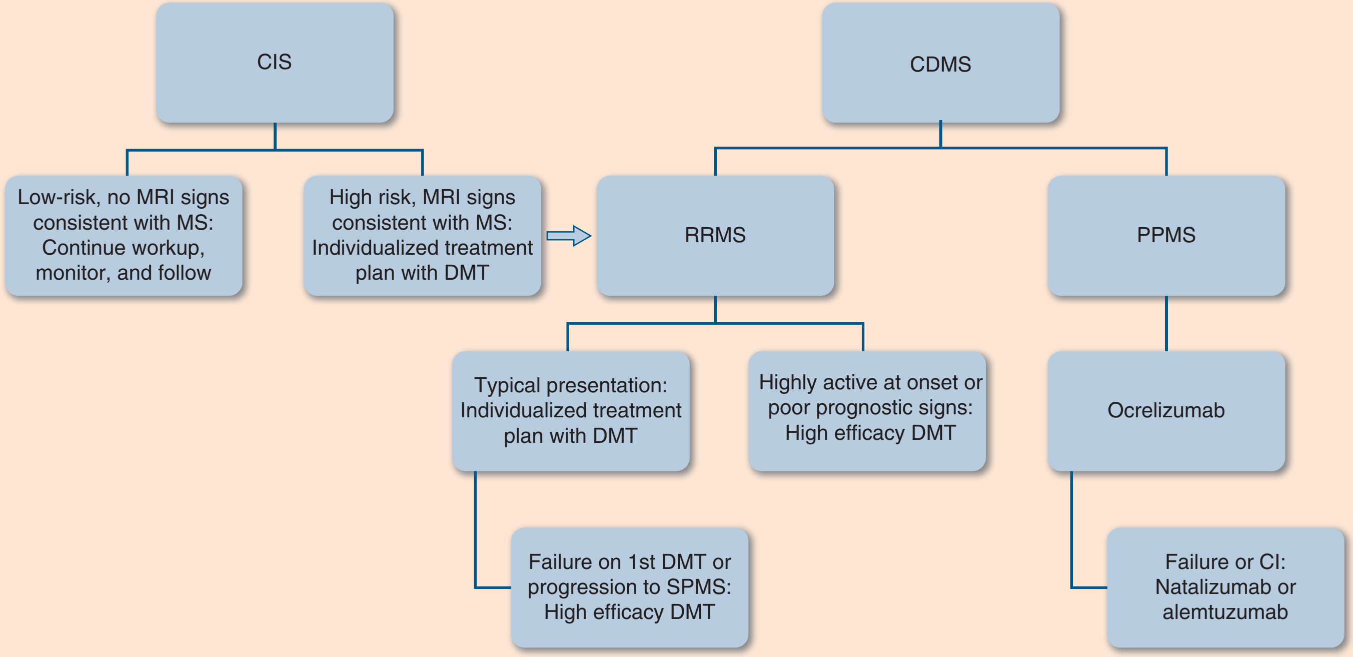
[a] Considered highly efficacious agents.

Data from References [18,19,26,27,30,33,37,49].



CIS
CDMS
Low-risk, no MRI signs consistent with MS: Continue workup, monitor, and follow
High risk, MRI signs consistent with MS: Individualized treatment plan with DMT
RRMS
PPMS
Typical presentation: Individualized treatment plan with DMT
Highly active at onset or poor prognostic signs: High efficacy DMT
Ocrelizumab
Failure on 1st DMT or progression to SPMS: High efficacy DMT
Failure or CI: Natalizumab or alemtuzumab

Abbreviations: CIS=clinically isolated syndrome; CDMS=clinically definite multiple sclerosis; MRI=magnetic resonance imaging; MS=multiple sclerosis; DMT=disease modifying therapy; RRMS=relapsing-remitting multiple sclerosis; SPMS=secondary progressive multiple sclerosis; PPMS=primary progressive multiple sclerosis; CI=contraindication

Definitions:

- Individualized treatment plan with DMT=patient factors such as age, gender, comorbidities, lifestyle, activity level of disease, preference on administration method, safety parameters, presence of JC virus antibody and insurance coverage should all be taken into consideration to determine the best therapeutic option for each individual patient when starting DMT therapy.
- Highly active disease=onset with significant disabling symptoms, poor recovery from relapses, recurrent or breakthrough disease over short period of time, significant MRI findings, or rapid progression to disability.
- High efficacy DMTs=monoclonal antibodies (natalizumab, ocrelizumab, alemtuzumab), fingolimod and cladribine.
- Poor prognostic signs=age above 40 years, male gender, African American, motor/sphincter/brainstem/cerebellar symptoms, MRI lesions on brainstem or spinal cord, 2 or more relapses in the first 2 years of onset with significant disability sustained following relapses.

FIGURE 31–5. Treatment algorithm for CIS and MS.[38] A definition of highly active MS has been proposed as follows: two or more relapses in the preceding year and two or more gadolinium-enhancing lesions on brain MRI scans or a significant T2 lesion burden.[39] There can also be poor recovery between relapses, rapid progression to disability, certain patient characteristics (age≥ 40, male gender, African American, lesions on brain stem and spinal cord), significant recurrent or breakthrough disease in a short-time period, and onset of disease accompanied with disability.[9]

Efficacy Dimethyl fumarate reduced relapses approximately 50% compared to placebo. It slowed RRMS progression in some studies.[25] Data from pharmacokinetic studies comparing dimethyl fumarate and diroximel fumarate were used to confirm the similar efficacy of both drugs.[26] The efficacy of monomethyl fumarate was based on bioavailability studies in healthy patients, which compared dimethyl fumarate to monomethyl fumarate.[27]

Adverse Effects Dimethyl fumarate causes a transient, dose-dependent flushing sometimes with itching that is likely due to histamine release. The incidence of this reaction decreases after the first month and may be improved by slower dose titration, administration with food, and/or H2-blocking antihistamines.[25] Gastrointestinal adverse effects may be lessened with a slow dose increase and administration with food but is the main reason for discontinuation in patients taking dimethyl fumarate.[25] Diroximel fumarate and monomethyl fumarate had lower incidences of gastrointestinal adverse effects compared to dimethyl fumarate.[27,28]

▶ *Sphingosine 1-Phosphate Receptor Modulators*

Pharmacology and Mechanism of Action Fingolimod, siponimod, and ozanimod are sphingosine 1-phosphate (S1P) receptor modulators. They retain T cells in lymphoid tissues, deplete peripheral blood and CNS lymphocytes, and reduce inflammatory cytokines.[24] The specific receptor subtypes affected by each agent differentiates their adverse effect profiles. Fingolimod modulates S1P1, S1P3, S1P4, and S1P5 and siponimod and ozanimod offer more selectivity by modulating S1P1 and S1P5.[29–31]

Pharmacokinetics Fingolimod has a half-life of 8 to 9 days (steady-state concentrations achieved in 1–2 months).[29] Siponimod's shorter half-life of 30 hours results in steady-state concentrations within 6 to 7 days.[32] Ozanimod has an active metabolite that extends its half-life to approximately 11 days.[24]

Efficacy Treatment with fingolimod reduced the ARR to 0.18 compared with 0.40 for placebo. It also slowed RRMS progression.[29] Siponimod reduced the number of active lesions on MRI scans and reduced the ARR compared to placebo at 24 months, with maximal improvement in outcomes occurring in patients receiving higher doses.[32] In phase 3 clinical trials, ozanimod reduced ARR and number of active lesions when compared with interferon β.[31]

Adverse Effects S1P receptor modulators target circulating lymphocytes, leading to an increased risk of infections and

Table 31–2

β-Interferon Adverse Effects Prevention or Treatment Strategies

Flu-Like Symptoms	Injection Site Reaction
Inject dose in the evening	Bring medication to room temperature
Begin at 1/4 dose for 2 weeks of treatment, then increase by 25% every 2 weeks to full dose	Ice injection site before and after injection
	Rotate injection sites
Use ibuprofen 200 mg or acetaminophen 325–650 mg before and between 6 and 12 hours after injection	Inject in buttocks or abdomen
	Use an autoinjection device
	If severe, use hydrocortisone 1% cream
	If necrotic, temporarily discontinue; consult dermatologist; do not use topical corticosteroids

Table 31–3

Monitoring Disease-Modifying Therapies

Therapy	Tests	Frequency
All therapies	EDSS, MSFC, neurologic examination	Baseline, every 3 months for 2 years; then every 6 months
β-Interferons	CBC with differential, bilirubin, electrolytes, AST, ALT, GGT, alkaline phosphatase, depression/suicidal ideation	Baseline, 1, 3, and 6 months; then every 3 months
	Thyroid function tests	Baseline and every 6 months in patients with a history of thyroid dysfunction
Cladribine	Hepatitis B and C screening, tuberculosis screening, pregnancy testing, AST, ALT, alkaline phosphatase, and total bilirubin	Baseline
	CBC	Baseline and prior to each infusion; at 2 and 6 months after start of treatment course; then as needed
Teriflunomide	CBC, screen for tuberculosis, pregnancy testing	Baseline
	ALT, AST, bilirubin	Baseline and monthly for first 6 months
	Blood pressure	Baseline; then periodically
Fumaric Acid Derivatives	CBC, ALT, AST, alkaline phosphatase, bilirubin, CYP2C9 genotype (siponimod), first-dose observation	Baseline and every 6 months
S1P Receptor Modulators	Varicella zoster immunity evaluation and/or vaccination and FEV_1, pregnancy test	Baseline
	CBC, ALT, AST, bilirubin	Baseline and every 6 months
	Pulse and blood pressure	Baseline; observe in clinical area for 6 hours after initial dose with hourly monitoring
	Ophthalmology evaluation	Baseline; 3–4 months; then as needed
	Dermatologic evaluation	Baseline; then as needed
	Electrocardiogram	Baseline and 6 hours after initial dose
Natalizumab	HIV, CBC, AST, ALT, MRI	Baseline; repeat MRI at 6 months; then yearly
	MRI, CSF JC virus	Periodically and at the onset of new neurologic symptoms
	Anti-JC virus antibody index	Baseline and every 6 months
Ocrelizumab	Hepatitis B screening	Baseline
	Infection assessment	Prior to every infusion
Ofatumumab	Hepatitis B screening, CBC, serum creatinine, serum immunoglobulins, MRI, signs/symptoms of PML	Baseline and every 6 months or as clinically necessary
Alemtuzumab	Thyroid function	Baseline, every 3 months until 48 months after last infusion
	CBC with differential, serum creatinine, urinalysis with cell counts	Baseline, monthly until 48 months after last infusion
	Varicella zoster immunity evaluation and/or vaccination, tuberculosis screening, hepatitis B and C screening	Baseline
	Vital signs	Baseline, during, and 2 hours after infusion
	Skin examination	Baseline and yearly
Mitoxantrone	CBC, bilirubin, AST, ALT, alkaline phosphatase, pregnancy test	Before each infusion
	Echocardiogram/MUGA scan	Baseline; prior to each infusion, and yearly after stopping mitoxantrone

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; CSF, cerebrospinal fluid; EDSS, Expanded Disability Status Scale; FEV_1, forced expiratory volume in 1 second; GGT, gamma-glutamyl transferase; HIV, human immunodeficiency virus; JC, John Cunningham; MRI, magnetic resonance imaging scan; MSFC, Multiple Sclerosis Functional Composite; MUGA, multiple-gated acquisition scan; S1P, sphingosine 1-phosphate.

Data from References [16,18,20,21,22,25,26,27,29,30,31,33,35,43].

malignancies.[24] Modulation of S1P receptors can cause first-dose bradycardia, although the risk is lower with siponimod and ozanimod because this effect is related to S1P3 and S1P4 receptors located on cardiac tissue. Other adverse effects associated with these drugs include macular edema, hypertension, and reduced forced vital capacity.[29] Use of S1P receptor modulators is contraindicated in patients with myocardial infarctions, unstable angina, stroke, transient ischemic attacks, or some types of congestive heart failure within the last 6 months or in patients with many types of atrioventricular block, prolonged QT interval, or who are taking class Ia or III antiarrhythmic medicines.[29] Siponimod is also contraindicated in patients with a CYP2C9*3/*3 genotype.[30,32] Ozanimod should not be used in individuals with severe sleep apnea or those taking monoamine oxidase inhibitors.[31] Baseline and first-dose monitoring is required (see Table 31–3); monitoring must be repeated if therapy is interrupted.[29] All of these agents require a medication guide when dispensed due to the risk of infection and bradycardia.

▶ *Cladribine*

Pharmacology and Mechanism of Action Cladribine is a deoxyadenosine analog. It reduces circulating lymphocytes by inhibiting DNA synthesis and promoting cell death.[33,34] Maximal lymphocyte reduction occurs approximately 2 to 3 months after each treatment cycle and is dose-dependent.[34]

Efficacy Two courses of oral cladribine lowered the ARR by 58% and prolonged the time to first relapse compared to placebo.[34] Maximum lifetime cumulative dosing is 3.5 mg/kg divided into two treatment courses (1.75 mg/kg per treatment course).

Adverse Effects Due to its safety profile, cladribine requires a medication guide and is recommended as a second-line treatment option and is not recommended for treatment of patients with CIS. Cladribine can increase the risk of malignancy and upper respiratory tract infections, and frequent complete blood count (CBC) monitoring is recommended before, during, and after treatment.[33,34] The most common adverse reactions include lymphopenia, leukopenia, alopecia, and viral upper respiratory tract infection.[34] Prophylaxis for herpes infection should be initiated in patients with lymphocyte counts less than 200 cells/microliter (0.2×10^9/L).[34] Cladribine is contraindicated in pregnant, breastfeeding, and immunosuppressed patients.

▶ *Natalizumab*

Pharmacology and Mechanism of Action Natalizumab is a α_4-integrin antagonist. It binds to $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins, preventing lymphocyte migration into the CNS and inflammation, and inhibits binding of α_4-positive leukocytes to fibronectin and osteopontin, decreasing the activation of leukocytes within the CNS.[35]

Efficacy Treatment with natalizumab reduced relapses in RRMS by 68% at 1 year and disability by 42% at 2 years versus placebo.[35] Natalizumab is considered to be a highly efficacious DMT compared to previously discussed DMTs.

Adverse Effects Hypersensitivity reactions (itching, dizziness, fever, rash, hypotension, dyspnea, chest pain, and anaphylaxis) may occur within 2 hours of administration and requires treatment discontinuation. A separate infusion reaction (headache, dizziness, fatigue, nausea, sweats, and rigors) may occur within 2 hours of dosing.[18] Histamine 1 and 2 receptor blockers prevent these symptoms, and discontinuation is not required. A serious, but rare, adverse effect is progressive multifocal leukoencephalopathy (PML). PML, caused by the John Cunningham (JC) polyomavirus virus, is rapidly progressive and often results in death or permanent disability. Though most associated with natalizumab, PML has been reported in patients treated with dimethyl fumarate, fingolimod, and alemtuzumab.[18] If a clinician decides to treat with any of these agents that carry a risk of PML, there are a few specific recommendations regarding monitoring parameters. Testing for JC virus before initiating therapy to determine serostatus and ongoing monitoring for seroconversion is recommended since JC virus–positive patients have a higher risk of developing PML than JC virus–negative patients. Carefully assess for immune compromise in patients previously treated with immunosuppression, radiation therapy, or chemotherapy as this also increases the risk of developing PML. Other recommendations include using these DMTs as monotherapy (never in combination) and carefully monitor patients for any signs or symptoms of the development of PML and JC virus antibodies.[18,35] Vigilance is paramount because PML can mimic MS symptoms.[35] **KEY CONCEPT** These concerns lead to the recommendation that natalizumab be reserved for patients with a highly active disease course who have failed other therapies and has an accompanying Risk Evaluation and Mitigation Strategy (REMS) known as the TOUCH program. Antinatalizumab antibodies develop in 9% to 12% of patients. If patients have antibodies 6 months after the start of therapy, relapse rates, disability, and hypersensitivity reaction risk increase.[35]

▶ *Alemtuzumab*

Pharmacology and Mechanism of Action Alemtuzumab is a monoclonal antibody that eliminates circulating B and T cells. Repopulation of these cells takes 8 to 35 months.[36]

Efficacy Treatment reduced relapse rates compared to interferon β with 77% of patients relapse free for 2 years.[36] Similar to natalizumab, alemtuzumab is also considered a DMT with higher efficacy.

Adverse Effects Infusion-associated reactions (headache, rash, pyrexia, nausea, itching, and fatigue) occur in more than 90% of patients, requiring pretreatment with methylprednisolone and often antihistamines and antipyretics.[37] Acyclovir cotreatment is required due to the risk of herpesvirus infections. Secondary autoimmune diseases can also develop as well as thyroid disorders.[36] Because of these safety concerns, alemtuzumab has a REMS program and is generally reserved for patients who have failed two therapies. Neutralizing antibodies are present in up to 94% of patients but do not seem to decrease efficacy.

▶ *Anti-CD20 Monoclonal Antibodies*

Pharmacology and Mechanism of Action Ocrelizumab, rituximab, and ofatumumab are monoclonal antibodies that specifically target and deplete B cells.[38] Ocrelizumab is the only drug that is FDA-approved for the treatment of relapsing or primary-progressive MS (PPMS); rituximab is commonly used off-label for MS and ofatumumab is approved for relapsing forms of MS.

Efficacy in Patients with RRMS Rituximab, ocrelizumab, and ofatumumab demonstrated significantly reduced ARR and disease progression in patients compared to placebo.[39–42]

Efficacy in Patients with PPMS Fewer patients had confirmed disability progression when treated with ocrelizumab compared to placebo.[39] Ocrelizumab is the only drug that is FDA-approved for the treatment of PPMS.[39–41] Studies evaluating rituximab did not show clinical benefit in patients with PPMS.

Adverse Effects Infusion reactions (pruritus, rash, erythema, bronchospasm, dyspnea, flushing, hypotension, pyrexia, headache, nausea, and tachycardia) can occur after administration of these medications.[40,41] Premedication with corticosteroids and antihistamines is required, and antipyretics considered before each infusion. Ocrelizumab and ofatumumab are contraindicated in patients with active hepatitis B infections.[41,42] Ocrelizumab has had few cases of PML associated with use but attributed to prior DMT use with higher risk, such as natalizumab.

▸ *Mitoxantrone*

Pharmacology and Mechanism of Action Mitoxantrone is an anthracenedione antineoplastic. It causes apoptosis in T cells and APCs, preventing initial T-cell activation; inhibits DNA and RNA synthesis, decreasing proliferation of T cells, B cells, and macrophages; decreases cytokine release, preventing inflammation; and inhibits macrophages, preventing myelin degradation.[43]

Efficacy Mitoxantrone reduces the relapse rate and attack-related MRI outcome measures and MS progression.[43] **KEY CONCEPT** Because of its potential for significant toxicities, mitoxantrone is reserved for patients with a highly active disease course who have failed in most other therapies.

Adverse Effects Bluish discoloration of the sclera and urine lasts 24 hours or more postinfusion.[18] Amenorrhea may be permanent and lead to infertility.[43] Cardiotoxicity is a serious adverse effect. Mitoxantrone is contraindicated in patients with cardiomyopathy, even if asymptomatic. Cyclooxygenase-2 inhibitors potentially worsen cardiac toxicity and should be avoided.[43] Maximum lifetime dose of mitoxantrone is 140 mg/m^2.

▸ *Issues with Self-Injected Disease-Modifying Therapies*

Adherence **KEY CONCEPT** Adherence to injectable medications is a significant problem, with 22% to 59% discontinuation. Providing realistic therapy expectations, higher educational levels and better patient injection techniques improve adherence. However, depression and cognitive problems lower adherence of β-interferon DMTs and may warrant a switch to another DMT.[46]

Patient Education Refer to Table 31–4 for patient self-injection education.

Table 31–4

Self-Injection Patient Education

Keep supplies together and out of reach of children/pets
Allow medication to warm to room temperature
Wash hands
Choose injection site, rotating among sites
Ice area (≤ 15 minutes) prior to injection, if desired
Clean site with alcohol or soap/water
Administer injection
Ice site (≤ 15 minutes) after injection, if desired

▸ *Other Therapy Considerations*

Pregnancy Because MS affects women of childbearing age, the teratogenicity potential of many DMTs can be concerning for patients and healthcare practitioners alike. Although none of the DMTs are specifically recommended for use during pregnancy, pregnancy registry analysis demonstrates minimal adverse outcomes with interferon β, glatiramer acetate, and natalizumab (first two trimesters only).[47] S1P receptors are important in fetal formation; thus, these medications should be discontinued for at least 2 months before conception. Mitoxantrone, cladribine, and teriflunomide are teratogenic and therefore contraindicated during pregnancy. Teriflunomide is contraindicated for men who have sexual intercourse with women who may become pregnant.[47] Because of the long half-life of teriflunomide, the accelerated elimination process is recommended for women who wish to become pregnant.[47] The risks and benefits of continuing a DMT throughout pregnancy should be weighed carefully. Pregnancy is considered to have a protective effect for the mother and may lower the risk of relapses during this time. If a patient is still at high risk of relapsing, one of the DMTs discussed above may be considered to continue throughout pregnancy. During the postnatal stage, the risk will return for mother, and the DMT should be reinitiated.

Vaccinations In general, patients taking DMT should avoid receiving live or live-attenuated virus vaccines.[48] Vaccines may be

Patient Encounter, Part 2

PMH: She has had periodic changes in her visual acuity that resolve spontaneously over weeks and previously experienced an acute episode of decreased sensation and tingling in both of her hands requiring corticosteroids. She also reports recently quitting her part-time job as a dog walker due to frequent loss of balance leading to multiple falls.

FH: Mother with trigeminal neuralgia; father alive and well

SH: Elementary school teacher. Married and actively trying to have children. She smokes one pack/day. She does not drink alcohol or use illicit drugs.

Allergies: Shellfish

Meds: None

ROS: (–) HA, SOB, chest pain, cough

PE:

VS: 122/76, P 76, RR 20, T 36°C (96.8°F)

Skin: Warm, dry

HEENT: Right pupillary response to light is sluggish, decreased visual acuity right eye

CV: RRR, normal S1 and S2, no m/r/g

Chest: CTA

Abd: Soft, NT/ND

Neuro: A & O × 3; CN II-XII intact

Motor: Paresthesia to touch and decreased pin sensation in bilateral upper extremities. Tandem gait mildly unstable

Labs: WNL

Imaging: T2-weighted MRI shows two enhancing T2-weighted lesions in left cortex and a nonenhancing T2-weighted lesion on the right optic nerve

less effective while on several disease-modifying therapies so they should be given 6 weeks before therapy starts. Vaccines should be held for 4 to 6 weeks after DMT dose.[48] See Table 31–3 for specific viral monitoring parameters and potential vaccines required prior to initiation with certain DMTs.

▶ *Outcome Evaluation*

- Assess symptom changes periodically (every 3–12 months).
- In β-interferon-treated patients with frequent relapses, test for neutralizing antibodies and consider switching therapy.[49]
- Monitor medication-specific adverse effects (see Tables 31–1 and 31–3).
- Assess adherence and provide continual patient education as needed.
- Assess disability with the Expanded Disability Status Scale[50] or the Multiple Sclerosis Functional Composite Score.[51]

▶ *Symptomatic Therapies*

Symptoms most unique to MS are fatigue, spasticity, impaired ambulation, and pseudobulbar affect. Treatment of other symptoms such as urinary incontinence, pain, depression, cognitive impairment, and sexual dysfunction is addressed elsewhere in this text and does not differ in MS.

Fatigue There are nonpharmacologic and pharmacologic strategies for coping with fatigue (Table 31–5).[50]

Spasticity Spasticity treatment goals are patient specific, and optimizing treatment may require multimodal therapy. For ambulatory patients, reducing spasticity may improve mobility and decrease pain. For bedbound patients, treating spasticity may relieve pain and facilitate care. Physical therapy is a nonpharmacologic treatment for spasticity.[53] **KEY CONCEPT** MS patients must be treated with agents specific for upper motor neuron spasticity (Table 31–6).[53] MS spasticity is classified as focal (one muscle group) or generalized. Botulinum toxin may benefit

Table 31–6

Antispasticity Agents

Place in Therapy	Medication	Mechanism of Action	Dose
First-line	Baclofen	Presynaptic and postsynaptic γ-aminobutyric acid type B receptor agonist	5 mg orally three times daily; increase by 5 mg/dose every 3 days; maximum 80 mg/day *Renal dysfunction:* Dose reduction
	Tizanidine	Centrally acting α_2-receptor agonist	2 mg orally three times daily; increase gradually by 2 mg at each dose every 1–4 days; maximum 36 mg/day *Hepatic and renal dysfunction:* Dose reduction
Second-line	Dantrolene	Direct inhibitor of muscle contraction by decreasing the release of calcium from skeletal muscle sarcoplasmic reticulum	25 mg orally daily; increase to 25 mg three to four times daily after 7 days; then increase by 25 mg every 4–7 days; maximum 400 mg/day
	Diazepam	γ-aminobutyric acid agonist	2–10 mg orally three to four times daily *Cirrhosis:* Reduce dose by 50%
	Nabiximols	CB_1 and CB_2 receptor agonist	Up to 12 sprays (2.7 mg delta-9-tetrahydrocannabinol and 2.5 mg cannabidiol) onto oromucosal surface in 24-hour period
Third-line	Intrathecal baclofen	Presynaptic and postsynaptic γ-aminobutyric acid type B receptor agonist	Titrated individually; usual range: 62–749 mcg/day
Focal spasticity	Botulinum toxin	Prevents release of acetylcholine in the neuromuscular junction	Individualized

Data from References [53,54].

Patient Encounter, Part 3

Based on the information available, create a care plan for this patient's MS. The plan should include (a) a statement of the drug-related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

focal spasticity.[53] Systemic medications are used for generalized spasticity. No conclusion can be reached regarding efficacy superiority of one agent.[53]

Impaired Ambulation Nonpharmacological treatment includes assistive devices, physical therapy, and/or exercise. Extended-release dalfampridine is indicated for improvement in walking speed in patients with MS. This potassium channel blocker prolongs action potentials, improving conduction in demyelinated neurons.[55] Not all patients respond to this agent so response can be assessed at 2 months and discontinued if not showing benefit.[55] Urinary tract infections, insomnia, dizziness, headache, nausea, asthenia, back pain, and balance disorder all occur frequently with dalfampridine.[55] Seizures are an uncommon adverse effect; therefore, patients with seizure disorders should not receive dalfampridine.[55]

Pseudobulbar Affect Ten percent of patients with MS develop pseudobulbar affect, which is characterized by inappropriate laughing or crying and can lead to social isolation.[56] A combination of dextromethorphan and quinidine is a treatment option for pseudobulbar affect. Dextromethorphan prevents the release of excitatory neurotransmitters. Low-dose quinidine blocks first-pass metabolism of dextromethorphan and increases serum concentrations. Episodes decrease 49% with this treatment.[56]

▶ *Outcome Evaluation*

- Assess symptom improvement/recurrence.
- Assess quality of life.
- Monitor adverse effects.
- Monitor adherence.

Patient Care Process

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary vitamins or supplements. Identify allergies to medications and other substances.
- Review the medical history and physical assessment findings.
- Speak with the patient and review records to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect medication access and care.

Assess the Information:

- Based on physical examination and review of systems, determine whether patient is experiencing an MS exacerbation currently. Determine the presence of other symptoms such as urinary incontinence.
- Based on the medical history and MRI findings, determine the following. Does the patient meet the 2017 McDonald Criteria for CDMS? How many relapses has the patient experienced? How active is the patient's MS disease course (Figure 31–5)? Is patient currently pregnant or wants to become pregnant in the near future?
- Review available laboratory tests.
- Based on the medication history, has patient been treated with any DMT or immunosuppressants previously? Is patient experiencing adverse effects from current therapy?
- If patient is receiving DMT or symptomatic pharmacotherapy, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?

Develop a Care Plan:

- If patient is having relapses, select corticosteroids.
- Select DMT (Table 31–1, Figure 31–5), considering:
- Route and frequency of administration
- Type of MS (RRMS, SPMS, PPMS) or CIS
- Pregnancy (if female)
- Adverse effect profile
- Cost, including insurance preauthorization needs

Implement the Care Plan:

- Obtain baseline laboratory testing (Table 31–2) and appropriate vaccine screenings.
- Educate patient regarding self-injection, if necessary (see Table 31–4), and adherence.
- Initiate needed symptomatic treatments.
- Address any concerns about MS and management.
- Refer patient to the National MS Society for information, newsletters, and local support groups (www.nationalmssociety.org).
- Instruct patient to contact clinician for any sudden symptom changes indicating relapse or adverse effects.

Follow-up: Monitor and Evaluate:

- Monitor patient for efficacy and adverse effects of DMT and symptomatic therapies (Table 31–2).
- Obtain MRI annually or more frequently as dictated by symptoms and selected therapy.
- Assess adherence to medications.
- Monitor quality of life, disability, and further symptom development.

Abbreviations Introduced in This Chapter

ALT	Alanine aminotransferase
APC	Antigen-presenting cell
ARR	Annualized relapse rate
AST	Aspartate aminotransferase
CBC	Complete blood count
CDMS	Clinically definite multiple sclerosis
CIS	Clinically isolated syndrome
CNS	Central nervous system
CrCl	Creatinine clearance
CSF	Cerebrospinal fluid
DC	Dendrite cell
DMT	Disease-modifying therapy
EDSS	Expanded Disability Status Scale
FEV_1	Forced expiratory volume in 1 second
HIV	Human immunodeficiency virus
IgG	Immunoglobulin G
IL	Interleukin
INF	Interferon
MHC	Major histocompatibility complex
MMP	Matrix metalloproteinase
MRI	Magnetic resonance imaging
MS	Multiple sclerosis
MSFC	Multiple Sclerosis Functional Composite
MUGA	Multiple-gated acquisition
OPC	Oligodendrocyte precursor cell
PML	Progressive multifocal leukoencephalopathy
PPMS	Primary progressive multiple sclerosis
RRMS	Relapsing-remitting multiple sclerosis
S1P	Sphingosine 1-phosphate
TGF	Transforming growth factor
Th1	T-helper-1 cells
Th2	T-helper-2 cells
TNF	Tumor necrosis factor
VCAM	Vascular cell adhesion molecule
VLA	Very late antigen

Epilepsy

Timothy E. Welty and Edward Faught

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology and social impact of epilepsy.
2. Define terminology related to epilepsy, including seizure, convulsion, and epilepsy.
3. Describe the basic pathophysiology of seizures and epilepsy.
4. Differentiate and classify seizure types given a description of the clinical presentation of the seizure and electroencephalogram.
5. Identify key therapeutic decision points and therapeutic goals in the treatment of epilepsy.
6. Discuss nonpharmacologic treatments for epilepsy.
7. Recommend an appropriate pharmacotherapeutic regimen with monitoring parameters for the treatment of epilepsy.
8. Devise a plan for switching a patient from one antiepileptic regimen to a different regimen.
9. Manage potential drug interactions with antiseizure medications (ASMs).
10. Determine when and how to discontinue ASM therapy.
11. Educate a patient or caregiver on epilepsy and pharmacotherapy for this disorder.

EPIDEMIOLOGY

Epilepsy is a disorder that afflicts approximately 2 million individuals in the United States, with an age-adjusted prevalence of approximately 4 to 7 cases per 1000 persons.[1] The incidence of epilepsy in the United States is estimated at 35 to 75 cases per 100,000 persons per year.[2,3] About 8% of the US population will experience a **seizure** during their lifetime. New-onset seizures occur most frequently in infants younger than 1 year and in adults after age 55.[2] Worldwide, there are 50 million people with epilepsy and 5 million new cases are diagnosed every year.[4] Nearly 80% of people with epilepsy live in low-income countries.

SOCIAL IMPACT

Epilepsy has a profound impact on a patient's life. Due to restrictions on driving, individuals who have recently had a seizure face major impediments to engage in simple activities.[5] Precisely 50% of patients with epilepsy report cognitive and learning difficulties.[6,7] Underemployment and unemployment are major concerns for individuals with epilepsy, due to limited transportation options, cognitive and learning difficulties, and seizures, resulting in problems paying for health care. Additionally, the social stigma of embarrassment or injury due to seizures in public results in isolation of the patient.[8]

Patients with epilepsy often depend on caregivers to assist with medications, transportation, and ensuring the patient's safety, so they should be informed about treatments and managing seizures.

ETIOLOGY

In approximately 80% of patients with epilepsy, the underlying etiology is unknown.[9] The most common causes of epilepsy are head trauma and stroke. Developmental and identifiable genetic defects cause about 5% of cases. Genetic causes are presumed in up to 25% of patients but are often unproven. Brain tumors, central nervous system (CNS) infections, and neurodegenerative diseases are other common causes. Human immunodeficiency virus infection and neurocysticercosis infection are also important causes.

Isolated seizures can be caused by stroke, CNS trauma, CNS infections, metabolic disturbances (eg, hyponatremia, hypoglycemia), and hypoxia. Failure to correct these causes may lead to the development of epilepsy. Drugs commonly associated with causing seizures are tramadol, bupropion, theophylline, select antidepressants and antipsychotics, amphetamines, cocaine, carbapenems, lithium, excessive doses of penicillins or cephalosporins, some antineoplastic agents, and sympathomimetics or stimulants. Alcohol intoxication and withdrawal can also cause seizures. Likewise, abrupt withdrawal of ASMs and benzodiazepines can precipitate seizures.

PATHOPHYSIOLOGY

Seizures

Regardless of the underlying etiology, all seizures involve a sudden electrical disturbance of the cerebral cortex. A population of neurons fires rapidly and repetitively for seconds to minutes. Cortical electrical discharges become excessively rapid, rhythmic, and synchronous. This phenomenon is presumably related to an excess of excitatory neurotransmitter action, a failure of inhibitory neurotransmitter action, or a combination of the two. In individual patients, it is usually impossible to identify which neurochemical factors are responsible.

Neurotransmitters

The primary excitatory neurotransmitter is glutamate.[10] When glutamate is released from a presynaptic neuron, it attaches to postsynaptic receptors. The result is the opening of membrane channels allowing sodium or calcium to flow into the neuron, depolarizing it, and transmitting an excitatory signal.[11] Many ASMs (eg, phenytoin, carbamazepine, and lamotrigine) work by blocking the release of glutamate or blocking sodium or calcium channels.[12] At usual doses, these drugs only halt the excessive rapid neuronal firing characteristic of seizures and do not affect normal brain function.

The primary inhibitory neurotransmitter is ***γ-aminobutyric acid*** (GABA). It attaches to neuronal membranes and opens chloride channels. Chloride flow into the neuron causes hyperpolarization and less excitability. This mechanism is probably critical for suppressing seizure activity. Barbiturates and benzodiazepines primarily enhance the action of GABA.

Cortical function is modulated by many other neurotransmitters, but their role in epilepsy is poorly understood.

Neuronal Mechanisms

Seizures originate in a group of neurons with abnormal electrical behavior, presumably due to an imbalance of neurotransmitter function.[12] In individual neurons, firing is excessively prolonged and repetitive. Instead of firing a single action potential, these neurons stay depolarized too long, firing many action potentials. This long, abnormal depolarization is called a paroxysmal depolarizing shift (PDS).

Excessive electrical discharges can spread to adjacent neurons or distant ones connected by fiber tracts.[13] The seizure spreads to other areas by recruiting neurons into uncontrolled firing patterns. Recruited neurons may be normal but are diverted from their normal functioning to participate in the excessive discharges, forming abnormal neuronal networks. The area of spread determines the clinical manifestations of the seizure.

Nearly all seizures stop spontaneously, because inhibitory mechanisms overcome abnormal excitation.

Epilepsy

Epilepsy is a disease where individuals have at least two unprovoked seizures more than 24 hours apart, one unprovoked seizure with at least a 60% probability of another seizure in the next 10 years, or diagnosis of an epilepsy syndrome.[14] Practically, this implies a permanent change in cortical function, rendering neurons more likely to participate in a seizure discharge, epileptogenesis.

Epilepsy may develop days, months, or years after a brain insult. A small group of abnormal neurons causes adjacent or connected normal neurons to gradually become abnormal. When a network of abnormal neurons becomes sufficiently large, it causes an excessive firing pattern for at least several seconds: a seizure.

If the change in cortical electrical characteristics is permanent, why do seizures not occur all the time? The occurrence of an individual seizure depends on an interplay of environmental and internal brain factors that intermittently results in loss of the normal mechanisms that control abnormal neuronal firing. It is impossible to determine what triggers a specific seizure.

Epilepsy may remain stable, decrease in severity, or worsen over time. Repeated seizures may cause further damage to the cortex and loss of neurons. Reorganization of connections between groups of neurons may strengthen excitatory connections and weaken inhibitory connections.

Epilepsy is associated with an increased mortality rate, from injuries with seizures or sudden death.[15] Early control of epileptic seizures may reduce permanent changes in brain function, although this hypothesis is unproven.

Genetic Factors

Patients with seizures may be concerned that their children or other family members will inherit epilepsy. Patients with acquired causes of seizures, such as head trauma or stroke, will not transmit epilepsy. Most patients with inherited epilepsy have generalized-onset epilepsy and develop seizures during childhood.[16,17] Complex inheritance patterns are usually seen, indicating the likely involvement of several abnormal genes or other factors for seizures to occur in offspring. Most patients can be reassured that their children and siblings are unlikely to develop epilepsy.

SEIZURE CLASSIFICATION AND PRESENTATION

General Principles

Careful diagnosis and identification of seizure types is essential to proper treatment of epilepsy. The International League Against Epilepsy (ILAE) established the classification of seizures (Table 32–1) that integrates the concept of onset of seizures with their clinical presentation.[18] Classification of epileptic seizures emphasizes electroencephalographic (EEG) findings combined with the clinical symptoms of the seizure events. Clinical presentation of seizures varies widely depending on the region and the amount of brain involved in the seizure.

Generalized Seizures

If the entire cerebral cortex is involved in the seizure from the onset, the seizure is classified as a **generalized seizure**. There are multiple types of generalized seizures. Two major categories of generalized seizures are motor, seizures that involve involuntary muscle activity, and nonmotor, seizures without involuntary muscle activity. In these seizures, the EEG demonstrates involvement of the entire brain from the onset of the seizure.

Focal Seizures

When the seizure begins in a localized area of the brain, it is defined as a **focal seizure**. There are two main types of focal seizures, with or without loss of consciousness. Focal seizures can be further categorized as motor and nonmotor. The EEG demonstrates that the seizure begins in a small region of the brain. Focal seizures can spread to involve the entire brain.

Unknown-Onset Seizures

Unknown-onset seizures are where the distinction between generalized and focal cannot be made. In these seizures, the EEG is unclear as to the start of the seizure.

Epilepsy Syndromes

Currently, there are no officially recognized epilepsy syndromes. Epilepsy syndromes that are often described in publications

Table 32–1

ILAE 2017 Classification of Seizure Types[17]

Focal Onset[a,b]			
Aware[c] or Impaired Awareness[d]	Generalized Onset[a,f]	Unknown Onset	Unclassified
Motor	**Motor**	**Motor**	
Automatisms	Tonic-clonic	Tonic-clonic	
Atonic	Clonic	Epileptic spasms	
Clonic	Tonic	**Nonmotor**	
Epileptic spasms	Myoclonic	Behavior arrest	
Hyperkinetic	Myoclonic-tonic-clonic		
Myoclonic	Myoclonic-atonic		
Tonic	Atonic		
Nonmotor	Epileptic spasms		
Autonomic	**Nonmotor (absence)[g]**		
Behavior arrest	Typical		
Cognitive	Atypical		
Emotional	Myoclonic		
Sensory	Eyelid myoclonia		
Focal to bilateral tonic-clonic[e]			

[a] The word "onset" is assumed when the seizure type begins with focal, generalized, or absence.

[b] Formerly partial seizures.

[c] Formerly simple partial seizures.

[d] Formerly complex partial seizures.

[e] Do not have a level of awareness specified.

[f] Formerly secondary generalized seizures.

[g] Formerly primary generalized seizures.

[h] Formerly absence seizures.

include Dravet syndrome, juvenile myoclonic epilepsy (JME), Lennox–Gastaut syndrome (LGS), mesial temporal lobe epilepsy (MTLE), severe myoclonic epilepsy of infancy (SMEI), and infantile spasms (West syndrome).

Sudden Unexpected Death in Epilepsy Patients

Sudden unexpected death in epilepsy patients (SUDEP) is a catastrophic event that results in the death of a patient. The precise causes of SUDEP are poorly understood. Abrupt discontinuation of ASMs may result in serious seizures associated with SUDEP. Patients should be told about SUDEP and strongly encouraged to be strictly adherent to their ASM therapy.

DIAGNOSIS

A correct and accurate diagnosis is essential prior to starting pharmacotherapy. KEY CONCEPT A distinction between a single seizure and epilepsy must be made, and other seizure-like disorders (eg, syncope, psychogenic, anxiety attacks, cardiac arrhythmias, hypoglycemia, transient ischemic attacks, tics, and complicated migraine headaches) should be ruled out. Seizures are typically brief spells, lasting less than 5 minutes. However, prolonged seizures lasting greater than or equal to 5 minutes or occurring one after another without recovery in between are status epilepticus, which requires immediate medical attention (Chapter 33).

A proper diagnostic workup of a patient presenting with seizures includes the following elements:

- Complete neurologic examination
- EEG
- Laboratory tests (complete blood count [CBC], complete serum chemistry, which includes liver function tests [LFTs], toxicology screening)
- Neuroimaging (preferably magnetic resonance imaging [MRI])

Many of the tests are done to rule out other causes of seizures (eg, infection, electrolyte imbalance, and overdose), and in most patients will be normal. Often the EEG appears normal between seizures. Sleep deprivation, photic stimulation, prolonged (> 20 minutes) EEG recording, and 24-hour EEG monitoring with video correlation can be done to capture seizure or seizure-like activity on the EEG.

TREATMENT

Desired Outcomes

The goal for any patient with epilepsy is elimination of all seizures without adverse effects from treatment. An effective treatment plan allows the patient to live a normal lifestyle with complete control of seizures. The treatment should enable the patient to drive, perform well in school, hold a reasonable job, and function effectively in the family and community. However, 30% to 50% of patients are not able to fully achieve these outcomes. In these cases, the goal of therapy is to provide a tolerable balance between reduced seizure frequency and/or severity and medication adverse effects, enabling the individual to live a lifestyle as nearly normal as possible.

General Approach to Treatment

Once it is concluded that the patient has epilepsy, the type of seizure must be determined.

Clinical Presentation and Diagnosis of Epilepsy

General

Typically, health care providers are not able to observe a patient's seizures, and for most types of seizures, the patient has no memory of the event. It is important to obtain a careful history from the patient and any individuals who witness the seizures.

Common Descriptions of Seizures

The clinical presentation of seizures varies from patient to patient depending on the portion of brain involved in the seizure. Events tend to be stereotypical for an individual patient.

Patients who experience seizures may complain of paroxysmal spells of:

- Lapses in memory, periods of altered consciousness
- Warnings or auras consisting of various sensations or automatic, uncontrolled movements
- Daydreaming
- Jerks, shoulder shrugs, sudden chills of spine
- Falling out

Associated Symptoms

- Incontinence, usually of urine
- Tongue or cheek biting
- Traumatic injuries, usually associated with falling during a seizure

Diagnosis

Description of events: The patient and any witnesses to the seizures should be carefully interviewed to obtain a full and complete description of typical seizures from start to end, and any behaviors after the seizure has stopped.

Neurologic examination: Usually, the neurologic physical examination is completely normal. Any neurologic deficits identified should be fully investigated, because seizures do not usually cause permanent, detectable neurologic deficits.

Electroencephalogram (EEG): A routine EEG can be helpful if epileptiform discharges are seen. However, the EEG may be normal between seizures, and most routine EEGs are not performed during a seizure. Maneuvers such as sleep deprivation, photic stimulation, hyperventilation, or prolonged monitoring can help expose EEG changes consistent with epilepsy.

Neuroimaging (preferably an MRI of the brain): Imaging of the brain is important to rule out obvious causes of seizures such as stroke or tumors. An MRI scan is also helpful in detecting hippocampal changes associated with focal seizures.

Video EEG monitoring: A procedure consisting of continuous video monitoring of the patient with a simultaneous EEG. Usually a patient is monitored in the hospital for 3 to 5 days. This procedure is used to determine if the patient is truly having seizures, to determine the specific type of seizures the patient is having, and to localize the area of the brain that is the origin of the seizures.

KEY CONCEPT Selection of appropriate pharmacotherapy depends on distinguishing, identifying, and understanding different seizure types. Without an accurate classification of the seizure type, it is possible to select a medication that is ineffective or even harmful to the patient.

KEY CONCEPT Prior to starting pharmacologic therapy, it is essential to determine the risk of having a subsequent seizure. If there is an underlying treatable etiology, such as hyponatremia or a CNS infection, the risks of another seizure and the development of epilepsy are very small. In these cases, the only necessary pharmacotherapy is to correct the underlying problem and possibly use an ASM short term. Risk factors for repeated seizures in patients without an underlying disorder include[19]

- Structural CNS lesion
- Abnormal EEG
- Focal seizure type
- Positive family history
- Postictal motor paralysis

If no risk factors are present, the risk of another seizure is 10% to 15%. However, if two or more risk factors are present, the risk of another seizure is 100%. If the estimated risk is over 60%, the patient has epilepsy by definition. When a patient is diagnosed with epilepsy, pharmacotherapy is usually started (Table 32–2). There are some ASM that are only used in very specific types of epilepsy (Table 32–3). The patient or caregiver should agree with the plan, be willing to take the medication, and be able to monitor seizure frequency and adverse drug effects. **KEY CONCEPT** Mechanisms of action, effectiveness for specific seizure types, common

Table 32–2

Evidence-Based Selection of Antiepileptic Drugs for Initial Monotherapy Treatment of Epilepsy[24–27]

Seizure Type	Drugs
Generalized onset: Motor	Carbamazepine (except myoclonic) Lamotrigine Levetiracetam Oxcarbazepine (except myoclonic) Perampanel Phenobarbital Phenytoin Topiramate Valproate
Generalized onset: Nonmotor (Absence)	Clobazam Clonazepam Ethosuximide (preferred) Lamotrigine Topiramate Valproate Zonisamide
Focal onset: Motor and nonmotor	Carbamazepine Cenobamate Gabapentin Lamotrigine Levetiracetam Oxcarbazepine Phenobarbital Phenytoin Topiramate Valproate

Table 32–3

Specialized Seizure Medications

Indication	Medication
Dravet Syndrome	Cannabidiol Fenfluramine Stiripentol
Tuberous Sclerosis	Cannabidiol Everolimus

adverse effects, and potential drug interactions are key elements in selecting a medication. Other patient factors such as gender, concomitant drugs, age, economic factors, and lifestyle also need to be considered.

Nonpharmacologic Therapy

Nonpharmacologic treatments for epilepsy include surgery, vagal nerve stimulation, deep brain stimulation, and dietary modifications. For some patients, surgery has the greatest probability of eliminating seizures. The most common surgery for epilepsy is temporal lobectomy. When the seizure focus can be localized and it is in a region of the brain that is not too close to critical areas, such as those responsible for speech or muscle control, surgical removal of the focus can result in 80% to 90% of patients becoming seizure free.[20] Other surgical procedures that are less likely to make a patient seizure free include corpus callosotomy and extratemporal lesion removal.

Vagal nerve stimulation is another nonpharmacologic approach to treating all types of seizures.[21] The unit that generates an intermittent electrical current is placed under the skin in the chest. A wire is tunneled under the skin to the left vagus nerve in the neck and delivers a small electrical stimulus to the vagus nerve. This efficacy of this treatment is essentially equivalent to starting a new medication, with fewer than 10% of refractory patients becoming seizure free. Vagal nerve stimulation is usually reserved for patients who do not respond to several drugs and are not surgical candidates. Deep brain stimulation devices are approved for individuals with seizures refractory to other treatments. Some ASM therapy is usually continued in patients with these devices.

Another nonpharmacologic treatment is the ketogenic diet.[22] This diet produces a keto-acidotic state through the elimination of nearly all carbohydrates. The diet consists of high dietary fats (eg, butter, heavy cream, and fatty meats) and low protein with no added sugar. Daily urinalysis for ketones is performed to ensure the patient remains in ketosis. Any inadvertent consumption of sugar results in the diet needing to be reinitiated. Clinicians must be vigilant in maintaining the diet, by determining the sugar or carbohydrate content of medications the patient is taking. This diet is typically used only in children with difficult-to-control seizures. In certain patients, the diet can be extremely effective, resulting in complete seizure control and reduction of ASMs. However, it is difficult to maintain, and palatability of the diet, growth retardation, and hypercholesterolemia are concerns. Less stringent diets, such as a modified Atkins diet, may produce seizure control similar to a rigorous ketogenic diet.

Pharmacologic Therapy

▶ *Special Considerations*

The use of ASMs presents some unique challenges due to their pharmacokinetic and pharmacodynamic properties.

Zero-order Pharmacokinetics Phenytoin metabolism is capacity limited. Small changes in doses result in large changes in serum concentrations. Individual differences in metabolism result in differing relationships between dose and serum concentrations. For routine clinical practice, dosage adjustments for adults with normal protein binding of phenytoin and a steady-state serum concentration can be made using the following plan:

- For serum concentrations less than 7 mcg/mL (mg/L; 28 μmol/L), the total daily dose is increased by 100 mg.
- For serum concentrations of 7 to 12 mcg/mL (mg/L; 28–48 μmol/L), the total daily dose is increased by 50 mg.
- For serum concentrations more than 12 mcg/mL (mg/L; 48 μmol/L), the total daily dose is increased by no more than 30 mg.[23]

Protein Binding Some ASMs, especially phenytoin and valproate, are highly bound to plasma proteins. When interpreting a reported concentration for these drugs, it is important to remember the value represents the total (ie, bound and unbound) concentration in the blood. Because of differences in the metabolism of these drugs, the clinical effects of altered protein binding are different.

For phenytoin and valproate, certain patient groups have decreased protein binding, resulting in an increased unbound percentage of drug. The clinical impact of protein binding changes with valproate is less than with phenytoin. These patient groups include:

- Those with kidney failure
- Those with hypoalbuminemia
- Neonates
- Pregnant women
- Those taking multiple highly protein-bound drugs
- Patients in critical care settings

In patients with suspected changes in protein binding, it is useful to measure unbound phenytoin concentrations.

When valproate protein binding is altered, the risk for severe dose-related adverse effects is less compared with phenytoin. Hepatic enzymes are able to efficiently metabolize the additional unbound portion.

Autoinduction Carbamazepine is a potent inducer of hepatic microsomal enzymes. It increases the rate of metabolism for many other drugs and the rate of its own metabolism. Hepatic enzymes become maximally induced over several weeks, necessitating a small initial dose of carbamazepine that is increased over time to compensate for the enzyme induction (Table 32–4). Most dosage regimens for carbamazepine use a starting dose that is 25% to 30% of the typical maintenance dose of 15 mg/kg/day. The dosage is increased weekly until the target maintenance dose is achieved within 3 to 4 weeks. Titration of the carbamazepine dose reduces the risk for severe dose-related adverse effects.

▶ *Drug Selection and Seizure Type*

The key to selecting effective pharmacotherapy is to base the decision on the seizure type. Several consensus treatment guidelines from the Scottish Intercollegiate Guidelines Network (SIGN), the National Institute for Clinical Excellence (NICE) in the United Kingdom, the American Academy of Neurology (AAN), and ILAE all link seizure type to the selection of pharmacotherapy (Table 32–2).[24-27] Table 32–2 summarizes recommendations from

Patient Encounter 1: New-Onset Seizures

BD is a 21-year-old woman who is brought to the ED following a seizure. Her friends describe the seizure as her falling and shaking all over. By the time emergency medical care arrived, she was groggy but no longer in a seizure.

Her physical examination is completely normal, and no focal neurologic deficits were observed. An MRI was ordered and reported as normal. An EEG shows occasional generalized 3- to 4-Hertz spike-wave activity consistent with generalized seizures.

What additional information is needed to decide about pharmacotherapy?

How should this information be used to make choices concerning ASM therapy?

She remembers several weeks ago that when she woke up in the morning, her muscles ached all over and there was some blood in her mouth and on her pillow.

Is pharmacotherapy indicated?

If it is indicated, what drug should be used and how should it be started?

What adverse effects are important to monitor?

Six months later, she still is having 1 to 2 episodes a month of single-body jerks, but no larger seizures.

What adjustments in pharmacotherapy should be made at this point?

Is it possible for her to discontinue ASM therapy at some time in the future?

these treatment guidelines and US Food and Drug Administration (FDA)-approved indications.

For initial treatment of generalized nonmotor seizures (absence), ethosuximide is preferred but valproate is an alternative. In generalized nonmotor (absence) and generalized motor (myoclonic) seizures, carbamazepine, oxcarbazepine, gabapentin, tiagabine, and pregabalin should be avoided due to association with worsening of these seizure types.

KEY CONCEPT ASM therapy should usually be initiated carefully using a titration schedule to minimize adverse events. Moderate target doses are chosen until the patient's response can be further evaluated in the clinic. If seizures continue, the dose is increased gradually until the patient becomes seizure free or adverse effects appear. For some drugs like lamotrigine, specific titration guidelines are established by the manufacturer.

Treatment of refractory seizures (ie, unresponsive to at least two first-line ASMs) is somewhat different. Combinations of drugs may be useful in patients with difficult-to-control seizures. All ASMs, except ethosuximide, are effective in combination therapy for focal seizures.

▸ Complications of Pharmacotherapy

Adverse effects of ASMs are frequently dose limiting or cause a drug to be discontinued. Two types of adverse effects occur with ASMs: serum concentration-related and idiosyncratic (Table 32–3). Concentration-related adverse effects occur with increasing frequency and severity as the dose or serum concentration of a drug is increased. Common concentration-related adverse effects include sedation, ataxia, and diplopia. Adverse effects should be considered in the selection of ASM. For example, if a patient has a job that requires mental alertness, it is best to choose an ASM that is less likely to cause sedation (eg, lamotrigine, levetiracetam).

Idiosyncratic adverse effects are not dose or concentration related and almost always result in the ASM being discontinued. Typically, these types of reactions occur during the first 6 to 12 months of taking the ASM. Rash is the most common of these. Prior to initiating carbamazepine and oxcarbazepine, genetic testing for human leukocyte antigen (HLA) HLA-B∗1502 and HLA-A∗3101 should be done for at-risk patients. Polymorphisms of these HLA genes are associated with increased risk of severe skin reactions. Likewise, with phenytoin, genetic polymorphisms of HLA-B∗1502 and the CYP 2C9∗3 have been associated with increased risk of severe skin reactions. Severe skin, hepatic, or hematological reactions occur rarely but are potentially life-threatening. The ASM should be discontinued immediately when these reactions occur. Carbamazepine, phenytoin, phenobarbital, valproate, lamotrigine, oxcarbazepine, and felbamate are most likely to cause reactions. There is a possibility of cross-reactivity for these adverse effects, especially for carbamazepine, phenytoin, phenobarbital, and oxcarbazepine.

▸ Chronic Adverse Effects

Because ASMs are administered for long periods of time, adverse effects due to prolonged drug exposure are of concern. Some chronic adverse effects associated with ASMs include peripheral neuropathy, cerebellar atrophy, and weight gain.

Osteoporosis is a major chronic adverse effect of several drugs.[28,29] Carbamazepine, phenytoin, phenobarbital, oxcarbazepine, and valproate decrease bone mineral density after 6 months of treatment. The risk of osteoporosis due to chronic ASM use is comparable to the risk with chronic use of corticosteroids. Patients taking carbamazepine, oxcarbazepine, phenytoin, phenobarbital, or valproate for more than 6 months should take supplemental calcium and vitamin D. Routine monitoring for osteoporosis should be performed every 2 years, and patients should be instructed on ways to protect themselves from fractures.

Psychiatric adverse effects may occur with ASM. All ASM have a warning for suicidality. There does seem to be some differences between seizure medications related to causing depression. Levetiracetam is associated with a greater risk of depression and agitation. Perampanel has a warning for suicidality and homicidality.

Patient Encounter 2: Managing Chronic Adverse Reactions

PL is a 45-year-old man with a long history of seizures. He has taken carbamazepine for 20 years with good control of his seizures. Other than some occasional dizziness, he reports no adverse effects from the carbamazepine.

What chronic adverse effects are important to monitor in this patient?

How should monitoring for these adverse effects be done?

What measures can be taken to prevent these adverse effects?

Table 32–4

Characteristics of Common ASMs

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Brivaracetam (Briviact)	Modulate synaptic vesicle protein 2A	*Maintenance Dose*: 50–100 mg twice daily	*Half-life*: 9 hours *Apparent Vd*: 0.5 L/kg *Protein binding*: 17.5% *Primary elimination route*: Hepatic	Not established	Ataxia, dizziness, fatigue, somnolence	Angioedema, bronchospasm, suicidal behavior and ideation
Cannabidiol (Epidiolex)	Unknown mechanism, does not work through cannabinoid receptors	*Maintenance Dose:* 10–20 mg/kg/day in two divided doses. Titrate by starting at 5 mg/kg/day in two divided doses and increase to target maintenance dose.	*Half-life:* 56–61 hours *Apparent Vd:* 300–600 L/kg *Protein Binding: > 94%* *Primary elimination route:* hepatic	Not established	Somnolence, fatigue, malaise	Hepatotoxicity, anorexia, pyrexia, vomiting, diarrhea
Carbamazepine (Tegretol and generic, Tegretol XR, generic), Carbatrol, Epitol, Equetro	Fast sodium channel inactivation	*Maintenance dose*: Titrate dosage to target over 3–4 weeks Adults: 800–1200 mg/day in divided doses Children: 20–30 mg/kg/day as a divided dose Intravenous: Indicated for oral replacement therapy at 70% of the total oral maintenance dose divided into four equal doses given every 6 hours	*Half-life*: 10–25 hours with chronic dosing *Apparent Vd*: 0.8–1.9 L/kg *Protein binding*: 67%–81% *Primary elimination route*: Hepatic	4–12 mcg/mL (mg/L; 17–51 µmol/L)	Diplopia, drowsiness, nausea, sedation	Aplastic anemia, hyponatremia, leukopenia, osteoporosis, rash
Cenobamate (Xcopri)	Modulate voltage-gated sodium channels, modulate $GABA_A$ ion channel	*Maintenance dose:* Target dose 200 mg/day; 12.5 mg/day for 2 weeks, 25 mg/day for 2 weeks, 50 mg/day for 2 weeks, 100 mg for 2 weeks, 150 mg for 2 weeks, then 200 mg/day. Titration schedule should not be exceeded	*Half-life:* 50–60 hours *Apparent Vd:* 0.6–0.7 L/kg *Protein binding: 60%* *Primary elimination route:* Hepatic	Not established	Somnolence, fatigue, diplopia	Drug reaction with eosinophilia and systemic symptoms, QT interval shortening
Clobazam (Onfi)	Enhance GABA activity	Weight< 30 kg, start 5 mg/day, titrate to 20 mg/day in divided doses Weight> 30 kg start 10 mg/day in divided doses, titrate to 40 mg/day in divided doses CYP 2C19 poor metabolizers: start 5 mg/day, titrate to 10–20 mg/day, maximum dose 40 mg/day	*Half-life*: 10–50 hours *Apparent Vd*: ~0.9 L/kg *Protein binding*: ~90% *Primary elimination route*: Hepatic; metabolized to active metabolite that is further metabolized by CYP 2C19	Not established	Sedation, somnolence, lethargy, pyrexia, irritability, drooling, aggression	
Clonazepam (Klonopin, generic)	Enhance GABA activity	*Maintenance dose*: Initiate at 0.5 mg one to three times daily, titrate dose to effectiveness, usually 3–5 mg daily in two or three divided doses Pediatric dosing in children < 10 years or < 30 kg: Initiate at 0.01–0.03 mg/kg/day in two to three divided doses, titrate dose to effectiveness	*Half-life*: 30–40 hours *Apparent Vd*:3.2 L/kg *Protein binding*: 47%–80% *Primary elimination route*: Hepatic	Not established	Ataxia, memory impairment, sedation, slowed thinking	

(Continued)

Table 32–4

Characteristics of Common ASMs (*Continued*)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Eslicarbazepine (Aptiom)	Fast sodium channel inactivation	*Maintenance dose*: Adults: Initiate at 400 mg daily and titrate in increments of 400–600 mg daily to a maintenance dose of 800–1600 mg daily Pediatrics: Initial, incremental increases, and maintenance dose based on body weight	*Half-life*: 13–20 hours in adults *Apparent Vd*: 0.85–0.9 L/kg *Protein binding*: < 40% *Primary route of elimination*: Renal	Not established	Ataxia, dizziness, diplopia, drowsiness, sedation, nausea, vomiting, hyponatremia	
Ethosuximide (Zarontin, generic)	Modulate calcium channels	*Maintenance dose*: Initiate at 250 mg twice daily and titrate to 500–1000 mg twice daily	*Half-life*: 60 hours *Apparent Vd*: 0.6–0.7 L/kg *Protein binding*: None *Primary elimination route*: Hepatic	40–100 mcg/mL (mg/L; 283–708 µmol/L)	Ataxia, sedation, GI upset	Hepatotoxicity, neutropenia, rash
Everolimus (Afinitor)	Inhibits mammalian target of rapamycin (mTOR) downstream of the PI3K/AKT pathway.	*Maintenance dose: 5 mg/m^2 adjusted to maintain concentrations in target range*	*Half-life: 30 hours* *Apparent Vd: highly variable depending on age* *Protein binding: 74%* *Primary elimination route: Hepatic*	5–15 mg/mL (mcg/L; 5.2-15.7 nmol/L)		Stomatitis, noninfectious pneumonitis, angioedema, myelosuppression, increase infections
Felbamate (Felbatol)	Inhibit glutamate activity	*Maintenance dose*: 1200–3600 mg/day in three or four divided doses	*Half-life*: Monotherapy: 20 hours Concurrent enzyme inducers: 11–16 hours *Apparent Vd*: 0.7–0.8 L/kg *Protein binding*: 25%–35% *Primary elimination route*: Hepatic	Not established	Anxiety, insomnia, nausea	Anorexia, aplastic anemia, headache, hepatotoxicity, weight loss
Fenfluramine (Fintepla)	Mechanism unknown	*Maintenance dose: 0.1 mg/kg twice daily with maximum daily dose of 26 mg without stiripentol; 0.1 mg/kg twice daily with maximum daily dose of 17 mg with stiripentol*	*Half-life:* 20 hours *Apparent Vd:* 11.9 L/kg *Protein Binding:* 50% *Primary elimination route:* Hepatic	Not established	Somnolence, fatigue, lethargy, ataxia, gait disturbance	Pulmonary arterial hypertension, valvular heart disease
Gabapentin (Neurontin, generic)	Modulate calcium channels and enhance GABA activity	*Maintenance dose*: Adults: 900–3600 mg/day in three or four divided doses Pediatrics: Age 3–4 Initial dose 10–15 mg/kg/day, titrate to a maximum of 50 mg/kg/day divided in divided three doses; age 5–11 initial dose 10–15 mg/kg/day, titrate to maximum of 50 mg/kg/day in three divided doses; age > 12 Initial dose 300 mg thrice daily, titrate to a maximum of 360 mg/day divided in three doses Renal dosing: CrCl 30–50 mL/min (0.50–0.84 mL/s) decrease by 25% and give twice daily; CrCl 10–29 mL/min (0.17–0.49 mL/s) decrease dose by 25% and give once daily; CrCl < 10 mL/min (0.17 mL/s) decrease dose 25% and give every other day	*Half-life*: 5–7 hours (proportional to creatinine clearance) *Apparent Vd*: 0.6–0.8 L/kg *Protein binding*: < 10% *Primary elimination route*: Renal	Not established	Drowsiness, sedation	Peripheral edema, weight gain

Lacosamide (Vimpat)	Slow sodium channel inactivation; modulate collapsin response; mediator protein-2	*Maintenance dose*: 200–400 mg/day; start at 100 mg/day in two divided doses and titrate upward according to response	*Half-life*: Approximately 13 hours *Volume of distribution*: 0.6 L/kg *Protein binding*: < 15% *Primary elimination route*: 40% renal 60% hepatic	Not established	Ataxia, dizziness, diplopia, headache, nausea, vomiting	PR interval prolongation. first-degree AV block
Lamotrigine (Lamictal, Lamictal XR, generic)	Fast sodium channel inactivation	*Initial dose*: With valproate 25 mg every other day for 2 weeks, then 25 mg daily for 2 weeks, then 25 mg twice daily for a week, increase by 25 mg/day every week until maintenance dose of 150 mg/day is achieved; without enzyme inhibitor or inducer 25 mg daily for 2 weeks, then 25 mg twice daily for 2 weeks, then increase by 25 mg daily every week maintenance dose of at least 200 mg/day is achieved; with enzyme inducer 25 mg twice daily for 2 weeks, then 50 mg twice daily for 2 weeks, then increase by 100 mg/day every week until maintenance dose of 300–500 mg/day is achieved *Maintenance dose*: 150–800 mg/day in two or three divided doses Pediatric: age 2–12 with valproate 0.15 mg/kg/day for 2 weeks, then 0.3 mg/kg/day for 2 weeks, then increase by 0.3 mg/kg/day every week until maintenance dose of 1–5 mg/kg/day achieved; without inhibitor or inducer 0.3 mg/kg/day for 2 weeks, then 0.6 mg/kg/day for 2 weeks, then increase by 0.6 mg/kg/day weekly until maintenance dose of 4.5–7.5 mg/kg/day achieved; with inducer 0.6 mg/kg/day in two divided doses for 2 weeks, then 1.2 mg/kg/day in two divided doses for 2 weeks, then increase by 1.2 mg/kg/day weekly until maintenance dose of 5–15 mg/kg/day is achieved	*Half-life*: Monotherapy: 24 hours Concurrent enzyme inducers: 12–15 hours Concurrent enzyme inhibitors: 55–60 hours *Apparent Vd*: 1.1 L/kg *Protein binding*: 55% *Primary elimination route*: Hepatic	Not established	Ataxia, drowsiness, headache, insomnia, sedation	Rash, cardiac arrhythmia

(*Continued*)

Table 32–4

Characteristics of Common ASMs (*Continued*)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Levetiracetam (Keppra, Keppra XR, generic)	Modulate synaptic vesicle protein 2A	*Adult Maintenance dose*: 1000–3000 mg/day. Start at 1000 mg/day and titrated upward as indicated by response *Pediatric*: 1–6 months 7 mg/kg twice daily titrate by 7 mg/kg twice daily every 2 weeks to maintenance dose of 21 mg/kg twice daily; 6 months to 4 years 10 mg/kg twice daily then increase by 10 mg/kg twice daily every 2 weeks to maintenance dose of 25 mg/kg twice daily; 4–16 years 10 mg/kg twice daily then increase by 30 mg/kg twice daily Renal failure: CrCl 50–80 mL/min (0.84–1.33 mL/s) 500–1000 mg twice daily, CrCl 30–50 mL/min (0.50–0.84 mL/s) 250–750 mg twice daily, CrCl < 30 mL/min (0.50 mL/s) 250–500 mg twice daily, end stage on dialysis 500–1000 mg daily	*Half-life*: 6–8 hours *Apparent Vd*: 0.5–0.7 L/kg *Protein binding*: < 10% *Primary elimination route*: 70% renal 30% hepatic	Not established	Somnolence, dizziness	Depression, agitation, aggressive behavior
Perampanel (Fycompa)	Antagonist of glutamate receptors on postsynaptic neurons	*Maintenance dose*: without CYP3A4 inducers 8–12 mg once daily. Start at 2 mg once daily, increase by 2 mg/day increments to desired response With CYP3A4 inducers Start at 4 mg once daily, increase by 2 mg/day increments to desire response with maximum dose of 12 mg daily	*Half-life*: 105 hours *Apparent Vd*: 0.7–1.5 L/kg *Protein binding*: 95%–96% *Primary elimination route*: Hepatic	Not established	Ataxia, dizziness, drowsiness, somnolence	Suicidal behavior and ideation, agitation, hostility, aggression, hypersensitivity reactions
Oxcarbazepine (Trileptal, generic)	Fast sodium channel inactivation	*Maintenance dose*: 600–1200 mg/day. Start at 300 mg twice daily and titrated upward as indicated by response Pediatric dosing *Maintenance dose*: 20 kg 300–450 mg twice daily; 25–30 kg 450–600 mg twice daily; 35–40 kg 450–750 mg twice daily; 40–50 kg 600–750 mg twice daily; 50–55 kg 600–900 mg twice daily; 60–65 kg 600–1050 mg twice daily Renal failure dosing CrCl < 30 mL/min (0.50 mL/s) starting dose of 150 mg twice daily and titrate at a slower rate to desired effect	*Half-life*: *Parent drug*: Approximately 2 hours *10-monohydroxy metabolite*: Approximately 9 hours *Apparent Vd*: 0.5–0.7 L/kg *Protein binding*: 40% *Primary elimination route*: Hepatic	Not established	Diplopia, dizziness, somnolence	Hyponatremia, 25%–30% cross-sensitivity in patients with hypersensitivity to carbamazepine

Phenobarbital (Luminal, generic) Primidone (Mysoline, generic) gets metabolized to phenobarbital	Fast sodium channel inactivation	*Loading dose*: 10–20 mg/kg as single or divided IV infusion or orally in divided doses over 24–48 hours *Maintenance dose*: Adults: 1–4 mg/kg/day as a single or divided dose Children: 3–6 mg/kg/day as divided dose Neonates: 1–3 mg/kg/day as divided dose	*Half-life*: Adults: 49–120 hours Children: 37–73 hours Neonates: approximately 115 hours *Volume of distribution*: 0.7–1 L/kg *Protein binding*: Approximately 50% *Primary elimination route*: Hepatic	15–40 mcg/mL (mg/L; 65–172 μmol/L)	Ataxia, drowsiness, sedation	Attention deficit, cognitive impairment, hyperactivity, osteoporosis, passive–aggressive behavior
Phenytoin (Dilantin, Phenytek, generic)	Fast sodium channel inactivation	*Loading dose*: Adults: 15–20 mg/kg single IV dose or divided oral dose Infants younger than 3 months: 10–15 mg/kg single IV dose Neonates: 15–20 mg/kg single IV dose *Maintenance dose*: Adults: 5–7 mg/kg/day, as single or divided dose Children: 6–15 mg/kg/day, as divided dose Neonates: 3–8 mg/kg/day, as divided dose	*Half-life*: Follows capacity-limited or Michaelis–Menten pharmacokinetics. Half-life increases as the dose and serum concentration increases. *Volume of distribution*: Adults: 0.7 L/kg Children: 0.8 L/kg Neonates: 1.2 L/kg *Protein binding*: Adults, children: 88%–92% Neonates: 65% *Primary elimination route*: Hepatic	10–20 mcg/mL (mg/L; 40–79 μmol/L) total concentration 1–2 mcg/mL (mg/L; 4–8 μmol/L) unbound concentration	Ataxia, diplopia, drowsiness, sedation, nystagmus	Anemia, gingival hyperplasia, hirsutism, lymphadenopathy, osteoporosis, rash IV ADE: phlebitis, hypotension
Rufinamide (Banzel)	Unknown, may enhance inactivation of sodium channels	*Maintenance dose*: Adults: 3200 mg/day; start at 400–800 mg/day in two divided doses and titrate upward according to response Children: 45 mg/kg/day or 3200 mg/day; start at 10 mg/kg/day in two divided doses and titrate upward according to response	*Half-life*: 6–10 hours *Apparent Vd*: Approximately 0.7 L/kg, varies with dose *Protein binding*: 34% (27% to albumin) *Primary elimination route*: Hepatic	Not established	Dizziness, fatigue, headache, nausea, somnolence, vomiting	
Stiripentol (Diacomit)	Mechanism unknown	*Maintenance dose: 50 mg/kg/day in two to three divided doses*	*Half-life: 4.5–13 hours* *Apparent Vd: 1 L/kg* *Protein binding: 99%* *Primary elimination route: hepatic*	Not established	Somnolence, anorexia, agitation, ataxia, nausea tremor, dysarthria	
Tiagabine (Gabitril, generic)	Enhance GABA activity	*Maintenance dose*: With concomitant hepatic enzyme inducers Initiate with 4 mg/day for 1 week, increase weekly by 4–8 mg/day in two to three divided doses with maximum dose of 56 mg/day Without concomitant hepatic enzyme inducers Initiate with 2–4 mg/day for 1 week, increase weekly by 2–4 mg/day to maintenance dose of 12–22 mg/day in two to three divided doses Pediatric dosing Age > 12 Initiate with 4 mg/day for 1 week, then 4 mg twice daily for 1 week, then titrate by 4–8 mg/day in two to four divided doses with maximum dose of 32 mg/day	*Half-life*: Monotherapy: 7–9 hours Concurrent enzyme inducers: 2.5–4.5 hours *Apparent Vd*: 0.6–0.8 L/kg *Protein binding*: 96% *Primary elimination route*: Hepatic	Not established	Dizziness, somnolence, irritability, slowed thinking	Suicidal ideation

(*Continued*)

Table 32–4

Characteristics of Common ASMs (*Continued*)

Drug	Mechanism of Action	Dose	Pharmacokinetic Parameters	Usual Serum Concentration Range	Dose-Related Adverse Effects	Idiosyncratic Adverse Effects
Topiramate (Topamax, generic) Qudexy, Trokendi XR, Topiragen	Fast sodium channel inactivation, inhibit glutamate activity, enhance GABA activity	*Maintenance dose*: 100–400 mg/day in two or three divided doses. Doses should be started at 25–50 mg/day and gradually titrated upward over 3–6 weeks to avoid excessive adverse effects Pediatric dosing Ages 2–16 Initiate at 5–9 mg/kg/day in two divided doses for 1 week, then titrate by 1–3 mg/kg/day every 1–2 weeks to desired response maximum dose of 400 mg/day	*Half-life*: Monotherapy: 21 hours Concurrent enzyme inducers: 11–16 hours *Apparent Vd*: 0.55–0.8 L/kg *Protein binding*: 13%–17% *Primary elimination route*: 60% renal 40% hepatic	Not established	Ataxia, dizziness, drowsiness, slowed thinking	Acute glaucoma, metabolic acidosis, oligohidrosis, paresthesia, renal calculi, weight loss
Valproic acid/ divalproex sodium (Depakene, Depakote, Depakote ER, Depacon, generic), Stavzor	Fast sodium channel inactivation	*Loading dose*: 20–40 mg/kg *Maintenance dose*: Adults: 15–45 mg/kg/day in two to four divided doses Pediatric dosing: 5–60 mg/kg/day in two to four divided doses Do not administer to children < 2 years of age Doses of extended release products should be 8%–20% higher than immediate release products	*Half-life*: Adults: 8–15 hours Children: 4–15 hours Infants younger than 2 months: 65 hours *Volume of distribution*: 0.1–0.5 L/kg *Protein binding*: 90% (decreases with increasing serum concentrations) *Primary elimination route*: Hepatic	50–100 mcg/mL (mg/L; 346–693 μmol/L) Children may require concentrations up to 150 mcg/mL (mg/L; 1040 μmol/L)	Drowsiness, nausea, sedation, tremor	Hepatotoxicity, osteoporosis, pancreatitis, weight gain, thrombocytopenia, alopecia
Vigabatrin (Sabril)	Inhibits GABA transaminase	*Adults*: Initiate at 1000 mg/day in two divided doses, titrate up to 3000 mg/day *Children*: 1 month–2 years: 50 mg/kg/day in two divided doses *Renal failure*: CrCl 50–80 mL/min (0.84–1.33 mL/s), decrease dose by 25%; CrCl 30–50 mL/min (0.50–0.84 mL/s), decrease dose by 50%; CrCl 10–30 mL/min (0.17–0.50 mL/s), decrease dose by 75%	*Half-life*: 7.5 hours, proportional to creatinine clearance *Volume of distribution*: 1.1 L/kg *Protein binding*: negligible *Primary route of elimination*: Renal	Not established	Convulsion, dizziness, headache, nasopharyngitis, somnolence, weight gain	Vision loss and blindness, suicidality
Zonisamide (Zonegran, generic)	Modulate sodium and calcium channels	*Maintenance dose*: 100–600 mg/day; start at 100 mg/day and titrated upward as indicated by response	*Half-life*: Approximately 63 hours *Apparent Vd*: 1.45 L/kg *Protein binding*: 40% *Primary elimination route*: Hepatic	Not established	Dizziness, somnolence	Metabolic acidosis, oligohidrosis, paresthesia, renal calculi

GABA, γ-aminobutyric acid.

Tiagabine and vigabatrin also seem to have higher rates of depression. Patients may not recognize these effects, but family members and other close friends often comment about these adverse effects. Patients should be regularly monitored for depression and agitation, and medication may need to be changed due to psychiatric adverse effects.

▶ *Practical Issues*

Comorbid Disease States Patients with epilepsy often have comorbid disease states. Care must be taken when treating comorbid conditions, as numerous drugs can interact with ASM. These interactions necessitate close monitoring for changes in efficacy or increased toxicity, and dosage changes of other drugs may be necessary when an ASM is added or removed. Patients with headaches need special attention in the selection of an ASM. Agents known to prevent headache (eg, valproate and topiramate) may be preferred.

Depression is common in patients with epilepsy. Approximately 30% of patients have symptoms of major depression at some point.[30] Routine assessment for depression should be done using a validated screening tool, and treatment initiated if necessary. Some ASMs (eg, levetiracetam) can exacerbate depression, and patients should be warned to watch for mood changes. Other ASMs (eg, lamotrigine, carbamazepine, and oxcarbazepine) may have a role in treating mood disorders. If treatment for depression is necessary, an agent that is unlikely to increase seizures and does not interact with ASMs should be chosen. However, treatment with an appropriate antidepressant should not be withheld because of a small risk of increasing seizure frequency.

Switching Drugs Changing from one ASM to another can be a complex process. If the first drug is stopped too abruptly, breakthrough seizures may occur. KEY CONCEPT Changes in ASM regimens should be done in a stepwise fashion, keeping in mind drug interactions that may be present and may necessitate dosage changes in concomitant drugs. Typically, the new drug is started at a low initial dose and gradually increased over several weeks. Once the new drug is at a minimally effective dose, the drug to be discontinued is gradually tapered while the dose of the new drug continues to be increased to the target dose. During a transition between drugs, patients should be cautioned about the possibility of increased seizures or adverse reactions.

Stopping Therapy Epilepsy is generally considered to be a lifelong disorder requiring ongoing treatment. However, some patients who are seizure free may desire to discontinue their medications.[31,32] Patients who become seizure free following surgery for epilepsy may have medications slowly tapered starting 1 to 2 years after surgery. Many patients will choose to stay on at least one medication, following successful surgery, to ensure they remain seizure free. Epilepsy is considered to be cured if a patient remains seizure free for 10 years and has been not taken an ASM for at least 5 years. KEY CONCEPT Discontinuation of ASMs should be done gradually, only after the patient has been seizure free for 2 to 5 years and with careful consideration of the following factors predictive of seizure recurrence:

- No seizures for 2 to 5 years
- Normal neurologic examination
- Normal intelligence quotient
- Single type of focal or generalized seizure
- Normal EEG with treatment

Individuals who fulfill all of these criteria have a 60% chance of remaining seizure free after ASMs are discontinued. Additionally, there is a direct relationship between the duration of seizure freedom with medications and the chance of remaining seizure free after medications are withdrawn. Withdrawal of ASMs is done slowly, usually with a tapering dose over at least 1 to 3 months.

▶ *Dosing*

Dosing of ASMs is determined by dosing guidelines and response of the patient. Serum concentrations may be helpful in benchmarking a specific response. Therapeutic ranges are broad guidelines for dosing but should never replace careful evaluation of the patient's response. It is usually best to obtain ASM concentrations immediately before a dose, preferably the first morning dose. Sufficient time should have elapsed for the ASM to be at steady state when a concentration is measured. In acute care, concentrations may be measured more frequently to ensure proper dosing and check for alterations in ASM pharmacokinetics (eg, altered protein binding, poor oral absorption, and increased metabolism). There is no standard initial dose of ASMs for all patients. Doses are established by balancing seizure control with adverse effects. Some patients may require doses higher than the usual recommended range, and some can be seizure free on unusually low doses. It is best to target initial doses in the middle of the usual therapeutic range and then adjusted according to patient response.

▶ *Drug Interactions*

ASMs are associated with many different drug interactions.[33-36] Most interactions occur due to alterations in absorption, metabolism, and protein binding. Tube feedings and antacids are known to reduce the absorption of phenytoin and carbamazepine. Phenytoin, carbamazepine, and phenobarbital are potent inducers of various CYP450 isoenzymes, increasing the clearance of other drugs metabolized through these pathways (Table 32–5). In contrast, valproate is a CYP450 and UDP-glucuronosyltransferase (UGT) isoenzyme inhibitor and reduces the clearance of some drugs. Phenytoin and valproate are highly protein bound and can be displaced when taken together or with other highly protein-bound drugs. Whenever a change in a medication regimen occurs, drug interactions should be considered and appropriate adjustments in the dose of ASMs made.

▶ *Special Populations*

KEY CONCEPT Children and women with epilepsy have unique problems related to the use of ASMs. In children, developmental changes occur rapidly, and metabolic rates are greater than those seen in adults. When treating a child, it is imperative to control seizures as quickly as possible to avoid interference with development of the brain and cognition. ASM doses are increased rapidly, and frequent changes in the regimen are made to maximize seizure control. Due to rapid metabolic rates seen in children, doses of ASMs are typically higher on a milligram-per-kilogram basis compared with adults, and serum concentrations are used more extensively to help ensure an adequate trial of a drug has been given.

For women, the treatment of epilepsy poses challenges, including teratogenicity, breastfeeding, interactions between ASMs and hormonal contraceptives, and reduced fertility.[37-39] Recommendations are developed for managing women of childbearing potential and who are pregnant (Table 32–6). Several ASMs are implicated in causing birth defects.[40] Neural tube defects (eg, spina bifida, microcephaly, and anencephaly) are associated most commonly with valproate and possibly carbamazepine. Additionally, valproate is associated with impaired cognitive development and increased risk of autism in children born to women taking valproate during pregnancy. The use of valproate should be avoided, if possible, in women of childbearing potential. All

Table 32–5

Cytochrome P450 and ASM Interactions

Enzyme	Substrate	Common Inducers	Common Inhibitors
CYP 1A2	Carbamazepine Fenfluramine Perampanel Stiripentol	Carbamazepine Phenytoin Phenobarbital Rifampin	Cimetidine Ciprofloxacin Erythromycin Fluvoxamine Clarithromycin
CYP 2C9	Brivaracetam Phenobarbital[a] Phenytoin[a] Carbamazepine Valproate	Carbamazepine Phenytoin Phenobarbital Rifampin	Amiodarone Cimetidine Fluconazole Valproate
CYP 2C19	Brivaracetam[a] Cannabidiol Phenobarbital Phenytoin Stiripentol Valproate Lacosamide		Felbamate Omeprazole Oxcarbazepine Ticlopidine Topiramate
CYP 2D6	Fenfluramine Zonisamide	Carbamazepine	
CYP 3A4	Cannabidiol Carbamazepine[a] Clobazam Clonazepam Ethosuximide Everolimus Lacosamide Perampanel[a] Stiripentol Tiagabine[a] Zonisamide[a]	Carbamazepine Oxcarbazepine Phenytoin Phenobarbital Topiramate (> 200 mg/day) Rifampin	Amiodarone Erythromycin Ketoconazole
Uridine diphosphate glucuronyl-transferase	Lamotrigine[a] Cannabidiol Carbamazepine Eslicarbazepine Valproate	Lamotrigine Phenobarbital Phenytoin Hormonal contraceptives	Valproate

[a] Primary route of metabolism.

women of childbearing potential who take ASMs should take 1 to 4 mg daily of supplemental folic acid to reduce the risk of birth defects. Many ASMs are excreted in breast milk. However, infants were exposed to higher concentrations of ASM in utero, so it is

Table 32–6

Management of ASMs During Pregnancy[40]

Give supplemental folic acid 1–4 mg daily to all women of childbearing potential
Use monotherapy whenever possible
Use lowest doses that control seizures
Continue pharmacotherapy that best controls seizures prior to pregnancy
Monitor ASM serum concentrations at start of pregnancy and monthly thereafter
Adjust ASM doses to maintain baseline serum concentrations
Administer supplemental vitamin K during eighth month of pregnancy to women receiving enzyme-inducing ASMs
Monitor postpartum ASM serum concentrations to guide adjustments of drug doses
Avoid valproate, if possible

Patient Encounter 3: Pregnancy

AM is a 28-year-old woman who is newly diagnosed with epilepsy. Her medications consist of lamotrigine and nonprescription antihistamines. She states that she and her husband want to start a family and she is concerned about her medications. She continues to titrate her lamotrigine upward in accordance with the recommended schedule. The seizures have decreased in frequency, but she is not at her target lamotrigine dose.

What advice should be given regarding birth control?

What is the risk of birth defects if she gets pregnant while taking ASMs?

What can be done to limit the risk of birth defects?

What ASMs should generally be avoided in women of childbearing potential?

How should lamotrigine be managed when she becomes pregnant and after delivery?

unclear if drugs in breast milk are harmful to the child. Decisions about breastfeeding are made on an individual basis.

Some ASMs induce hepatic microsomal enzyme systems and reduce the effectiveness of hormonal contraceptives. Women taking ASMs that may reduce the effectiveness of hormonal contraceptives should also use other forms of birth control. In contrast to these interactions, oral hormonal contraceptives induce glucuronidation of lamotrigine and valproate and cause reductions in serum concentrations of these drugs during days of the cycle when hormones are taken; serum concentrations increase during days when hormones are not taken. Serum concentrations of many ASMs drop during pregnancy and dose increases based on frequent serum concentration monitoring is necessary. Following delivery of the baby, serum concentration monitoring is helpful in guiding reduction of doses to the prepregnancy baseline. Due to induction or inhibition of sex hormone metabolism and changes in binding of hormones to sex hormone-binding globulin, some ASMs reduce fertility. Valproate has been associated with a drug-induced polycystic ovarian syndrome. Women who experience difficulties with fertility should seek the advice of health care professionals with expertise in fertility.

KEY CONCEPT Outside of infants, adults older than 55 years have the highest incidence of newly diagnosed epilepsy and face unique challenges in treatment. Cerebrovascular disease, tumors, trauma, and neurodegenerative diseases are the primary causes of epilepsy in this age-group. Diagnosis of epilepsy in older adults is difficult. This is due to the subtle symptoms of seizures, often compromised memory in the elderly, and the fact that many older adults live alone. Carbamazepine, lamotrigine, levetiracetam, topiramate, and gabapentin are effective in controlling seizures in older adults. Elderly patients are more sensitive to adverse events, so smaller doses tend to be used in this age-group. Patients in this age-group are at a greater risk for drug interactions due to age-related changes in drug clearance and the likelihood they are taking concomitant medications for other disease states.

Patient Encounter 4: Seizures in Older Adults

A 72-year-old woman reports new episodes of loss of time for a few seconds that occur several times a day. A friend has seen her have a few of these spells and notes some movement of her right hand and arm. An EEG shows possible epileptiform activity in the left temporal lobe.

Should pharmacotherapy be started in this patient?

If medication is started, which ASM should be started?

How should the efficacy and toxicity be monitored in this patient?

OUTCOME EVALUATION

KEY CONCEPT Patients receiving ASMs for seizures should be instructed on and have regular monitoring for seizure frequency, seizure patterns, acute adverse effects, chronic adverse effects, comorbid conditions, and possible drug interactions.

Patient Care Process

Collect Information:

- Description of seizure events
- EEG report
- Neuroimaging report
- Laboratory results (eg, serum chemistry, complete blood count, renal function, hepatic function, toxicology screen, ASM serum concentrations)
- History of prematurity or difficult delivery at birth, febrile seizures, head injury, infections of the central nervous system
- Family history of seizures or other neurological disorders
- Medication history
- Adherence to medications
- Allergies
- Social history (eg, employment, driving, living situation, recreational activities)

Assess the Information:

- Type of seizure
- Risk of a recurrent seizure
- Impact of potential pharmacotherapy on lifestyle
- Ability to adhere to medication regimen
- Need for modifying lifestyle (eg, ability to drive, modifications at work, avoidance of recreational activities that could result in harm with a seizure)

Develop a Care Plan:

- Determine optimal goals of pharmacotherapy.
- Select medication that is effective for the seizure type and minimizes the risk of adverse effects that negatively impact the patient's lifestyle; evaluate the risk of important drug interactions.
- Design a dosing schedule to optimize adherence.
- Identify important patient education points (eg, driving, safety, pregnancy, birth control, adherence).
- Determine when emergency medical services should be accessed.
- Select a seizure rescue medication, if indicated.

Implement the Care Plan:

- Select and initiate the best medication for the patient at an appropriate starting dose.
- Provide a medication titration schedule, if needed.
- Assist patient to determine the best ways to monitor efficacy (eg, seizure frequency and severity) and adverse events.
- Instruct patient on important patient education points (eg, driving, safety, pregnancy, birth control, adherence).

Follow-up: Monitor and Evaluate:

- Seizure frequency and severity
- Adverse events (eg dose-related, idiosyncratic, chronic)
- Serum concentrations, when appropriate
- Possible drug interactions
- Adherence

Efficacy

- Seizure counts are the standard way to evaluate the efficacy of treatment.
- Encourage patients to keep a seizure calendar that notes the time and day a seizure occurs and the type of seizure. Compare seizure counts on a monthly basis to determine the level of seizure control.

Toxicity

- Monitor acute toxicity of ASMs at every clinic visit.
- Question patients about common adverse effects of the ASMs they are receiving. Weigh the impact of acute adverse effects against the extent of seizure control. If it is determined that the adverse effects negatively impact the patient more than the extent of seizure control benefits the patient, adjust the therapeutic regimen. Continuously monitor chronic adverse effects of ASMs.

Comorbid Conditions

Routinely evaluate patients for signs and symptoms of depression.

Abbreviations Introduced in This Chapter

AAN	American Academy of Neurology
ASM	Antiseizure Medication
CBC	Complete blood count
CNS	Central Nervous System
CYP	Cytochrome P450
EEG	Electroencephalograph
GABA	γ-aminobutyric acid
HLA	Human leukocyte antigen
ILAE	International League Against Epilepsy
JME	Juvenile myoclonic epilepsy
LFT	Liver function tests
LGS	Lennox–Gastaut syndrome
MRI	Magnetic resonance imaging
MTLE	Mesial temporal lobe epilepsy
NICE	National Institute for Clinical Excellence in the United Kingdom
PDS	Paroxysmal depolarizing shift
SIGN	Scottish Intercollegiate Guidelines Network
SMEI	Severe myoclonic epilepsy in infancy
SUDEP	Sudden Unexpected Death in Epilepsy Patients
UGT	Uridine 5’-diphospho-glucuronosyltransferase

Status Epilepticus

Eljim P. Tesoro and Gretchen M. Brophy

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of status epilepticus.
2. Explain the urgency in diagnosis and treatment of status epilepticus.
3. Recognize the signs and symptoms of status epilepticus.
4. Identify the treatment goals for a patient with status epilepticus.
5. Formulate an initial treatment strategy for a patient in generalized convulsive status epilepticus.
6. Compare the pharmacotherapeutic options for refractory status epilepticus.
7. Describe adverse drug events associated with the pharmacotherapy of status epilepticus.
8. Recommend monitoring parameters for a patient in status epilepticus.

INTRODUCTION

KEY CONCEPT Status epilepticus (SE) is a neurologic emergency that can lead to permanent brain damage or death. **KEY CONCEPT** SE is defined as continuous seizure activity lasting more than 5 minutes or 2 or more seizures without a complete recovery of consciousness.[1] Refractory status epilepticus (RSE) is unresponsive to emergent (first-line) and urgent (second-line) therapy.

SE can present as nonconvulsive status epilepticus (NCSE) or generalized convulsive status epilepticus (GCSE). NCSE is characterized by persistent impaired consciousness without physical convulsions and is diagnosed with electroencephalography (EEG). GCSE is characterized by full-body motor seizures and involves the entire brain.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of SE ranges from 9.9 to 41 per 100,000/year, with a mortality rate of 26%,[2] and an estimated annual direct cost for inpatient admissions of $4 billion.[3] It occurs most frequently in males, African Americans, children, and the elderly.

KEY CONCEPT It is important to evaluate etiologies of SE for timely and optimal seizure control. Causes of SE include metabolic disturbances (e.g., hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, hypoglycemia), central nervous system (CNS) disorders, infections, injuries, hypoxia, and drug toxicity (e.g., theophylline, isoniazid, cyclosporine, cocaine).[4] Chronic causes of SE include preexisting epilepsy, chronic alcoholism (withdrawal seizures), CNS tumors, and strokes.[4] In patients with epilepsy, common causes of SE are anticonvulsant withdrawal or subtherapeutic levels.

PATHOPHYSIOLOGY

Status epilepticus occurs when the brain fails to stop isolated seizures, due to a mismatch of neurotransmitters. Glutamate, the primary excitatory neurotransmitter, stimulates postsynaptic *N*-methyl-D-aspartate (NMDA) receptors, causing neuronal depolarization. Sustained depolarization causes neuronal injury and death.[5] The primary inhibitory neurotransmitter, γ-aminobutyric acid (GABA), opposes excitation by stimulating GABA_A receptors, producing hyperpolarization and inhibition of the postsynaptic cell membrane. GABA-mediated inhibition diminishes with continuous seizure activity, causing a decreased response to GABA-receptor agonists.[6] Seizures lasting more than 30 minutes cause significant injury and neuronal loss because of excessive electrical activity and cerebral metabolic demand. Decreased GABA_A-receptor response and increasing neuronal injury with prolongation of seizure activity necessitate rapid control of SE.

Systemic changes appear in two phases during SE. Phase I occurs during the first 30 minutes, and phase II occurs after 30 to 60 minutes.[7]

Phase I

During phase I, autonomic activity increases, resulting in hypertension, tachycardia, hyperglycemia, hyperthermia, sweating, and salivation. Cerebral blood flow increases to preserve oxygen supply to the brain. Increases in sympathetic and parasympathetic stimulation with muscle hypoxia can cause ventricular arrhythmias, severe acidosis, and rhabdomyolysis, which can lead to hyperkalemia, hypotension, acute kidney injury, and shock.

Phase II

After 30 to 60 minutes of continuous seizure activity, loss of cerebral autoregulation, decreased cerebral blood flow, increased intracranial pressure (ICP), and systemic hypotension occur. Cerebral metabolic demand remains high; however, the body is unable to compensate, resulting in hypoglycemia, hyperthermia, respiratory failure, hypoxia, respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and uremia. Motor activity may not be clinically evident during prolonged seizures, but electrical activity may still exist (i.e., NCSE) requiring prompt recognition and aggressive treatment.

Patient Encounter 1, Part 1

A 46-year-old woman with a history of hypertension, diabetes, hypothyroidism, and COPD was admitted with bilateral traumatic epidural hematomas, skull fractures, and frontal contusions after being involved in a motor vehicle accident. She underwent surgery 2 days ago to treat the hematomas and skull fractures and is currently recovering in the intensive care unit (ICU). She was initiated on fosphenytoin for seizure prophylaxis upon admission along with her home medications. She has only one peripheral intravenous (IV) line and has very poor vascular access. Her nurse reports that she was alert and awake at the start of his shift, but now she is unarousable and is having jerky, convulsive movements on both sides of her body. The intensivist comes and quickly evaluates her when the shaking activity stops but resumes after 5 minutes. She never regained consciousness between these episodes. Her diagnosis is status epilepticus. Ht 165 cm (5′5″), Wt 117 kg (257 lbs).

What initial assessments should be performed?

What are some possible etiologies for her seizure?

What nonpharmacologic interventions are needed at this time?

CLINICAL PRESENTATION AND DIAGNOSIS

History

KEY CONCEPT When a patient presents with seizures, a thorough history is needed to determine the type and duration of previous seizure activity. This will help guide therapy and clarify necessary laboratory and diagnostic tests. Emergent treatment should not be delayed if seizure activity is diagnosed or is suspected based on the patient's family or emergency response personnel.

Physical Examination

Once clinical seizures are halted, a neurologic examination should evaluate the level of consciousness (coma, lethargy, or somnolence), motor function and reflexes (rhythmic contractions, rigidity, spasms, or posturing), and pupillary response. A physical examination can identify secondary injuries.

Clinical Symptoms

Patients with SE usually present with generalized, convulsive, tonic-clonic seizures. They may also be hypertensive, tachycardic, febrile, and diaphoretic, which resolve after seizure termination. A loss of bowel or bladder function, respiratory compromise, and nystagmus may also be observed. When seizure activity exceeds 30 to 60 minutes, muscle contractions may no longer be visible, necessitating an EEG to diagnose SE. Twitching of the face, hands, or feet may be seen in these comatose patients with prolonged seizures.

Laboratory Parameters

It is important to obtain a serum chemistry profile to help identify possible causes of SE, such as hypoglycemia, hyponatremia or hypernatremia, hypomagnesemia, and hypocalcemia; patients with renal and liver failure are at high risk as well.[1] In febrile patients with elevated white blood cell (WBC) counts, active infections should be considered and treated appropriately. Cultures from the blood, cerebrospinal fluid (CSF), respiratory tract, and urine should be collected once seizures are controlled. Blood alcohol level and urine toxicology screen should be ordered to determine if SE is caused by alcohol withdrawal, illicit drug use, or a drug overdose. Serum drug levels should be obtained in an overdose situation to rule out toxicity. **KEY CONCEPT** Knowing the cause of SE will guide initial antiepileptic therapy and increase the probability of seizure termination.

In patients taking anticonvulsants, a baseline serum concentration can help determine if the concentration is below the desired range and whether a loading dose (LD) is needed. Albumin levels

Clinical Presentation of Status Epilepticus

General

- The patient may present with or without clinically noticeable seizures.

Symptoms

- Impaired consciousness, from lethargy to coma
- Disorientation after GCSE cessation
- Pain from associated injuries (e.g., tongue lacerations, dislocated shoulder, head/facial trauma)

Signs

Phase I (≤ 30 minutes of SE):	Phase II (> 30 minutes of SE):
Generalized convulsions	Cardiac failure (arrhythmias, shock)
Hypertension, tachycardia	Hypotension
Fever and sweating	Hyperthermia
Muscle contractions, spasms	Rhabdomyolysis and multiorgan failure
Respiratory compromise	Respiratory failure with pulmonary edema
Incontinence	

Laboratory Tests

- Hyperglycemia (phase I) and hypoglycemia (phase II) can occur.
- Hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, and hypoglycemia can cause SE.
- The white blood cell (WBC) count may slightly increase.
- Abnormal arterial blood gases (ABGs) due to hypoxia and respiratory or metabolic acidosis.
- Elevated serum creatinine will be present in renal failure patients.
- Myoglobinuria can occur in patients with continuous seizures.

Diagnostic Tests

EEG to confirm seizure activity.

Computed tomography (CT) or magnetic resonance imaging (MRI) may reveal mass lesions or hemorrhage.

and renal and liver function tests should also be utilized to assess therapy.

Hypoxia and respiratory or metabolic acidosis are common in patients with SE. Pulse oximetry and arterial blood gas (ABG) measurements are used to assess pulmonary status and determine the need for protection or supplemental oxygen. Metabolic acidosis may resolve without treatment after the termination of clinical seizures.

Diagnostic Tests

EEG is required to identify SE in a comatose patient.[1] Continuous EEG monitoring should be used in patients who remain unconscious after initial antiepileptic treatment, those receiving long-acting paralytic agents, or those requiring prolonged RSE therapy. Treatment should not be delayed while awaiting EEG results. CT and MRI scans are useful to identify traumatic injury, mass lesions, or evidence of infection as the cause of SE.

TREATMENT

Desired Outcomes

KEY CONCEPT The goal of therapy is to terminate physical and electroencephalographic evidence of seizures, prevent recurrence, and minimize adverse drug events. Poor outcomes are associated with prolonged SE and refractory SE.[8] Complications of SE should also be treated.

General Approach

The initial approach to SE involves removing the patient from harmful surroundings and ensuring maintenance of airway, breathing, and circulation. Benzodiazepines are the preferred initial drugs to stop acute seizure activity (emergent therapy), followed by an anticonvulsant (urgent therapy) for suppression of subsequent seizures.[1] Medications are given intravenously for immediate onset of action, but if IV access is not available, select medications may be given rectally, intramuscularly (IM), buccally, or nasally. After seizures stop, clinicians must identify and treat underlying causes of the seizures, such as toxins, hypoglycemia, or brain injury. Patients with known seizure disorders should be evaluated for abrupt cessation of their medications, nonadherence, or drug interactions. Clinical guidelines provide treatment algorithms for SE.[1,9]

Nonpharmacologic Treatment

Oxygen administration or intubation for mechanical ventilation should be performed in cases of hypoxia, and temperature management should be considered for febrile seizures. Specialists in neurology or epileptology should be consulted as appropriate. Admission to an intensive care unit (ICU) allows for aggressive treatment and monitoring.

Pharmacologic Treatment

▶ *Initial Treatment*

Hypoglycemia-induced SE is treated with IV dextrose. Intravenous thiamine is given to patients with alcohol use disorder and acute toxicity prior to administering any dextrose-containing solution to prevent encephalopathy.

▶ *Benzodiazepines*

KEY CONCEPT Initial or emergent drug therapy begins with IV administration of a benzodiazepine. This class of agents is highly effective in terminating seizures.[10,11] Intravenous bolus doses of diazepam, lorazepam, and midazolam have been used in SE because of their rapid effects on GABA receptors. Lorazepam is the preferred agent of most clinicians. When treating patients on chronic benzodiazepine therapy, consider using higher doses to overcome tolerance. Diazepam and lorazepam should be diluted 1:1 with normal saline before parenteral administration via peripheral veins to avoid vascular irritation from the propylene glycol diluent.

Diazepam Being extremely lipophilic, diazepam penetrates the CNS quickly but rapidly redistributes into body fat and muscle.[1] This results in a rapid decline in CNS levels and early recurrence

Patient Encounter 1, Part 2

Physical examination, chart review, and recent laboratory studies reveal the following information:

PE:

VS: BP 188/87 mm Hg, HR 115 beats/min, RR 25 breaths/min, T 39.2°C (102.6°F)

CNS: Unresponsive, unarousable

CV: Sinus tachycardia; normal S1, S2; no murmurs, rubs, gallops

Pulm: Tachypneic; oxygen saturation 84% (0.84) on room air; no rhonchi, wheezes, rales

Abd: Deferred

Exts: Rhythmic tonic-clonic movements of all extremities

GU: Incontinent of urine and stool

HEENT: Persistent upward gaze

Current medications: Fosphenytoin 100 mg phenytoin equivalent (PE) IV every 8 hours; famotidine 20 mg IV every 12 hours; fluticasone furoate 100 mcg/umeclidinium 62.5 mcg/vilanterol 25 mcg inhaler 1 puff daily; levothyroxine 150 mcg PO daily; metoprolol 50 mg orally every 12 hours; Insulin glargine 25 units subcutaneous (SQ) at bedtime; insulin aspart 5 units SQ with meals; acetaminophen/hydrocodone 325 mg/5 mg tablet PO every 4 hours as needed for pain; morphine 2 mg IV push (IVP) every 2 hours as needed for pain

Labs: Sodium 125 mEq/L (mmol/L), potassium 4.5 mEq/L (mmol/L), phenytoin 2.7 mcg/mL (mg/L; 11 μmol/L), albumin 3.1 g/dL (31 g/L), chloride 105 mEq/L (mmol/L), carbon dioxide 12 mEq/L (mmol/L), blood urea nitrogen 12 mg/dL (4.3 mmol/L), serum creatinine 1.2 mg/dL (106 μmol/L), glucose 54 mg/dL (3.0 mmol/L); WBC 14 × $10^3/\text{mm}^3$ (14 × 10^9/L), hemoglobin 9.2 g/dL (92 g/L or 5.71 mmol/L), hematocrit 28% (0.28 volume fraction), platelets 215 × $10^3/\text{mm}^3$ (215 × 10^9/L), prothrombin time 14 seconds; international normalized ratio 1.2, activated partial thromboplastin time 31 seconds.

What is your assessment of the cause of this patient's condition?

What pharmacologic interventions are needed at this time?

Identify goals of therapy for this patient.

What therapies must be instituted next?

of seizures. Doses can be given every 5 minutes until seizure activity stops or toxicities are seen (e.g., respiratory depression).[1] Diazepam can be administered as a rectal gel enabling nonmedical personnel to provide timely therapy at home or in public areas.[12] Intramuscular administration of diazepam is not recommended because of erratic absorption.[13]

Lorazepam Less lipophilic than diazepam, lorazepam has a longer redistribution half-life, resulting in longer duration of action and decreased need for repeated doses.[14] Both lorazepam and diazepam are effective in stopping seizures,[15] but lorazepam is currently preferred due to a longer duration of action. It can be redosed every 5 to 10 minutes (up to a maximum cumulative dose of 8 mg) until seizure activity stops or side effects such as respiratory depression occur. Intramuscular administration is not preferred due to slow and unpredictable absorption.[14]

Midazolam Midazolam is water soluble and can be administered IM,[16] buccally,[17,18] and nasally.[19,20] Compared to diazepam and lorazepam, it has less respiratory and cardiovascular side effects. Its short half-life requires that it be redosed frequently or administered as a continuous IV infusion.[14] Liquid or injectable formulations can be given buccally or intranasally (0.2 mg/kg, maximum of 5 mg per dose in one nostril, may repeat once in other nostril) in pediatric patients. Rapid breathing and increased secretions can interfere with nasal administration. A study in adults and children showed that IM midazolam was as safe and effective as IV lorazepam for prehospital termination of seizures.[21]

▶ *Anticonvulsants*

KEY CONCEPT After administering the first dose of benzodiazepine, an anticonvulsant such as phenytoin, valproate sodium, levetiracetam, or phenobarbital should be started to prevent further seizures (urgent therapy). Anticonvulsants must not be given as first-line therapy since they are infused relatively slowly to avoid adverse effects, delaying their onset of action. If the underlying cause of the seizures has been corrected (e.g., hypoglycemia) and seizure activity has ceased, an anticonvulsant may be unnecessary. This may be reasonable when patients become alert and oriented or if an EEG confirms the absence of seizure activity.

After the LD of the anticonvulsant is administered, maintenance doses should be initiated to ensure that therapeutic levels are sustained. Chronic and idiosyncratic side effects and potential drug interactions should be considered if the patient continues anticonvulsant therapy. Drugs should be adjusted for any hepatic or renal dysfunction. Table 33–1 summarizes the doses used in SE, and Table 33–2 is an example algorithm for the treatment of patients in SE.

Phenytoin The most widely used anticonvulsant for urgent treatment of SE is phenytoin. It is available in its original form or as a prodrug, fosphenytoin, which is the most commonly used dosage form. Phenytoin doses are infused no faster than 50 mg/min due to risks of hypotension or arrhythmias. Continuous monitoring of electrocardiogram (ECG) and blood pressure is recommended. Maintenance doses can be started 12 hours after the LD. Phenytoin should not be infused with other medications to avoid instability (it is soluble in propylene glycol and compatible only in 0.9% sodium chloride solutions). It should not be given IM due to its alkalinity. Extravasation of phenytoin can cause local tissue discoloration, edema, pain, and, sometimes, necrosis (purple glove syndrome). Oral loading is not recommended due to the limitations of single-dose absorption (i.e., doses > 400 mg are not fully absorbed) and delayed peak concentrations when given orally.[22] Phenytoin/fosphenytoin loading doses for obese patients (≥ 30 kg/m^2) can be calculated based on actual body weight: 15mg/kg for obese males and 20 mg/kg for obese females.[23] Another option is to calculate a dosing weight (DW) using total body weight (TBW) and ideal body weight (IBW): DW = IBW + 1.33(TBW – IBW). Volume of distribution (V_d) can be calculated as follows: $V_d = 0.7$ L/kg × DW (in kg). An LD can then be calculated using V_d and a target concentration: LD = $C_{target} \times V_d$.

Patient Encounter 2, Part 1

A 29-year-old man is admitted for an elective cervical discectomy. He has a past medical history of epilepsy for which he takes levetiracetam (he has an allergic rash to phenytoin) and atrial fibrillation for which he is taking apixaban. He tells the nurse he has not taken any of his medications for 2 days because he was told to stop taking them in preparation for surgery. Suddenly, he becomes unresponsive and begins shaking his arms. His diagnosis is status epilepticus after this seizure activity does not stop over the next 5 minutes.

VS: BP 115/75 mm Hg, HR 118 beats/min, RR 25 breaths/min, T 37.0°C (98.6°F), Wt 73 kg (160 lb), Ht 183 cm (6 ft).

What is the most likely cause of this patient's SE?

What are possible treatment options at this time?

How would you optimize his outcome?

Fosphenytoin Fosphenytoin is a water-soluble phosphoester prodrug that is rapidly converted to phenytoin in the body. It is compatible with most IV solutions. It is dosed in phenytoin equivalents (PEs), and it can be infused up to 150 mg PE/min. Although it has fewer cardiovascular side effects than phenytoin, clinicians should continuously monitor blood pressure, ECG, and heart rate. Paresthesias, especially around the lips and groin, are common but typically resolve within a few minutes and should not necessitate stopping the infusion. If a postload serum level is desired, it should be obtained 2 hours after an IV load; if subtherapeutic, an additional LD is indicated.

Valproate Sodium Valproate sodium has been successfully used as an IV in various types of SE, including generalized tonic-clonic, myoclonic, and NCSE.[24] It is particularly useful in patients with cardiorespiratory compromise and/or those allergic to phenytoin and phenobarbital.[25]

Phenobarbital If phenytoin or valproate sodium fails to prevent seizure recurrence, phenobarbital can be considered.[1] However, phenobarbital may not be effective if SE persists despite benzodiazepines and phenytoin. This may be due to progressive resistance of the $GABA_A$ receptor, where barbiturates also act.[26] Adverse reactions of phenobarbital include sedation, hypotension, and respiratory depression; therefore, patients receiving a rapid IV LD of phenobarbital should have hemodynamic monitoring and be mechanically ventilated if at high risk of respiratory compromise. Its long half-life makes it a popular agent for both acute treatment and chronic maintenance therapy or as adjunct therapy to prevent withdrawal seizures when weaning refractory SE patients off pentobarbital infusions.

▶ *Levetiracetam*

Levetiracetam does not have the cardiopulmonary, hepatic, and sedative side effects seen with the other agents, nor does it have significant drug interactions. Both IV and oral formulations

Table 33–1

Medications Used in Adult Status Epilepticus[1]

Drug Name (Brand Name)	Loading Dose and RSE Maintenance Dose (If Applicable)	Administration Rate	Therapeutic Level	Side Effects	Comments
Diazepam (Valium)	0.15 mg/kg (up to 10 mg/dose); may repeat in 5 minutes	5 mg/min (IVP)	N/A	Hypotension, respiratory depression	Rapid redistribution rate; can be given rectally
Lorazepam (Ativan)	0.1 mg/kg (up to 4 mg/dose); repeat in 5–10 minutes	2 mg/min (IVP)	N/A	Hypotension, respiratory depression	May be longer acting than diazepam
Midazolam (Versed)	13-40kg: 5mg IM >40kg: 10mg IM RSE: 0.2 mg/kg (2 mg/min) IV then 0.05–2 mg/kg/hour		N/A	Sedation, respiratory depression	Can also be given buccally, intranasally
Phenytoin (Dilantin)	20 mg/kg	Up to 50 mg/min	Total phenytoin level: 10–20 mcg/mL (mg/L; 40–79 μmol/L) Free phenytoin level: 1–2 mcg/mL (mg/L; 4–8 μmol/L)	Arrhythmias, hypotension	Hypotension, especially in older adults
Fosphenytoin (Cerebyx)	20 mg PE/kg	Up to 150 mg PE/min	Total phenytoin level: 10–20 mcg/mL (mg/L; 40–79 μmol/L) Free phenytoin level: 1–2 mcg/mL (mg/L; 4–8 μmol/L)	Paresthesias, hypotension	Less CV adverse effects than phenytoin
Phenobarbital (Luminal)	20 mg/kg	50–100 mg/min	15–40 mcg/mL (mg/L; 65–172 μmol/L)	Hypotension, sedation, respiratory depression	Long-acting
Valproate sodium (Depacon)	20–40 mg/kg	3–6 mg/kg/min	50–150 mcg/mL (mg/L; 347–1040 μmol/L)		Less CV adverse effects than phenytoin
Levetiracetam (Keppra)	1000–3000 mg IV or 60 mg/kg (max 4500 mg)	2–5 mg/kg/min			Minimal drug interactions
Lacosamide (Vimpat)	200–400 mg IV	Over 15 minutes		PR prolongation, hypotension	
Topiramate (Topamax)	200–400 mg NG/PO every 6 hours		2–20 mcg/mL (mg/L; 6–59 μmol/L)	Metabolic acidosis	
Propofol (Diprivan)	Bolus: 1–2 mg/kg RSE: 30–250 mcg/kg/min	Approximately 40 mg every 10 seconds	N/A (typically titrated to EEG)	Hypotension, respiratory depression, PRIS	Requires mechanical intubation; high lipid load (increased calories)
Pentobarbital (Nembutal)	Bolus: 10–15 mg/kg RSE: 0.5–4 mg/kg/hour	Up to 50 mg/min	10–20 mcg/mL (mg/L; 44–89 μmol/L) (typically titrated to EEG)	Hypotension, respiratory depression, cardiac depression, infection, ileus	Requires mechanical intubation, vasopressors, hemodynamic monitoring
Ketamine (Ketalar)	RSE: 0.5–4.5 mg/kg IV bolus, then infusion up to 5 mg/kg/hour		N/A	Hypertension, arrhythmias	Associated cerebral atrophy

CV, cardiovascular; EEG, electroencephalogram; IM, intramuscular; IV, intravenous; IVP, intravenous push; N/A, not applicable; NG, nasogastric; PE, phenytoin equivalents; PO, by mouth; PR, per rectum; PRIS, propofol-related infusion syndrome; RSE, refractory status epilepticus.

have been used in SE patients with some success, and evidence is emerging for use of IV loading doses (60 mg/kg up to 4500 mg) earlier in SE.[34,35]

Treatment of Refractory Status Epilepticus

KEY CONCEPT Seizure activity unresponsive to emergent and urgent therapy is considered RSE.[27] Refractory SE can occur in up to 30% of patients with SE and has a mortality rate approaching 50%.[28] Patients in RSE are unlikely to regain independent function, even if seizures are controlled. Clinical signs may become subtle and an EEG may be required to detect ongoing seizure activity. **KEY CONCEPT** Even patients in SE without clinical signs of seizing are at risk for brain damage or death.

Optimal therapy for RSE is undetermined.[29] Clinicians must aggressively investigate and treat possible causes, including infection, tumors, drugs or toxins, metabolic disorders, liver failure,

Table 33–2

Algorithm for Treatment of Status Epilepticus

Time (minutes)	Assessment/Monitoring	Treatment
0	Vital signs (HR, RR, BP, T) Assess airway Monitor cardiac function (ECG) Pulse oximeter Check blood glucose Check laboratory tests: complete blood count, serum chemistries, liver function tests, arterial blood gas, blood cultures, serum anticonvulsant levels, urine drug/alcohol screen	Stabilize airway (intubate if necessary) Administer oxygen Secure IV access and start fluids Give IV thiamine (100 mg), then IV dextrose (50 mL of 50% solution) if hypoglycemic
0–10	Vital signs Physical examination Patient history, including medications (prescription, OTC, and herbals)	Lorazepam 0.1 mg/kg (maximum 4 mg) IVP at 2 mg/min (may repeat in 5–10 minutes to maximum of 8 mg if no response) If no IV access, can give diazepam 10 mg PR (may repeat in 10 minutes if no response); midazolam 10mg IM if > 40kg (may repeat in 10 minutes if no response) Anticonvulsant may not be necessary if underlying cause is corrected and seizures have ceased
10–20	Vital signs Review laboratory results and correct any underlying abnormality CT scan (if seizures controlled)	Phenytoin 15–20 mg/kg IV at a maximum rate of 50 mg/min (or fosphenytoin 15–20 mg PE/kg IV at a maximum rate of 150 mg PE/min) In patients allergic to phenytoin, give valproate sodium 20 mg/kg IV at a maximum rate of 6 mg/kg/min Treat for possible infection
20–30	Vital signs Consult neurologist/epileptologist Consider admission to ICU Consider EEG	If seizures continue, additional phenytoin bolus 5–10 mg/kg (or fosphenytoin 5–10 mg PE/kg) **OR** start phenobarbital at 20 mg/kg IV at a maximum rate of 100 mg/min **OR** start valproate sodium 20 mg/kg IV at a maximum rate of 6 mg/kg/min in patients who are not intubated
> 30–60 *refractory status epilepticus*	Vital signs Transfer to ICU Obtain EEG Consider MRI when controlled	Midazolam 0.2 mg/kg IV bolus followed by 0.05–2 mg/kg/hour CI **OR** propofol 1 mg/kg bolus followed by 30–250 mcg/kg/min CI **OR** pentobarbital 10–15 mg/kg bolus over 1–2 hours followed by 0.5–4 mg/kg/hour Consider intubation and/or vasopressor support if needed Optimize anticonvulsant levels: repeat boluses of phenobarbital 10 mg/kg **OR** valproate sodium 20 mg/kg at 6 mg/kg/min max
> 24 hours *super refractory status epilepticus*	Vital signs Continuous EEG	Optimize anticonvulsant therapy Consider ketamine infusion, immunomodulation (e.g., steroids, IV immunoglobulin), inhaled anesthetics, ketogenic diet

BP, blood pressure; CI, continuous infusion; CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalograph; HR, heart rate; ICU, intensive care unit; IM, intramuscular; IV, intravenous; IVP, intravenous push; MRI, magnetic resonance imaging; OTC, over the counter; PE, phenytoin equivalents; PR, per rectum; RR, respiratory rate; T, temperature.

or fever. In general, patients with RSE are managed in an ICU with hemodynamic and respiratory support and frequent monitoring. Continuous EEG monitoring is essential and should not be delayed. Any anticonvulsant initiated before the treatment for RSE should be continued, and their serum levels optimized to prevent breakthrough or withdrawal seizures. KEY CONCEPT Treatment of RSE consists of intensive monitoring, supportive care, and a continuous intravenous infusion of midazolam, propofol, or pentobarbital to suppress clinical and EEG evidence of seizures (Tables 33–1 and 33–2).[30] These agents are typically titrated to achieve burst suppression on the EEG, although this practice lacks strong evidence.[1] Patients should be intubated and mechanically ventilated before initiating treatment for RSE. Seizure control per EEG should be maintained for 24 to 48 hours before considering the tapering therapy.[1] Consultation with neurologists or epileptologists is highly recommended.

▶ *Midazolam*

Midazolam infusions must be adjusted, especially in patients with renal impairment, as the active metabolite can accumulate.[31] Breakthrough seizures are common with midazolam infusions and usually respond to boluses and a 20% increase in infusion rate. Despite this, tachyphylaxis can occur, and patients should be switched to another agent if seizures continue.[14]

Patien Encounter 2, Part 2

Over the next hour, he is treated with your recommendations for emergent and urgent treatment of SE as above. His jerky movements have stopped, but he remains comatose.

VS: BP 95/62 mm Hg, HR 120 beats/min, RR 14 breaths/min, T 37.1°C (98.8°F)

A continuous EEG is started and reveals the patient *remains* in SE.

What is your assessment of the patient's current condition?

What do you recommend for further nonpharmacologic and pharmacologic therapy?

How would you optimize his outcomes?

▶ *Propofol*

LDs of the anesthetic propofol can be given every 3 to 5 minutes until clinical response, after which an infusion can be initiated. Propofol causes hypotension, especially with LDs; therefore, some clinicians avoid LDs and quickly titrate with a continuous infusion. Long-term, high-dose (> 80 mcg/kg/min) propofol infusions are associated with rhabdomyolysis, acidosis, and cardiac arrhythmias (propofol-related infusion syndrome), especially in children.[32] Propofol has a very short serum half-life and should be tapered off slowly to avoid withdrawal seizures. Propofol infusions are a source of calories (1 kcal/mL [4.2 kJ/mL]), so nutritional support must be adjusted accordingly.

▶ *Pentobarbital*

Barbiturate infusions are reported to be highly effective in treating RSE[33] and decreasing elevated ICP, but they cause significant hypotension, myocardial and respiratory depression, ileus, and infections. Therefore, patients require mechanical ventilation and invasive hemodynamic monitoring. Patients often require IV vasopressor therapy and total parenteral nutrition.

A meta-analysis reported a lower incidence of treatment failure with pentobarbital (3%) compared to midazolam (21%) or propofol (20%), although the risk of hypotension requiring vasopressor therapy was higher with pentobarbital.[33] This relative efficacy for pentobarbital must be considered together with its complications when determining which agent to use. Patients who fail midazolam and/or propofol should be switched to pentobarbital.

▶ *Other Agents*

Ketamine,[36] topiramate, and inhaled anesthetics have also been used for RSE. Ketamine is an NMDA-receptor antagonist that has been given orally and intravenously for pediatric RSE.[37] Topiramate is an oral anticonvulsant with multiple mechanisms of action in RSE. The oral dose in adults ranges from 300 to 1600 mg/day.[38] Children have also been administered topiramate at a starting dose of 2 to 3 mg/kg/day and titrated to a maintenance dose of 5 to 6 mg/kg/day.[18] Topiramate can induce metabolic acidosis, requiring careful monitoring. The inhaled anesthetics, desflurane, and isoflurane[39] require special equipment for administration in an ICU. Lacosamide, an enhancer of slow inhibition of sodium channels, has limited drug interactions.[40] It has been used orally[41] and intravenously[42] in the setting of refractory partial SE and NCSE.[43]

Special Populations

Certain patients require special considerations due to their altered metabolism, unique volume of distribution, or increased risk for side effects.[44] Although many of these patients are excluded from clinical trials in SE, the standard algorithm for SE still applies in terms of immediate care, assessment, and drugs (see Table 33–2).

▶ *Pediatrics*

The treatment approach for SE in children is similar to that in adults with a few exceptions (see Table 33–3). The doses are also weight-based but are typically higher than those used in adults due to increased hepatic clearance. Timely IV access in children may be difficult, so alternate routes of administration have been used, including intranasal, buccal, rectal, and IM. Early administration of benzodiazepines and reduced time to hospital admission are important in decreasing prolonged seizures.[45]

▶ *Geriatrics*

Older adults are often vulnerable because of multiple disease states and polypharmacy. Seizures in older adults often arise from metabolic disorders, drug interactions, or incorrect dosing of medications in patients with impaired renal and hepatic function and decreased protein binding.[46] Clinicians treating older adult patients with SE should investigate drug- and disease state–induced causes, since treating these etiologies alone may terminate seizures. Acute treatment with benzodiazepines and anticonvulsants is no different in older adults, but they may experience more profound sedative and cardiorespiratory side effects.[46] Phenytoin/fosphenytoin LDs should be carefully calculated in older adults

Table 33–3

Medications Used in Pediatric Status Epilepticus[9]

Drug	Dose	Comments
Diazepam (Valium injection, Diastat rectal gel)	IV: 0.2–0.3 mg/kg over 2–5 minutes	Maximum dose in children < 5 years: 5 mg Maximum dose in children > 5 years: 15 mg
	PR: 2–5 years: 0.5 mg/kg 6–11 years: 0.3 mg/kg > 12 years: 0.2 mg/kg	A second rectal dose can be given 4–12 hours after the first dose if necessary
Lorazepam (Ativan)	0.05–0.1 mg/kg IV over 2–4 minutes	May redose twice in 10–15 minutes if necessary
Midazolam (Versed)	IM dose: 0.2mg/kg (maximum 10mg) RSE dose: 0.2 mg/kg IV bolus followed by 0.05–0.6 mg/kg/hour continuous infusion	Bolus dose may also be given intranasally, buccally, or intramuscularly
Phenytoin (Dilantin)	15–20 mg/kg IV at 1–3 mg/kg/min *max*	
Fosphenytoin (Cerebyx)	15–20 mg PE/kg IV at 3 mg PE/kg/min *max*	
Phenobarbital (Luminal)	15–20 mg/kg IV at 100 mg/min *max*	
Levetiracetam (Keppra)	20–60 mg/kg IV at 2 mg/kg/min	Few drug interactions
Valproate sodium (Depacon)	15–20 mg/kg IV at 1.5–3 mg/kg/min	May have fewer cardiovascular side effects than other agents
Propofol (Diprivan)		Not recommended due to adverse events (e.g., propofol-related infusion syndrome)
Pentobarbital (Nembutal)	10–15 mg/kg IV over 1–2 hours followed by continuous infusion at 1 mg/kg/hour	Titrated to EEG

EEG, electroencephalograph; IV, intravenous; PE phenytoin equivalent; PR, per rectum.

Patient Care Process

Collect Information:

- Review time of onset of seizure activity and past medical/surgical history.
- Obtain vital signs and relevant laboratory testing.
- Perform a medication history of prescription and nonprescription medications and identify medication allergies.
- Obtain patient's weight.

Assess the Information:

- Determine airway patency, breathing status, and circulatory status.
- Determine precipitating factors or etiology of SE.
- Identify drug interactions.
- Assess efficacy of and adherence to anticonvulsants if appropriate.
- Review laboratory results for electrolyte and glucose abnormalities and anticonvulsant serum levels.

Develop a Care Plan:

- Correct reversible causes of SE.
- Select initial benzodiazepine agent, route, and dose appropriate for patient.
- Select initial anticonvulsant for patient based on IV access and vital signs.
- If patient is taking anticonvulsants that can be monitored, evaluate for subtherapeutic serum levels and calculate appropriate LDs.

Implement the Care Plan:

- Administer therapeutic doses within the appropriate time frame (see Tables 33–1 and 33–2). Provide maintenance dosing of anticonvulsants when indicated.
- Identify potential drug interactions and adjust therapy as needed.
- Obtain expertise of a neurologist or epileptologist when appropriate.

Follow-up: Monitor and Evaluate:

- Determine if physical seizures have stopped and the patient regains consciousness. If not, consider continuous EEG monitoring for at least 24 to 48 hours to identify possible nonconvulsive SE.
- Obtain trough serum anticonvulsant levels at steady state, or sooner if seizures continue. Adjust anticonvulsants based on levels, maximizing seizure control and minimizing adverse effects.

whose weights may be overestimated, and who may not tolerate high doses. They should also be infused more slowly to minimize hypotension and arrhythmias. Phenobarbital may cause respiratory depression earlier in older adults, especially after benzodiazepines. Clinicians should consider using smaller doses and evaluate for renal and hepatic insufficiency if repeated doses are to be given.

▶ *Pregnancy*

The main concern in the treatment of pregnant women in SE is the safety of the fetus which is at risk of hypoxia during periods of prolonged seizures. Although many drugs used in SE are teratogenic, clinicians should still use them acutely to stop seizures but consider alternative agents with lower risks, such as lamotrigine, for maintenance therapy.[47] The volume of distribution and clearance of many drugs are increased during pregnancy and must be considered when calculating doses.[48]

OUTCOME EVALUATION

Start pharmacologic treatment as soon as possible.

- First-line (emergent) treatment for SE should halt seizure activity within minutes of administration.
- In patients who are unarousable following treatment, confirm termination of seizures with an EEG.
- Perform a physical examination and evaluate laboratory results to help determine if the cause or complications of seizure activity are being appropriately treated.
- Once seizure activity has ceased and the patient has stabilized, review the patient's therapeutic regimen.
- Evaluate and monitor serum trough concentrations of anticonvulsants with defined target ranges to determine patient-specific therapeutic goals.
- In patients with RSE on multiple continuous infusion agents, slowly decrease the dose of one drug at a time while continuing to evaluate the patient for seizure activity.
- Continue to monitor anticonvulsant serum trough concentrations approximately every 3 to 5 days until the anticonvulsants have reached steady-state concentrations.
- Monitor for signs of drug toxicity and seizures until drug concentrations have stabilized.
- Closely evaluate medication profiles, and change drugs or doses to minimize any drug interaction, if possible.

Abbreviations Introduced in This Chapter

ABG	Arterial blood gas
CNS	Central nervous system
CSF	Cerebrospinal fluid
CT	Computed tomography
ECG	Electrocardiogram
EEG	Electroencephalography
GABA	γ-Aminobutyric acid
GCSE	Generalized convulsive status epilepticus
ICP	Intracranial pressure
ICU	Intensive care unit
IM	Intramuscular
IV	Intravenous
LD	Loading dose
MRI	Magnetic resonance imaging
NCSE	Nonconvulsive status epilepticus
NMDA	*N*-methyl-D-aspartate
PE	Phenytoin equivalent
RSE	Refractory status epilepticus
SE	Status epilepticus
WBC	White blood cell

Parkinson Disease

Thomas R. Smith

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of Parkinson disease (PD) related to neurotransmitter involvement and targets for drug therapy.
2. Recognize the cardinal motor symptoms of PD and determine a patient's clinical status and disease progression based on clinical signs, symptoms, and assessment tools.
3. When initiating therapy for PD, recommend appropriate drug therapy and construct patient-specific treatment goals.
4. Recognize and recommend appropriate treatment for nonmotor symptoms.
5. Formulate a plan to minimize patient off time and maximize on time including timing, dosage, and frequency of medications as well as the use of adjunctive medications.
6. Recognize and treat motor complications in PD.
7. Construct appropriate patient counseling regarding medications and lifestyle modifications for PD.
8. Develop a monitoring plan to assess effectiveness and adverse effects of treatment.

INTRODUCTION

KEY CONCEPT Parkinson disease (PD) is a slow, progressive neurodegenerative disease of the extrapyramidal motor system. Dopamine neurons in the **substantia nigra** are primarily affected, and degeneration of these neurons causes a disruption in smooth motor control. Cardinal features of PD include tremor at rest, rigidity, **akinesia**/bradykinesia, and postural instability; however, nonmotor symptoms are also common and may present earlier than these motor symptoms. There is no cure, and treatment aims at controlling symptoms and maintaining quality of life (QOL) or functioning.[1-3]

EPIDEMIOLOGY AND ETIOLOGY

PD is the second most common neurodegenerative illness occurring in 1% to 2% of people older than 60 years.[2] While it is typically diagnosed in older patients, juvenile onset is possible but rare, and an early onset before age 50 can also occur. Genetics play a role in this disorder with about 10% to 15% of patients having an affected relative.[2,4]

The etiology of neuron degeneration in PD remains unknown, but aging is a primary risk factor.[4] Pigmented cells in the substantia nigra that make and store dopamine are lost.[3] Neurons have lost about 30% to 70% of their activity in the striatum at the onset of PD.[2] Cortical **Lewy bodies** along with Lewy neurites in the central nervous system (CNS) and the gastrointestinal (GI) system may explain some of the nonmotor symptoms (e.g., psychiatric, autonomic) of PD.[1,5]

The cause of cell death and PD symptoms is likely multifactorial, with both endogenous and exogenous factors such as genetic susceptibility and environmental toxin exposure (eg, pesticides and solvents).[6] Numerous genetic mutations are linked to PD, and particular mutations may predict early versus late onset of the disease, possibly explaining why the presentation and course of illness varies substantially. Genome-wide association studies have linked at least 26 single-nucleotide polymorphisms (SNPs) to PD.[6] In contrast, protective factors have also been documented and include a history of smoking and coffee consumption.[6]

PATHOPHYSIOLOGY

The extrapyramidal motor system controls muscle movement through pathways that connect the cerebral cortex, **basal ganglia**, thalamus, cerebellum, reticular formation, and spinal neurons. The substantia nigra, where dopamine neurons in PD are lost, sends nerve fibers to the corpus striatum. The corpus striatum is composed of the caudate nucleus and the lentiform nuclei that consist of the pallidum (globus pallidus) and putamen (**Figure 34–1**).[7] As dopamine neurons die, dopamine-relayed messages cannot communicate to other motor centers of the brain, and patients develop motor symptoms. Lewy bodies, inclusions of proteins (primarily alpha-synuclein) which accumulate in neurons, contribute to cell death and may start in the peripheral autonomic nervous system and then spread.[8] A variety of other neurotransmitters active in the basal ganglia lose concentration as well. These deficits possibly explain specific nonmotor symptoms seen in PD; losses of dopamine and norepinephrine in the limbic system correlates with depression and anxiety, while losses of acetylcholine and serotonin in the limbic system are associated with cognitive impairment.[8,9]

Theorized to begin in the autonomic system, olfactory system, or vagus nerve in the lower brainstem, the disease may then spread to the upper brainstem and cerebral hemisphere affecting dopamine pathways later.[9] This would explain why it is typical for patients to recall nonmotor symptom onset prior to manifestation

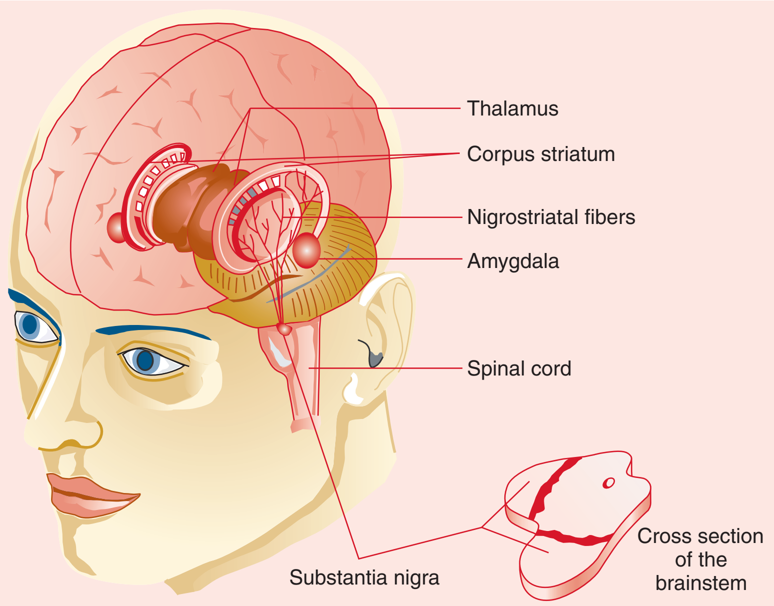

FIGURE 34–1. Anatomy of the extrapyramidal system. The extrapyramidal motor system controls muscle movement through a system of pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with PD have a loss of dopamine neurons in the substantia nigra in the brainstem that leads to depletion of dopamine in the corpus striatum. The corpus striatum is made up of the caudate nucleus and the lentiform nuclei that are made up of the putamen and the globus pallidus.

of classic motor symptoms and diagnosis. It is essential to rule out drug-induced pseudoparkinsonism due to dopamine antagonists such as antipsychotics, metoclopramide, and antiemetics (prochlorperazine) before diagnosis. Removing the offending agent generally resolves symptoms.[7,9]

Clinical Presentation of PD

Motor Symptoms (TRAP)

T = Tremor at rest ("pill rolling")

R = Rigidity (stiffness and cogwheel rigidity)

A = Akinesia or bradykinesia

P = Postural instability and gait abnormalities

Nonmotor Symptoms (SOAP)

S = Sleep disturbances (insomnia, REM sleep behavioral disorder RLS)

O = Other miscellaneous symptoms (nausea, fatigue, speech, pain, **dysesthesias**, vision problems, seborrhea)

A = Autonomic symptoms (drooling, constipation, sexual dysfunction, urinary problems, sweating, orthostatic hypotension, dysphagia)

P = Psychological symptoms (anxiety, psychosis, cognitive impairment, depression)

Response Fluctuations (MAD)

M = Motor fluctuations (delayed on, wearing off, random off, freezing)

A = Akathisia

D = Dyskinesias (eg, chorea, dystonia, diphasic dyskinesia)

CLINICAL PRESENTATION AND DIAGNOSIS

The diagnosis of PD is based substantially on signs and symptoms rather than diagnostic tests or imaging; however, this can be difficult as other illnesses have characteristics similar to PD and patients' presentations vary initially and progression is patient-specific.[2] DaTscan, a radiopharmaceutical contrast agent, may help differentiate PD from other disorders such as essential

Patient Encounter Part 1: Initial Visit—Medical History

A 66-year-old woman presents to the movement disorder clinic for assessment after a diagnosis of suspected PD 6 months prior by her PCP. Her complaints initially included "stiff muscles, trouble with balance, and a tremor that is bothersome." She was started on rasagiline 1 mg by mouth daily; however, she does not believe this to be very effective. She works as an adjunct professor at a community college and is having problems delivering her lectures (walking, balance, and her voice is softer), working on her computer, and grading papers (her handwriting has changed and the tremor is bothersome). She complains of some dizziness upon standing. Her affect is flat and she can be difficult to hear at times during the interview.

What questions should be asked to determine if a correct diagnosis was made?

What assessments should be completed at this time?

Identify this patient's motor and nonmotor symptoms of PD and assess her functioning.

Assess the choice of her initial drug therapy and make recommendations for optimizing her plan.

tremor but not from similar Parkinson-plus syndromes.[4] Therefore, a thorough patient history and detailed description of symptoms are essential.

Motor Symptoms

KEY CONCEPT As the pathophysiology of PD affects the extrapyramidal motor system, classic motor symptoms of tremor, rigidity, akinesia/bradykinesia, and postural/gait instability (TRAP) develop. Diagnostic criteria developed by the International Parkinson and Movement Disorder Society (MDS) focus on identifying parkinsonism (bradykinesia with rigidity or resting tremor) with supporting signs and symptoms and ruling out "red flags" that are present that would indicate another illness.[2,10] The onset of PD is gradual, and movement impairment may initially go unnoticed. Tremor occurs during rest and disappears with purposeful movement. Hand tremor may mimic a patient rolling a pill between his or her fingers. Rigidity manifests as stiffness with uniform muscle resistance on examination. Examiners may notice cogwheel rigidity on extension or flexion of extremities and feel rhythmical jerking as if hitting a series of teeth on the rim of a wheel. Bradykinesia presents as hesitancy in movement initiation, slowness in movement, or rapid fatiguing. Decreased automatic activity (eg, eye blinking, **hypomimia**, minimal arm swing while walking) is common. Rigidity and bradykinesia may make handwriting difficult as **micrographia** is common. Loss of reflexes to maintain balance as well as stooped posture causes postural instability and unsteadiness. This, combined with gait abnormalities such as slow shuffling, leg dragging, **festination**, or **freezing**, increases the risk of falls.[2,10-15]

Nonmotor Symptoms

Nonmotor symptoms in PD may precede the onset of motor symptoms by many years and result from PD itself or medications. Sleep disturbances, autonomic impairment, psychological disturbances, and sensory disturbances (**anosmia**) are common.[2,12,15,16]

Speech problems manifest as **hypophonia**, slurring, monotone speech, rapid speech, or stammering. When ocular muscles are impaired, difficulty reading, double vision, decreased blinking, and burning or itchy eyes are possible.[2,12,15,17]

Autonomic nervous system disruption may produce orthostatic hypotension as well as GI, urinary, sexual, and dermatologic symptoms. Orthostatic hypotension may cause dizziness, lightheadedness, fainting, or falls. Constipation is very common and **dysphagia** may lead to weight loss, **sialorrhea**, and aspiration.[15,16,17] Genitourinary symptoms include incontinence, urgency, and frequency causing nocturia. Sexual dysfunction includes reduced libido or the inability to achieve orgasm and erectile or ejaculatory dysfunction. Dermatologic symptoms include sweating and intolerance to temperature changes.[12,15,16]

Psychological symptoms of psychosis, dementia, impaired cognitive function, depression, and anxiety may result from PD, during symptom exacerbation, or from medications. Psychosis occurs in nearly 60% of PD patients.[18] Depression is common, but decreased facial expression and bradykinesia may give a false appearance of depression; thus, proper assessment of mood is necessary. Anxiety may be present and can correlate with motor fluctuations.[15,16]

Sleep disorders may be due to PD itself or medication adverse effects. Excessive daytime sleepiness, insomnia, and abnormal sleep events, such as rapid eye movement sleep behavior disorder (REM SBD), may occur.[12,15,16,19]

Motor Complications

Motor complications appear with either disease progression or as a complication of treatment, particularly with levodopa. Motor complications include **delayed peak response (delayed on)**, early and unpredictable wearing off, freezing, and **dyskinesias**—namely, **chorea** and **dystonia**.[3] Risk factors for developing motor complications include younger age at diagnosis, high dosage of levodopa, and longer duration and severity of disease.[3] Wearing off occurs when the therapeutic window of levodopa—the minimum effective concentration required to control PD symptoms (on without dyskinesia) through the maximum concentration before experiencing side effects from excessive levodopa (on with dyskinesia)—narrows over time.[3] Although the plasma half-life of levodopa is 1.5 to 2 hours, the therapeutic effect in early PD lasts about 5 hours, and the patient experiences no dyskinesias. This is due to supplemental dopamine production in the CNS. As PD progresses, this endogenous supply is lost, the therapeutic window narrows, and each dose of levodopa acts less functionally, with the effect decreasing to only 2 to 3 hours.[9,20] Additionally, dyskinesias manifest during the on state, particularly as the dosage of levodopa is increased.[21]

KEY CONCEPT The Unified Parkinson Disease Rating Scale (MDS UPDRS) describes total symptom burden, tracks disease progression, and assesses treatment efficacy. This clinician and patient-rated scale has four parts, which allow for evaluation of nonmotor symptoms, activities of daily living (ADL), motor symptoms, and complications of therapy. Each symptom is given a numerical score from 0 to 4 (none to severe) to describe severity.[22] The scale is used in both the research and clinical setting and available in multiple languages. Higher scores indicate more severe illness, and similarly, change in score over time will indicate a worsening of illness or improvement of symptoms.

TREATMENT

Desired Outcomes

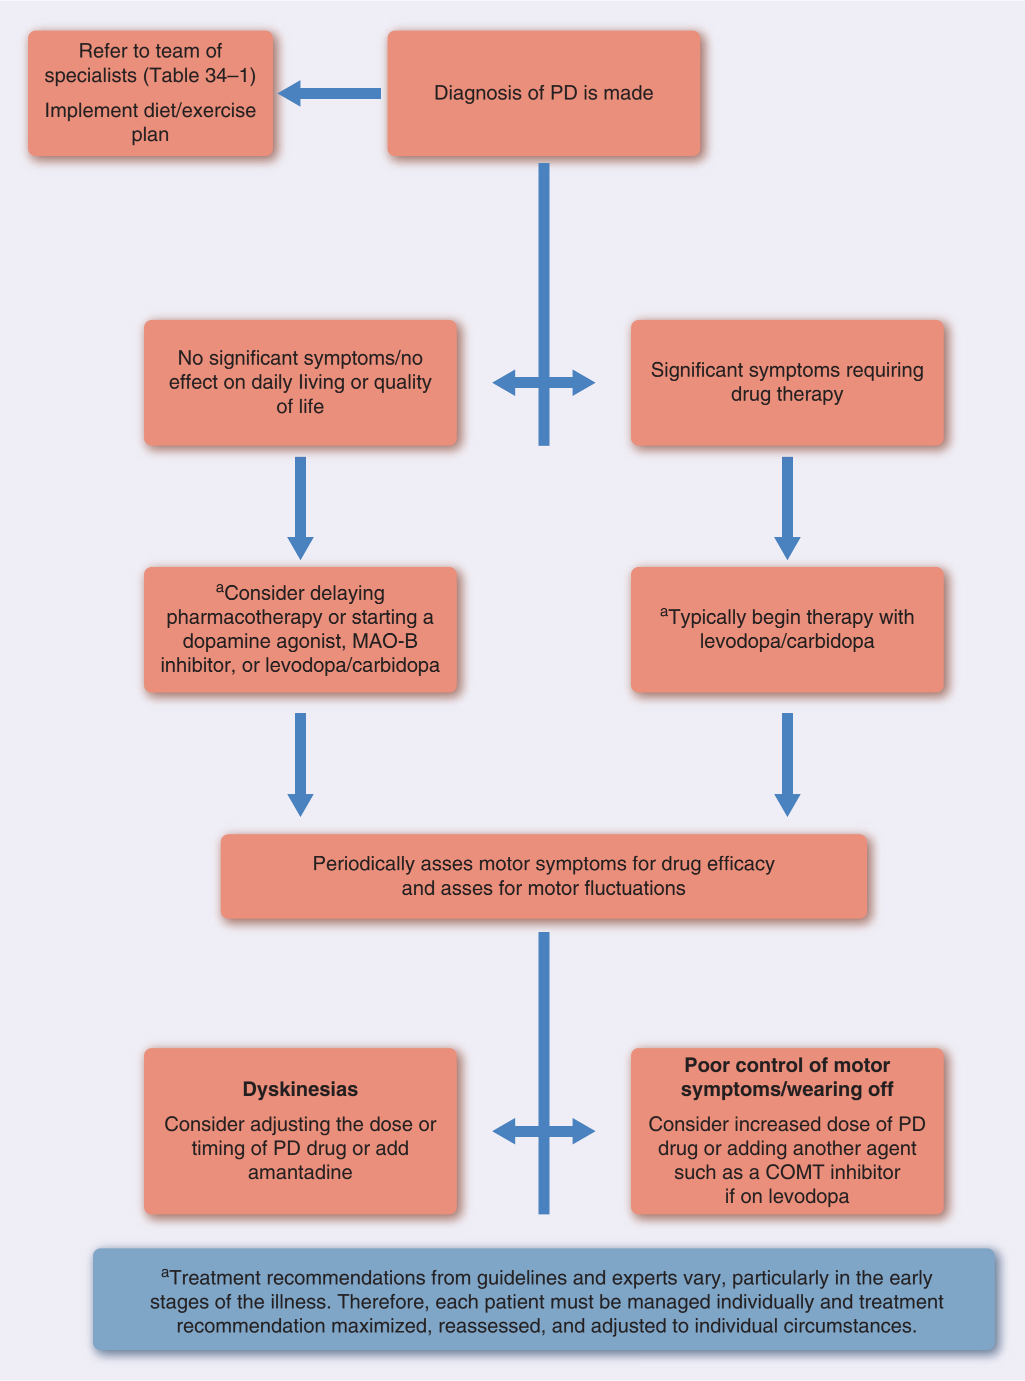
KEY CONCEPT The goals of treatment include: (a) maintaining patient independence, ADL, and QOL, (b) minimizing motor complications, and (c) limiting medication-related adverse effects.

General Approach to Treatment

KEY CONCEPT Treatment of PD is categorized into three types: (a) lifestyle changes, nutrition, and exercise; (b) pharmacologic intervention; and (c) surgical or other advanced treatments after pharmacologic interventions fail.

Generally, nonpharmacologic approaches such as nutritional adjustments and implementation of an exercise regimen are utilized early and throughout therapy; pharmacologic treatment depends on the patient's age, risk of adverse effects, degree of physical impairment, and readiness to initiate therapy (**Figure 34–2**).[1,23,24]

While older guidance and experts recommended delaying pharmacologic treatment to achieve long-term success, the 2017 guidelines by the National Institute for Health and Care Excellence (NICE) recommend dopamine agonists, levodopa, or monoamine oxidase B (MAO-B) inhibitors be offered to patients even before QOL is affected.[24,25] Ideally, a drug could be utilized early to attain a disease-modifying effect and delay progression of the illness, but no agent has conclusively demonstrated this effect.[15] One must decide when it is best to initiate pharmacotherapy for each individual patient.[5,25-28] Surgical approaches are withheld until after pharmacologic therapies fail or are problematic for most patients.



Refer to team of specialists (Table 34–1)
Implement diet/exercise plan
Diagnosis of PD is made
No significant symptoms/no effect on daily living or quality of life
Significant symptoms requiring drug therapy
aConsider delaying pharmacotherapy or starting a dopamine agonist, MAO-B inhibitor, or levodopa/carbidopa
aTypically begin therapy with levodopa/carbidopa
Periodically asses motor symptoms for drug efficacy and asses for motor fluctuations
Dyskinesias
Consider adjusting the dose or timing of PD drug or add amantadine
Poor control of motor symptoms/wearing off
Consider increased dose of PD drug or adding another agent such as a COMT inhibitor if on levodopa
aTreatment recommendations from guidelines and experts vary, particularly in the early stages of the illness. Therefore, each patient must be managed individually and treatment recommendation maximized, reassessed, and adjusted to individual circumstances.

Nonpharmacologic Therapy

▶ *Lifestyle Modifications*

Nonpharmacologic therapy and patient education is ideally implemented early and continued throughout treatment. Interventions include maintaining good nutrition, physical condition, and social interactions.[10,29] These treatments may improve ADLs, gait, balance, and mental health. Coordinated care with multiple health care professionals maximizes patient outcomes as each specialist plays a necessary role in the treatment team (Table 34–1).

Surgery

Consider surgery with deep brain stimulation (DBS) when inadequate control of motor symptoms develops despite pharmacotherapy. This procedure electrically stimulates the subthalamic nucleus (STN) or globus pallidus interna. DBS may significantly reduce motor symptoms and complications and improve QOL compared to medication management. Targeting various parts of the brain may decrease the need for escalating drug exposure and better control motor symptoms or decrease the burden of

Patient Encounter Part 2: Initial Visit—Physical Examination and Diagnostic Tests

Chief Complaint: New-onset unilateral tremor and upper body muscle stiffness; decreased sleep quality, depression, problems functioning at work

PMH: Major depressive disorder for 10 years, insomnia for 5 years, hypertension for 3 years

SH: Works part-time as an adjunct professor. Denies alcohol, drug, or tobacco use.

Meds: Rasagiline 1 mg orally once daily, fluoxetine 40 mg orally once daily, metoprolol ER 100 mg orally once daily, doxylamine 50 mg orally at bedtime as needed for insomnia

ROS: (–) Psychosis; reports depression; denies nausea, vomiting, diarrhea, headache, dizziness, or pain

PE:

Gen: Flat affect, looks older than stated age, speaks softly and often difficult to hear, handwriting when completing the intake forms is difficult to read

VS: BP: sitting 135/85, P 60 beats/min, RR 18/min, Wt 47 kg (104 lb), Ht 165 cm (65 in.)

HEENT: Decreased eye blinking and facial expression, CN II-XII intact, PERRLA, TMs intact

CV: RRR, normal S1, S2; no murmurs, rubs, gallop

Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly

Exts: Mild-to-moderate tremor in her left arm most noticeable at rest. Mild cogwheel rigidity bilateral elbows

Neuro: Slow, sensory function intact, normal muscle strength, normal reflexes, alert, mental status examination normal

Rating Scales: Patient Health Questionnaire (PHQ-9) = 16; Mini Mental State Examination (MMSE) = 29/30; UPDRS = 65 at current visit; no prior history to compare to

Labs: Normal metabolic profile and CBC

The patient has read about new medications for PD that have been introduced. She would like information on these medications and how to prevent worsening of her symptoms. Plan:

- Discontinue rasagiline
- Initiate pramipexole XR 0.375 mg PO daily

Identify treatment goals for the patient.

Describe nonpharmacologic treatments that should be started for the patient.

Assess the treatment plan and counsel the patient on risks and benefits.

Educate the patient on recently approved drug therapies and on disease modification.

dyskinesias. These surgeries carry risks and are utilized after suboptimal response to drug therapy.[24]

Pharmacologic Therapy of Motor Symptoms

KEY CONCEPT Drug therapy aims to enhance dopaminergic activity in the substantia nigra; they minimize motor symptoms and improve QOL but are not curative (Table 34–2).[7] Even with pharmacotherapy, Patients with PD have greater mortality and morbidity than the general population.[15] **KEY CONCEPT** Choice of pharmacologic agent should be individualized based on patient-specific parameters, and dose regimens based on individual response to maximize on time and minimize off time.

Table 34–1

Specialist Care for Patients with PD[10,34]

Provider	Reason for Referral
Dentist	PD medications may decrease saliva flow and increase the risk of dental caries
Dietician	Recommend appropriate caloric intake, meal selection, and protein consumption which may: • Improve constipation and nausea • Decrease weight loss and aspiration • Minimize erratic drug absorption
Speech therapist	Improved swallowing, articulation, and force of speech
Physical therapy	Improve strength, activity, sleep quality, and reduce fall risk
Occupational therapist	Educate on adaptive environment of home, specialized clothing, and personal training to maximize: • Independence • Safety • ADLs • Driving ability
Social worker	Arrange for community assistance programs and family counseling

Pharmacologic options for motor symptoms in PD include anticholinergics (Ach), amantadine, MAO-B inhibitors, dopamine agonists, levodopa/carbidopa, catechol-*O*-methyltransferase (COMT) inhibitors, and istradefylline. Most experts recommend initial treatment with either levodopa/carbidopa, a monoamine oxidase inhibitor (MAOI) or a dopamine agonist.[14,16,29,30]

Choice between drugs varies based on patient status and preference. Starting with a dopamine agonist may delay the onset of dyskinesias and response fluctuations seen with long-term levodopa use; however, less motor benefit and greater risk of hallucinations or somnolence may occur.[4] Levodopa causes the greatest motor improvement and should be used as initial therapy in the elderly but may increase the risk of motor fluctuations over time.[27] Data are insufficient to recommend initiating treatment with combined drug classes. Initiating treatment with anticholinergic medication or amantadine is recommended only for patients who have mild symptoms because their efficacy is questionable.[16,28-30]

Regardless of the drug initially chosen, the initial dose is low and increased gradually based on symptoms (see Table 34–2). Dose timing and frequency is then adjusted based on the patient's report of on-time duration and wearing off symptoms.[31] Dyskinesias may develop with the use of

Table 34–2

Dosing of Medications Used to Treat PD[35]

Generic Name (Trade Name)	Initial Dose	Titration and Maintenance Dose	Available Formulations	Hepatic or Renal Adjustments
Levodopa Formulations				
Levodopa with carbidopa (Sinemet)	Half tablet (100-mg LD, 25-mg CD) twice daily for 1 week, then half tablet three times daily	Increase by half tablet daily every week; usual MD is 300–2000 mg daily; because the duration of LD is 2–3 hours, patients may require doses every 2 hours	Stalevo—CD/LD/Entacapone tablet	
Sinemet CR	One tablet (100-mg LD, 25-mg CD) two to three times daily	Increase to 200-mg LD tablet two to four times daily; usual MD is 200–2200 mg daily	Sustained-release tablet	
Rytary (extended-release levodopa with carbidopa)	In levodopa-naïve patients: 23.75 mg/95 mg taken orally three times a day for the first 3 days	On the fourth day of treatment, the dosage may be increased to 36.25 mg/145 mg taken three times a day. Individual doses may be increased and doses may be given up to five times a day based on individual response; patients previously on immediate-release levodopa should follow recommended conversions.	Extended-release capsule	
Duodopa (intestinal infusion of LD/CD)	Convert patients to Sinemet and calculate a total daily dose	Dose consists of a morning dose, a continuous infusion, and additional doses. One extra dose per 2 hours is the maximum. Maximum dose is 2000 mg of LD over 16 hours	Intestinal suspension	
Inbrija (inhaled levodopa)	84 mg inhaled up to five times daily as needed	Use as needed for off episodes	Capsule for inhalation	
Dopamine Agonists				
Apomorphine (Apokyn)	Start trimethobenzamide 300 mg for 3 days; then give apomorphine 2 mg SC injection (1 mg if outpatient) while monitoring blood pressure	Continue trimethobenzamide as necessary (generally no longer than 2 months). Increase apomorphine by 1–2 mg every ≥ 2 hours; usual MD is 2–6 mg three to five times daily for off periods	Subcutaneous solution	Reduce initial dose to 1 mg in mild-to-moderate renal failure
Bromocriptine (Parlodel)	1.25 mg twice daily	Increase by 2.5 mg daily every 14–28 days	Capsule, tablet	Dosing adjustments may be necessary with hepatic impairment
Pramipexole (Mirapex)	0.125 mg three times daily	Increase about weekly by 0.375–0.75 mg/day to a MD of 0.5–1.5 mg three times daily	Tablet	Dosage reduction needed in CrCl < 50 mL/min (0.83 mL/s)
Mirapex ER	0.375 mg once daily	Increase up to 0.75 mg/day after a minimum of 5 days. Dose may then be increased in increments of 0.75 mg/day no more frequently than every 5–7 days	Extended-release tablet	
Ropinirole (Requip)	0.25 mg three times daily	Increase about weekly by 0.75–1.5 mg daily to a MD dose of 3–9 mg three times daily Then may increase by 3 mg/day on a weekly basis to a maximum of 24 mg/day	Tablet	
Requip XL	2 mg once daily for 1–2 weeks	Increase by 2 mg/day in 1-week intervals; maximum dose is 24 mg/day	Extended-release tablet	
Rotigotine (Neupro)	2-mg patch once daily for early-stage PD; 4-mg patch for advanced-stage PD	Increase by 2 mg/24 hours on a weekly basis	Patch	

(Continued)

Table 34–2

Dosing of Medications Used to Treat PD[35] (*Continued*)

Generic Name (Trade Name)	Initial Dose	Titration and Maintenance Dose	Available Formulations	Hepatic or Renal Adjustments
MAOIs				
Selegiline (Eldepryl)	5 mg in the morning	If symptoms continue, add 5 mg at noon; 5 mg daily may be as clinically effective as 10 mg daily with fewer side effects	Tablet, capsule	Use is not recommended for CrCl < 30 mL/min (0.5 mL/s) or severe hepatic impairment
Selegiline ODT (Zelapar)	1.25 mg once daily	If symptoms continue after 6 weeks, increase dose to 2.5 mg every morning. Avoid food or liquid for 5 minutes before or after the dose	Dispersible tablet	
Rasagiline (Azilect)	If used with levodopa, 0.5 mg daily	If symptoms continue, increase to 1 mg daily	Tablet	Use 0.5 mg/day in mild hepatic impairment. Do not use in moderate-to-severe impairment
Safinamide (Xadago)	50 mg once daily	May increase after 2 weeks to 100 mg once daily	Tablet	Maximum dose is 50 mg once daily in moderate hepatic impairment and use is contraindicated in severe impairment
COMT Inhibitors				
Tolcapone (Tasmar)	100 mg with first Sinemet dose once daily	If symptoms continue, increase to two and then three times daily, then to 200 mg each dose; usual MD is 100–200 mg three times daily	Tablet	Do not use in patients with active liver disease or SGPT/ALT or SGOT/AST > the upper limit of normal
Entacapone (Comtan)	200-mg tab with each Sinemet dose	Usual MD is 200 mg three to four times daily (up to eight tablets per day)	Tablet	Decrease dose by 50% with hepatic impairment
Opicapone (Ongentys)	50 mg at bedtime	None	Capsule	25 mg in moderate hepatic impairment; avoid in severe impairment
Others				
Amantadine (Symmetrel)	100 mg daily at breakfast	After 1 week, add 100 mg daily; usual MD is 200–300 mg daily with last dose in afternoons	Capsule, tablet, oral syrup	Decrease dose for CrCl < 80 mL/min (1.33 mL/s)
Amantadine XR (Gocovri)	137 mg once daily at bedtime	After 1 week, increase to 274 mg once daily	Extended-release capsule	Start with 68.5 mg once daily in moderate renal impairment and use a maximum dose of 137 mg. In severe renal impairment, use 68.5 mg once daily. Do not use in end-stage renal disease
Amantadine ER (Osmolex ER)	129 mg daily	May increase in weekly intervals to a maximum of 322 mg daily	Extended-release tablet	Start with 129 mg every other day for CrCl 30–59 mL/min (0.5–0.99 mL/s); 129 mg every 96 hours for CrCl 15–29 mL/min (0.25–0.49 mL/s); contraindicated in CrCl < 15 mL/min (0.25 mL/s)
Benztropine (Cogentin)	0.5–1 mg at bedtime	Assess if dose is adequate and titrate by 0.5 mg increments at 5- to 6-day intervals to a maximum of 6 mg if necessary	Tablet, solution for injection	
Istradefylline (Nourianz)	20 mg daily	May increase to 40 mg once daily	Tablet	20 mg daily in moderate hepatic impairment; avoid in severe impairment

Ach, acetylcholine; ALT, alanine transaminase; AST, aspartate aminotransferase; CD, carbidopa; COMT, catechol-*O*-methyltransferase; CR, controlled-release; CrCl, creatinine clearance DA, dopamine; ER, extended-release; LD, levodopa; MAO, monoamine oxidase; MAOI, monoamine oxidase inhibitor; MD, maintenance dose; NMDA, *N*-methyl-D-aspartate; ODT, orally disintegrating tablet; PD, Parkinson disease; SC, subcutaneous; XL, extended release; SGOT, serum glutamic oxaloacetic transaminase; SGPT, serum glutamic pyruvic transaminase; XR, extended-release.

PD drugs and generally relate to dopamine concentrations. Decreasing the dose, frequency, or number of dopaminergic medications may be beneficial. If a PD medication is discontinued, gradual withdrawal is recommended with monitoring of worsening motor symptoms.[30]

▸ *Levodopa/Carbidopa*

Levodopa, a dopamine precursor, remains the most effective agent for PD. Patients experience a 40% to 50% improvement in motor function with levodopa versus 30% with dopamine agonists.[28] However, after 10 years of therapy, close to 90% of patients experience motor complications.[21] Despite this, levodopa is recommended as initial drug therapy and most patients with PD will eventually be treated with it.[15,25,31,32]

Levodopa usually peaks in the plasma in 30 to 120 minutes but the concentration is sensitive to GI variables. Excess stomach acid, food, or medications with anticholinergic properties delay gastric emptying and decrease the amount of levodopa absorbed. Levodopa absorption requires active transport by a large neutral amino acid transporter protein (Figure 34–3). Amino acids in food compete for this transport mechanism. Thus, in advanced disease, avoidance of protein-rich meals in relationship to levodopa doses may be helpful.[3,9]

Controlled-release (CR) formulations act longer than immediate-release tablets but may have erratic absorption. CR preparations are not directly interchangeable with immediate-release but can be added to immediate-release to extend the duration of action. An extended-release (ER) formulation of levodopa (Rytary) is also approved and may provide a more sustained release of levodopa compared to the older CR formulations.[3]

Converting patients from oral formulations to enteral or duodenal levodopa administration improves motor fluctuations and UPDRS scores. The levodopa/carbidopa combination can be administered directly to the duodenum via a small tube. This formulation (Duodopa) is reserved for advanced PD with severe motor fluctuations.[31] Another novel formulation of levodopa includes a dry power inhaler (Inbrija) that can be used for treating off episodes in PD. This is typically reserved for when motor complications develop with standard oral levodopa therapy and as an adjunctive treatment rather than initial monotherapy.[33]

Levodopa is usually administered as a combination product with carbidopa, a dopa-decarboxylase inhibitor, which decreases the peripheral conversion of levodopa to dopamine. This allows for lower levodopa doses and minimizes levodopa peripheral side effects (nausea, vomiting, anorexia, and hypotension). Carbidopa does not cross the blood–brain barrier and does not interfere with

FIGURE 34–3. Levodopa absorption and metabolism. Levodopa is absorbed in the small intestine and distributed into the plasma and brain compartments by an active transport mechanism. Levodopa is metabolized by dopa-decarboxylase, monoamine oxidase, and catechol-*O*-methyltransferase. Carbidopa does not cross the blood–brain barrier. Large neutral amino acids in food compete with levodopa for intestinal absorption (transport across gut endothelium to plasma). They also compete for transport into the brain (plasma compartment to brain compartment). Food and anticholinergics delay gastric emptying resulting in levodopa degradation in the stomach and a decreased amount of levodopa absorbed. If the interaction becomes a problem, administer levodopa 30 minutes before or 60 minutes after meals.

levodopa conversion in the brain. Generally, 75 to 100 mg daily of carbidopa is required to adequately block peripheral dopa-decarboxylase. Higher doses of carbidopa may reduce nausea when initiating levodopa.[9,34]

Initial levodopa side effects include orthostatic hypotension, dizziness, anorexia, nausea, vomiting, and discoloration of urine/sweat. Most of these effects can be minimized by taking levodopa with nonprotein food and by slowly titrating the dose. Side effects that develop later in therapy include dyskinesias, sleep attacks, **impulse control disorders** (ICDs), and psychiatric effects (confusion, hallucinations, nightmares, and altered behavior). Dyskinesias caused by adding other PD drugs to levodopa may be improved by decreasing the levodopa dose.[9,27,34]

▶ *Catechol-O-Methyltransferase (COMT) Inhibitors*

Inhibitors of COMT, an enzyme that catalyzes levodopa to 3-*O*-methyldopa, are added to levodopa/carbidopa to increase levodopa concentrations, extend its half-life, and decrease wearing off time. Using the COMT inhibitors, entacapone, tolcapone, or opicapone, may allow for a decrease in daily levodopa dose while increasing on time by 1 to 2 hours. Side effects include diarrhea, nausea, vomiting, anorexia, dyskinesias, urine discoloration, daytime sleepiness, sleep attacks, orthostatic hypotension, and hallucinations.[9,27]

Tolcapone should be used only in patients who do not tolerate or respond to others in the class due to its hepatic safety profile. Serum liver function tests should be monitored at baseline and throughout therapy.[35,36]

▶ *MAO-B Inhibitors*

Safinamide, selegiline, and rasagiline work through a selective blockade of dopamine metabolism through MAO-B. These provide a mild symptomatic benefit for patients who choose to delay dopaminergic medications and use MAO-B inhibitors as initial therapy. For patients with motor fluctuations, they reduce off time when added to levodopa therapy.[3,12,28]

Selegiline is generally well tolerated. Adverse effects include nausea, confusion, hallucinations, jitteriness, insomnia, and orthostatic hypotension. Selegiline is available as an orally disintegrating tablet (ODT) designed to avoid first-pass metabolism. This improves bioavailability and decreases serum concentrations of its amphetamine-like metabolite that may cause insomnia.[3,15] Daily doses are limited to 10 mg because MAO-B selectivity may be lost at higher doses, increasing the risk of drug and food interactions. Doses for the ODT are lower because this selectivity may be lost at smaller doses with this formulation.[35]

Rasagiline has a similar, generally well-tolerated adverse effect profile but is less likely to cause insomnia compared to selegiline as it lacks the amphetamine-like metabolite. In contrast to nonselective MAOIs, restriction of tyramine-containing foods is not required at recommended dosages, but high tyramine-containing food or exceeding recommend dosing of rasagiline may increase the risk of hypertensive crisis.[35,37]

Safinamide is a newer MAO-B approved for PD. It is indicated specifically in conjunction with levodopa/carbidopa after patients begin to experience off episodes; however, it will likely be used in similar situations as the other MAO-B antagonists.[37,38]

Risk of dyskinesias is minimized by decreasing the levodopa dose when adding any of these agents. Serotonin syndrome and hypertensive crisis may occur in patients using these medications with opioid analgesics, antidepressants and other serotonergic agents, or sympathomimetic amines (cold and weight loss products) (see Chapter 38).[9,15]

▶ *Dopamine Agonists*

Dopamine agonists bind to postsynaptic dopamine receptors and are reasonable as initial therapy. Their advantages include delay of levodopa therapy and smaller risk of developing motor fluctuations during the first 3 to 5 years of treatment. Eventually, they inadequately control the patient's symptoms, and levodopa is necessary. In advanced disease, they can be added to levodopa to minimize response fluctuations, decrease off time, improve wearing off symptoms, and allow a reduction in levodopa dose.[1,15,29,38]

Dopamine agonists include the ergot derivatives (bromocriptine) and the nonergot derivatives (rotigotine, pramipexole, ropinirole, and apomorphine). Generally, the nonergot agents are preferred due to a more favorable adverse-effect profile. Rotigotine is available as a once-daily skin patch and has demonstrated to improve sleep and control of symptoms in the early morning.[1,25] Apomorphine is subcutaneously injected for acute off episodes in advanced PD when rapid rescue therapy is needed. It requires premedication with an antiemetic due to nausea and vomiting.[1,9]

Common side effects with all dopamine agonists include nausea, sedation, pedal edema, orthostatic hypotension, and psychiatric effects that are greater than with levodopa (nightmares, confusion, and hallucinations). Rare, but serious ergot side effects include painful reddish discoloration of the skin over the shins and pleuropulmonary, retroperitoneal, and cardiac fibrosis.[9,30,35] Patients should be given warning information regarding the potential for ICDs and the dopamine dysregulation syndrome (DDS). DDS includes drug seeking and possibly complex stereotyped behavior (**punding**); ICDs manifest as gambling, compulsive shopping, compulsive sexual behavior, or binge eating. While these can occur with other PD drugs, the dopamine agonists are the most risky, particularly in older patients. Data show ICDs may occur in up to 40% of patients with dopamine agonists and are related to dose and duration.[30] Reducing or eliminating the agonist typically resolves these adverse effects.[39]

Dopamine agonists may cause excessive daytime sleepiness in PD patients including sudden sleep attacks that are potentially dangerous.[37,40]

▶ *Anticholinergics*

Ach (typically benztropine and trihexyphenidyl) minimize resting tremor and drooling but are not as effective as other agents for rigidity, bradykinesia, and gait problems. Because of their side effects including cognitive impairment, Ach are typically avoided in older patients, and tend to be used only early in therapy with younger patients.[28] Their inhibition of gastric motility may lead to erratic and decreased levodopa absorption. Lastly, they may worsen urinary retention or constipation.[1]

▶ *Amantadine*

Amantadine is an *N*-methyl-D-aspartate (NMDA)-receptor antagonist that blocks glutamate transmission, promotes dopamine release, and blocks acetylcholine.[35] It is likely effective as monotherapy and adjunct therapy for off time and for dyskinesias.[37,41] ER formulations are approved specifically for dyskinesias in PD making it the only FDA (Food and Drug

Administration)-approved option for this complication.[35,42] Side effects include nausea, dizziness, livedo reticularis, peripheral edema, orthostatic hypotension, hallucinations, restlessness, anticholinergic effects, and insomnia. Insomnia is minimized by taking the ER formulation at bedtime and the immediate release formulation earlier in the day. It should be avoided in the elderly who cannot tolerate its anticholinergic effects.[43]

▸ *Istradefylline*

Approved in the United States in 2019, the adenosine receptor antagonist istradefylline offers a nondopaminergic option for PD patients who experience off episodes. Initial studies found between one half and one hour increase in on time without dyskinesias when added to levodopa therapy. Dizziness, nausea, and hallucinations were among the most common adverse effects seen in clinical trials and concerns with dyskinesia are present with this drug similar to other PD therapies.[44]

▸ *Herbs and Supplements*

There is very little support for using herbals in PD. Patients should eat a balanced diet and monitor weight.[29] Because of osteoporosis and fall risk, consider providing a vitamin D supplement in patients with low concentrations.[24,28]

Treatment of Nonmotor Symptoms

KEY CONCEPT Treatment of nonmotor symptoms should be based on whether they are exacerbated by an off state or might be related to other neurotransmitter dysfunction.

Treatment of nonmotor symptoms includes both pharmacologic and nonpharmacologic approaches with goals of maintaining ADLs, a positive self-image, family communication, and a safe environment.

Psychological Symptoms

Psychological symptoms are common complaints in PD. When these are present, infections, metabolic changes, electrolyte disturbances, or toxic exposures are examined first to rule out other etiologies.

▸ *Depression*

Depression is common in patients with PD, affecting 35% or more of patients, and it often precedes the disease.[36] Although evidence supports efficacy of tricyclic antidepressants, their adverse effects are limiting. Alternatively, selective serotonin reuptake inhibitors may be considered because of their increased tolerability. Antidepressants are also useful for the treatment of anxiety disorders. Pramipexole has demonstrated to improve depression as well in patients with PD.[19,22] Because off periods can both precipitate anxiety and worsen depression, PD therapy should be adjusted to maximize on periods.[11,16]

▸ *Dementia*

Dementia occurs in approximately 80% of patients with PD 20 years after diagnosis. Rivastigmine is considered useful with the highest quality of evidence and is FDA approved for dementia in PD.[11,16,36,37]

Psychosis

Treating psychosis in PD can be difficult as most antipsychotics act as dopamine antagonists, mechanistically opposing PD drugs thus worsening motor symptoms. Additionally, all antipsychotics carry a black box warning of increased risk of death when used in patients with dementia.[35,36] Therefore, first treat any underlying medical causes for psychosis; then, gradually decrease and stop low-efficacy PD medications. If these strategies fail, antipsychotics may be considered.[18] Pimavanserin is the only antipsychotic specifically approved for PD psychosis and has the lowest risk of worsening motor symptoms. However, it is expensive, needs to be dispensed through a specialty pharmacy, interacts with CYP3A4 drugs, and can prolong QT interval.[18,35,45] Two other antipsychotics are recommended over others: clozapine is more effective, but traditionally, low-dose quetiapine has been preferred because clozapine requires monitoring for neutropenia (see Chapter 38). Neither is approved in PD but are preferred because of their weak dopamine antagonism and less frequent movement adverse effects.[11,45] While antipsychotics appear in the Beers criteria with a general recommendation to avoid in the elderly, these three drugs are listed as exceptions in PD patients.[46]

Sleep Problems

Sleep problems and fatigue are common in PD and may be due to medications, uncontrolled symptoms, or other causes such as nocturia, sleep attacks during the day, depression, SBD, or restless legs syndrome (RLS).[36,40] Amantadine and selegiline may worsen insomnia and some antidepressants and antipsychotics may worsen RLS; therefore, careful evaluation of drug regimens is necessary in patients with sleep complaints.

Reducing RLS may be achieved through PD medications. The rotigotine patch improves overall sleep quality as well as morning motor symptoms.[47] Iron supplementation for RLS may decrease levodopa absorption in addition to worsening constipation.[11,16] Improving nighttime motor symptoms, maximizing sleep hygiene, or implementing cognitive behavioral therapy may help as well.[16,47]

Many over-the-counter sleep aids have anticholinergic properties and should be used with caution in this population.

Autonomic and Other Problems

Drooling may accompany speech problems and dysphagia. Ach, botulinum toxin injections, and sublingual atropine can decrease drooling.[30,36]

Sexual dysfunction may respond with increased on time, removal of drugs that decrease sexual response, and pharmacologic therapy (eg, sildenafil).[15,16]

Patients with urinary frequency may find a bedside urinal and decreased evening fluid intake helpful. Improvement in PD symptoms can decrease urinary frequency, but symptoms may require catheterization or pharmacologic measures (eg, solifenacin).[19]

Constipation may improve with increased fluid intake, a fiber-rich diet, probiotics, and physical activity. Stool softeners or other laxatives may help including lubipristone.[15,16,19]

Treating orthostasis includes the removal of offending drugs, increasing carbidopa doses, increasing salt or fluids to the diet, and adding compression stockings or drugs (fludrocortisone, midodrine, and droxidopa). Droxidopa, a norepinephrine synthetic precursor, is approved for treating orthostatic hypotension associated with PD. It can cause supine hypertension, which may be mitigated with elevation of the head of the bed and requires monitoring of blood pressure with treatment. Patients should not take this within 3 hours of bedtime and should take it consistently with or without food.[19,35,37]

Table 34–3

Management of Motor Complications in Advanced PD[2,3,11,13,20,27,29]

I. Motor Fluctuations

Nonpharmacologic Approaches	Drugs to Alter Formulation or Dose	Drugs to Add
A. Suboptimal or delayed peak response		
Take Sinemet on an empty stomach Decrease dietary protein and fat around the delayed dose Minimize constipation Assess for *Helicobacter pylori* infection	Crush Sinemet or make liquid Sinemet Substitute standard Sinemet for some of the Sinemet CR Withdraw drugs with anticholinergic properties	Intermittent subcutaneous apomorphine
B. Optimal peak but early wearing off		
	Decrease dose and increase frequency of standard Sinemet Substitute Sinemet CR for some of the standard Sinemet	Dopamine agonist MAO-B inhibitor Amantadine COMT inhibitor
C. Optimal peak but unpredictable offs		
Adjust time of medications with meals and avoid high-protein meals or redistribute the amount of protein in diet Deep brain stimulation procedure	Substitute or add liquid Sinemet Switch to a different dopamine agonist if already on an agent Consider continuous infusion of levodopa or apomorphine	COMT inhibitor Dopamine agonist if not using one
D. Freezing		
Gait modifications (use visual cues such as walkover lines, tapping, rhythmic commands, rocking; use rolling walker) Physical therapy	Difficult to treat—adjust current medications based on other PD symptoms. Guide changes based on: On freezing, reduce dopamine medications, inject botulinum toxin Off freezing, increase Sinemet dose or add dopamine agonists	If present, treat anxiety with pharmacologic agents

II. Dyskinesias

Nonpharmacologic Approaches	Drugs to Alter Formulation or Dose	Drugs to Add
A. Chorea		
Deep brain stimulation	Decrease risk of occurrence by lowering Sinemet dose when adding other PD medications Evaluate the value of adjunctive PD medications and discontinue if motor complications outweigh benefit Adjust levodopa formulation, dose, or frequency	Amantadine Clozapine
B. Off period dystonia in the early morning		
No recommendations	Add or change short acting to long-acting formulations at bedtime if having nighttime off periods Change morning Sinemet CR dose to immediate-release with or without CR	Apomorphine
C. Diphasic dyskinesia		
Deep brain stimulation	Change CR preparations to immediate release; consider liquid Sinemet Increase Sinemet dose and frequency	Dopamine agonist Amantadine COMT inhibitor

COMT, catechol-*O*-methyl transferase; CR, controlled-release; MAO-B, monoamine oxidase B; PD, Parkinson disease

Treatment of Response Fluctuations

KEY CONCEPT As the disease progresses, most patients develop response fluctuations. Treatment capitalizes on the pharmacokinetic and pharmacodynamic properties of PD medications.

Treatment includes adjusting or adding medications to maximize the patient's on time, minimizing the time with dyskinesia, and minimizing off time (Table 34–3). Levodopa doses and intervals are adjusted for suboptimal or delayed peak levodopa concentrations. Longer acting formulations decrease wearing off periods. Adding or adjusting medications to combat unpredicted off periods and providing treatments that decrease freezing episodes may be necessary. Treatment plans also involve adjusting medication plans or surgery to decrease chorea, dystonia, diphasic dyskinesias, or akathisia.[3,11,14,29]

Patient Encounter Part 3: Follow-up Visit 6 Months Later

Six months have passed since the patient was last seen and her medication was altered. She is still complaining of depression, motor symptoms, and dizziness. Her UPDRS score is unchanged. Her husband has noticed that she is requesting early refills on her pramipexole and is demanding on taking them on time.

Create a problem list and provide an assessment of each problem.

Considering the goals of therapy, treatment options, and your assessment of each of the problems, create a care plan for each problem.

Patient Care Process

Collect Information:

- Review the physical examination and note the specific set of symptoms including their frequency and exacerbating factors.
- Collect diagnostic data such as the UPDRS and compare this to previous encounters.
- Obtain a complete medication list.

Assess the Information:

- Assess PD symptom impact on quality of life (QOL) and ADLs.
- Identify worsening of motor symptoms or disease progression.
- Determine if on time is maximized and whether medications require adjustment.
- Identify drug-induced dyskinesias and note specific times when these occur.
- Evaluate for the appropriate use of each medication including noting drugs, which may worsen PD symptoms as well as polypharmacy for PD.
- Assess if nonmotor symptoms are being adequately addressed.
- Assess the complete PD pharmacologic profile for drug or diet interactions, adverse drug reactions, adherence, and patient understanding of medication regimens.

Develop a Care Plan:

- Identify other specialists to engage in a complete health care team plan.
- Recommend a therapeutic regimen for motor symptoms that increases quality of life and daily functioning.
- Adjust dosages and timing of medications to maximize on time and reduce dyskinesia.
- Recommend drug therapy and other options for nonmotor symptoms that will not worsen motor symptoms.
- Develop a detailed medication administration schedule that is simple for the patient to follow, especially if medications with multiple daily dosing schedules are used.

Implement the Care Plan:

- Educate the patient about lifestyle modifications that will improve symptoms and sustain independence.
- Provide instruction on how to use medications including timing of doses with food.
- Educate the patient on how to adjust medications for fluctuations in response.
- Provide information to the patient and family and document about risks with dopaminergic drugs such as impulse control disorders, sudden sleep attacks, and psychosis.
- Refer the patient and family members to further information such as books and websites (http://www.parkinson.org). Provide information concerning local PD support groups when available.

Follow-up: Monitor and Evaluate:

- Instruct the patient to follow up for assessment of symptoms and disease progression.
- Follow up at least every 6 to 12 months, determine control of symptoms and if drug interactions or adverse reactions are present.
- Provide patient education on changes to medication regimens and nonpharmacologic options.

OUTCOME EVALUATION

KEY CONCEPT Patient monitoring involves a regular systematic evaluation of efficacy and adverse events of medication, referral to appropriate specialists, and patient education. Evaluate clinical outcomes over time by assessing the change in the UPDRS. Instruct patients to record the amount of on and off times daily to guide medication adjustment. Assess fall risk and implement safety measures to prevent falls. Scales assessing QOL, depression, anxiety, and sleep disorders are useful to track progression.

Abbreviations Introduced in This Chapter

Ach	Anticholinergics
ADL	Activities of daily living
COMT	Catechol-*O*-methyltransferase
CR	Controlled-release
DBS	Deep brain stimulation
DDS	Dopamine dysregulation syndrome
GI	Gastrointestinal
ICD	Impulse control disorder
MAO	Monoamine oxidase
NMDA	*N*-methyl-D-aspartate
PD	Parkinson disease
QOL	Quality of life
REM SBD	Rapid eye movement sleep behavior disorder
RLS	Restless legs syndrome
TRAP	Tremor, rigidity, akinesia/bradykinesia, postural/gait instability
UPDRS	Unified Parkinson Disease Rating Scale

Pain Management

Christine Karabin O'Neil

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify characteristics of the types of pain: nociceptive, inflammatory, neuropathic, and nociplastic.
2. Explain the mechanisms involved in pain transmission.
3. Select an appropriate method of pain assessment.
4. Recommend an appropriate choice of analgesic, dose, and monitoring plan for a patient based on type and severity of pain and other patient-specific parameters.
5. Perform calculations involving equianalgesic doses, conversion of one opioid to another, rescue doses, and conversion to a continuous infusion.
6. Educate patients and caregivers about effective pain management, dealing with chronic pain, and the use of nonpharmacologic measures.

INTRODUCTION

Pain is defined by the International Association for the Study of Pain (IASP) as "an unplesant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1] KEY CONCEPT Pain is an unpleasant subjective experience that is the net effect of a complex interaction of the ascending and descending neurons involving biochemical, physiologic, and psychological processes. Pain can affect all areas of a person's life including sleep, thought, emotion, and activities of daily living. There are no reliable objective markers for pain; thus, the patient is the only person who can describe the intensity and quality of their pain.

EPIDEMIOLOGY AND ETIOLOGY

Prevalence of Pain

Most people experience pain at some time in their lives, and pain is a symptom of a variety of diseases. Thus, identifying the exact prevalence of pain is a difficult task. Prevalence rates for a variety of different types of pain have been described (Table 35–1). Patients 65 years and older bear a significant burden of pain. The prevalence of pain in people older than 60 years is twice that in those younger than 60 years.[2] Studies suggest that 25% to 50% of community-dwelling elderly suffer pain. Pain is quite common among nursing home residents. It is estimated that 45% to 80% of nursing home patients and 25% of those with daily pain received neither analgesic medication nor nonpharmacologic treatment for their pain, contributing to functional impairment and a decreased quality of life.[2]

The financial impact of pain is considered to be significant. The total cost of pain in the United States has been estimated at $560 to $635 billion annually; about half of this cost is due to direct costs of health care while the other half is due to lost productivity.[3]

Challenges in Pain Management

Effective pain management should be balanced and multimodal, including, in some cases, the use of opioid analgesics. However, there is growing controversy over both the efficacy and the safety of opioid analgesics in managing patients with chronic pain. In 2011, the Institute of Medicine outlined several other important principles to guide the transformation of pain care, which included the following[4]:

- Effective pain management is a "moral imperative."
- Pain should be considered a disease with distinct pathology.
- There is a need for interdisciplinary treatment approaches.
- The effectiveness of pain treatment depends on a strong clinician–patient relationship.

Barriers to adequate pain management may be due to the fear of becoming addicted to opioids or cultural beliefs. Patients might not report pain for a variety of reasons including belief that pain is something they must live with, fear of consequences (eg, hospitalization, loss of independence), fear that the pain might be forecasting impending illness, the inability to understand terminology used by health care providers, or a belief that showing pain is unacceptable behavior.

Concerns about adequate pain management must be balanced with concerns about opioid misuse and diversion to achieve optimal pain management. Opioid use, misuse, and adverse effects have risen to epidemic proportions since the 1990s. While the United States has 4.4% of the global population, the country used 80% of the world's opioid supply.[5] Over the last 18 years, there has been an increase in deaths related to prescription opioids and increase in over doses due to illicit opioids.[6] Several recent guidelines have been published by the Centers for Disease Control and Prevention (CDC) and American Society of Interventional Pain

Table 35–1

Prevalence of Selected Pain Diagnoses[44–49]

Pain Diagnoses	Prevalence (%)
Back pain	74.7
Cancer	14–100
Chronic pain	10.4
Complex regional pain syndrome	1.2
Degenerative spine disease	63.6
Fibromyalgia	2
Limb pain	50
Migraine	12
Neuritis/radiculitis	52.8
Neuropathic pain	9.8

Physicians (ASIPP) to provide guidance for the use of opioids to ensure patients have access to safer, more effective chronic pain treatment while reducing the number of people who misuse or overdose from these drugs.[7,8] Risk assessment and monitoring of opioid use includes a clinical interview with special attention to the effects of opioids or illnesses suggestive of substance abuse, pain characteristics, and consequences, use of prescription drug monitoring program and risk assessment tools (ie, Opioid Risk Tool), initial urine drug screens, and screening for sleep disorders and mental health issues. Implementation of risk assessment and mitigation strategies along with a heightened awareness by clinicians of the potential deleterious effects of opioids has led to a plateau or decline in diversion and abuse of prescription opioids in recent years.[9]

PATHOPHYSIOLOGY

Types of Pain

Several distinct types of pain have been described, for example, nociceptive, inflammatory, neuropathic, and nociplastic.[1] Nociceptive pain is a transient pain in response to a noxious stimulus at nociceptors that are located in cutaneous tissue, bone, muscle, connective tissue, vessels, and viscera. Nociceptors are classified as thermal, chemical, or mechanical. The nociceptive system extends from the receptors in the periphery to the spinal cord, brainstem, and the cerebral cortex where pain sensation is perceived. This system is a key physiologic function that prevents further tissue damage due to the body's autonomic withdrawal reflex. When tissue damage occurs despite the nociceptive defense system, inflammatory pain ensues. The body now changes focus from protecting against painful stimuli to protecting the injured tissue. The inflammatory response contributes to pain hypersensitivity that serves to prevent contact or movement of the injured part until healing is complete, thus reducing further damage.

Neuropathic pain is defined as spontaneous pain and hypersensitivity to pain associated with damage to or pathologic changes in the peripheral or central nervous system (CNS).[1] Nociplastic pain, a relatively newer concept, is pain sensitivity due to an abnormal processing or functioning of the CNS in response to normal stimuli. Several conditions considered to have this abnormal sensitivity or hyperresponsiveness include fibromyalgia and irritable bowel syndrome.

Mechanisms of Pain

▶ *Pain Transmission*

The mechanisms of nociceptive pain are well defined and provide a foundation for the understanding of other types of pain.[10] Following nociceptor stimulation, tissue injury causes the release of substances (bradykinin, serotonin, potassium, histamine, prostaglandins, and substance P) that might further sensitize and/or activate nociceptors. Nociceptor activation produces action potentials (transduction) that are transmitted along myelinated Aδ-fibers and unmyelinated C-fibers to the spinal cord. The Aδ-fibers are responsible for first, fast, sharp pain, and release excitatory amino acids that activate α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors in the dorsal horn. The C-fibers produce second pain, which is described as dull, aching, burning, and diffuse. These nerve fibers synapse in the dorsal horn of the spinal cord, where several neurotransmitters are released including glutamate, substance P, and calcitonin gene-related peptide. Transmission of pain signals continues along the spinal cord to the thalamus, which serves as the pain relay center, and eventually to the cortical regions of the brain where pain is perceived.

▶ *Pain Modulation*

Modulation of pain (inhibition of nociceptive impulses) can occur by a number of processes. Based on the gate-control theory, pain modulation might occur at the level of the dorsal horn.[11] Because the brain can process only a limited number of signals at one time, other sensory stimuli at nociceptors might alter pain perception. This theory supports the effectiveness of counterirritants and transcutaneous electrical nerve stimulation (TENS) in pain management. Pain modulation can occur through several other complex processes. The endogenous opiate system consists of endorphins (enkephalins, dynorphins, and β-endorphins) that interact with μ-, δ-, and κ-receptors throughout the CNS to inhibit pain impulses and alter perception. The CNS also includes inhibitory descending pathways from the brain that can attenuate pain transmission in the dorsal horn. Neurotransmitters involved in this descending system include endogenous opioids, serotonin, norepinephrine, γ-aminobutyric acid (GABA), and neurotensin. The perception of pain involves not only nociceptive stimulation but also physiologic and emotional input. Consequently, cognitive behavioral treatments such as distraction, relaxation, and guided imagery can reduce pain perception by altering pain processing in the cortex.

▶ *Peripheral Sensitization, Central Sensitization, and Windup*

Under normal conditions, a balance generally exists between excitatory and inhibitory neurotransmission. Changes in this balance can occur both peripherally and centrally, resulting in exaggerated responses and sensitization, such as that observed in inflammatory, neuropathic, or nociplastic chronic pain. Pain in these settings might occur spontaneously without any stimulus or might be evoked by a stimulus. Evoked pain might arise from a stimulus that normally does not cause pain (allodynia) such as a light touch in neuropathic pain. Hyperalgesia, an exaggerated and/or prolonged pain response to a stimulus that normally causes pain, can also occur as a result of increased sensitivity in the CNS.

During normal pain transmission, the AMPA receptors are activated, but the *N*-methyl-ᴅ-aspartate (NMDA) receptor is blocked by magnesium.[10] Repeated nerve depolarization causes release of the magnesium block, allowing the influx of calcium and sodium, and results in excessive excitability and amplification of signals. Continued input from C-fibers and subsequent increases in substance P and glutamate causes the activation of the NMDA receptor, a process referred to as windup. Windup increases the number and responsiveness of neurons in the dorsal horn irrespective of the input from the periphery. Recruitment of neurons not normally involved in pain transmission or spread occurs, leading to allodynia, hyperalgesia, and spread to uninjured tissues.[12] The windup phenomenon supports the observation that untreated acute pain can lead to chronic pain and the belief that pain processes are plastic and not static.

CLINICAL PRESENTATION AND DIAGNOSIS

Classification of Pain

Pain has always been described as a symptom. However, recent advances in the understanding of neural mechanisms have demonstrated that unrelieved pain might lead to changes in the nervous system known as neural plasticity. Because these changes reflect a process that influences a physiologic response, pain, particularly chronic pain, might be considered a disease unto itself.

Pain can be divided into two broad categories: acute and chronic pain. Acute pain is also referred to as adaptive pain because it serves to protect the individual from further injury or promote healing.[11] However, chronic pain has been called maladaptive, a pathologic function of the nervous system or pain as a disease.

► *Acute Pain*

Acute pain is pain that occurs as a result of injury or surgery and usually self-limited, subsiding when the injury heals. Untreated acute pain can produce physiologic symptoms including tachypnea, tachycardia, and increased sympathetic nervous system activity, such as pallor, diaphoresis, and pupil dilation. Furthermore, poorly treated pain can cause psychological stress and compromise the immune system due to the release of endogenous corticosteroids. Somatic acute pain arises from injury to skin, bone, joint, muscle, and connective tissue, and it is generally localized to the site of injury. Visceral pain involves injury to nerves on internal organs (eg, intestines, liver) and can present as diffuse, poorly differentiated, and often referred pain. Acute pain should be treated aggressively, even before the diagnosis is established, except in conditions of head or abdominal injury where pain might assist in the differential diagnosis.

► *Chronic Pain*

Chronic pain persists beyond the expected normal time for healing and serves no useful physiologic purpose. Chronic pain might be nociceptive, inflammatory, neuropathic, or nociplastic in origin; however, all forms share some common characteristics. Chronic pain can be intermittent or persistent, or both. Physiologic responses observed in acute pain are often absent in chronic pain; however, other symptoms might predominate. The four main effects of chronic pain include (a) effects on the physical function, (b) psychological changes, (c) social consequences, and (d) societal consequences. Effects of chronic pain on physical function include impaired activities of daily living and sleep disturbances. Psychological components of chronic pain might include depression, anxiety, anger, and loss of self-esteem. As a result of physical and psychological changes, social consequences might ensue, such as changes in relationships with friends and family, intimacy, and isolation. Management of chronic pain should be multimodal and might involve cognitive interventions, physical manipulations, pharmacologic agents, surgical intervention, and regional or spinal anesthesia.

Chronic Malignant Pain Chronic malignant pain is associated with a progressive disease that is usually life-threatening such as cancer, acquired immunodeficiency syndrome (AIDS) AIDS, progressive neurologic diseases, end-stage organ failure, and dementia.[13] The goal is pain alleviation and prevention, often through a systematic and stepwise approach. Tolerance, dependence, and addiction are often not a concern due to the terminal nature of the illness.

Clinical Presentation and Diagnosis of Pain

General

Patients may be in acute distress (acute pain) or have no signs or symptoms of suffering (chronic pain).

Symptoms

Pain is described based on the following characteristics: onset, duration, location, quality, severity, and intensity. Other symptoms may include anxiety, depression, fatigue, anger, fear, and insomnia.

Signs

Acute pain may cause hypertension, tachycardia, diaphoresis, mydriasis, and pallor.

Diagnosis

The patient is the only person who can describe the intensity and quality of their pain. There are no laboratory tests that can diagnose pain.

Chronic Nonmalignant Pain Pain not associated with a life-threatening disease and lasting more than 6 months beyond the healing period is referred to as chronic nonmalignant pain. Pain associated with low back pain, osteoarthritis, previous bone fractures, peripheral vascular disease, genitourinary infection, rheumatoid arthritis, and coronary heart disease is considered nonmalignant. The numerous causes of this type of chronic pain make treatment complex and involves a multidisciplinary approach. Treatment is initially conservative utilizing a combination of nonpharmacologic and pharmacologic modalities such as acetaminophen, oral and topical nonsteroidal anti-inflammatory agents, and adjunctive treatment based on the cause of the pain. In cases of inadequate response to an adequate trial of initial therapy, the use of more potent analgesics including opiates may be considered with careful monitoring.[14]

Neuropathic Pain Neuropathic pain is considered to be a type of chronic nonmalignant pain involving disease of the central and peripheral nervous systems. Neuropathic pain might be broadly categorized as peripheral or central in nature. Examples of neuropathic pain include postherpetic neuralgia (PHN), which is pain associated with acute herpetic neuralgia or an acute shingles outbreak. Peripheral or polyneuropathic pain is associated with the distal polyneuropathies of diabetes, human immunodeficiency virus (HIV), and chemotherapeutic agents. Types of central pain include central stroke pain, trigeminal neuralgia, and a complex of syndromes known as complex regional pain syndrome (CRPS). CRPS includes both reflex sympathetic dystrophy and causalgia, both of which are neuropathic pain associated with abnormal functioning of the autonomic nervous system.

The symptoms of neuropathic pain are characterized as tingling, burning, shooting, stabbing, electric shock-like quality, or radiating pain. The patient might describe either a constant dull throbbing or burning pain, or an intermittent pain that is stabbing or shooting. Damage to the peripheral nerves might frequently be referred to the body region innervated by those nerves.

Pain Assessment

Effective pain management begins with a thorough and accurate assessment of the patient. Even though pain is a common presenting complaint, lack of regular assessment and reassessment of pain remains a problem and contributes to the mismanagement of pain.[15]

KEY CONCEPT Following initial assessment of pain, reassessment should be done as needed based on medication choice and the clinical situation.

▶ *Methods of Pain Assessment*

A patient-oriented approach to pain is essential, and methods do not differ greatly from those used in other medical conditions. A comprehensive history (medical, family, and psychological) and physical are necessary to evaluate underlying disease processes for the source of pain and other factors contributing to the pain.[12] A thorough assessment of the characteristics of the pain should be completed, including questions about the pain (onset, duration, location, quality, severity, and intensity), pain relief efforts, and efficacy and side effects of current and past treatments for pain. A common mnemonic for pain assessment is PQRST (Palliative/precipitating, Quality, Radiation, Severity, and Time).[16] Some clinicians have suggested the addition of U ("understanding how pain affects you") to this mnemonic.[17] During the interview, the impact of pain on the patient's functional status, behavior, and psychological status should also be assessed. Evaluation of psychological status is especially important in patients with chronic pain because depression and other affective disorders might be common comorbid conditions. A history of drug and alcohol use should be elicited due to the potential for addiction in patients who take opioids or other pain medications with a potential for misuse. Other conditions, such as renal or hepatic dysfunction, diabetes, and conditions that affect bowel function, can influence therapy choices and goals. A discussion of the patient's expectations and goals with respect to pain management (level of pain relief, functional status, and quality of life) should also be part of any pain interview.

▶ *Pain Assessment Tools*

Pain, particularly acute pain, might be accompanied by physiologic signs and symptoms, but there are no reliable objective markers for pain. Many tools have been designed for assessing the severity of pain including rating scales and multidimensional pain assessment tools.

Rating scales provide a simple way to classify the intensity of pain, and they should be selected based on the patient's ability to communicate (Figure 35–1).[18] Numeric scales are widely used and ask patients to rate their pain on a scale of 0 to 10, with 0 indicating no pain and 10 being the worst pain possible. Using this type of scale, 1 to 3 is considered mild pain, 4 to 6 is moderate pain, and 7 to 10 is severe pain. The visual analog scale (VAS) is similar to the numerical scale in that it requires patients to place a mark on a 10-cm line where one end is no pain, and the worst possible pain is on the other end. For patients who have difficulty assigning a number to their pain, a categorical scale might be an option to communicate the intensity of the pain experience. Examples of this include a simple descriptive list of words and the Wong–Baker FACES of Pain Rating Scale.[19]

Multidimensional assessment tools obtain information about the pain and impact on quality of life, but they are often more time-consuming to complete. Examples of these types of tools include the Initial Pain Assessment Tool, Brief Pain Inventory, McGill Pain Questionnaire, the Neuropathic Pain Scale, and the Oswestry Disability Index.[20–24] The Pain, Enjoyment of Life and General Activity (PEG) assessment tool is an ultrabrief pain assessment tool derived from the Brief Pain Inventory and recommended by the CDC.[25] The PEG score is the average of three individual scores.

▶ *Pain Assessment in Challenging Populations*

Children Pain interviews can be conducted with children as young as 3 or 4 years of age; however, communication might be limited by vocabulary.[26] Terms familiar to children such as "*hurt*", "*owie*", or "*boo boo*" might be used to describe pain. The VAS is best used with children older than 7 years. Other scales based on numbers of objects (eg, pokers chips), increasing color intensity,

Patient Encounter, Part 1

HPI: A 72-year-old woman with a tumor of the right fallopian tube is to undergo surgery to remove the tumor.

PMH: Hypothyroidism for 40 years; hypertension for 20 years; atrial fibrillation for 5 years; depression for 2 years.

FH: Mother had osteoporosis; father had diabetes

SH: Lives with husband; has four grown children

Meds: Metoprolol succinate ER 50 mg daily; rivaroxaban 20 mg daily; levothyroxine 150 mcg daily; polyethylene glycol 3350 17 g daily; lisinopril 2.5 mg daily; amiodarone 200 mg daily; sertraline 50 mg daily

Pain Assessment: Patient rates pain as 4 on a scale of 0 to 10

Based on the type of injury, what type of pain is this patient likely to experience?

What type of pain management regimen would you recommend in the postoperative period? Explain your answer.

or faces of pain might be helpful for children between 4 and 7 years of age. In children younger than 3 to 4 years, behavioral or physiologic measures, such as pulse or respiratory rate, might be more appropriate. Pain assessment in newborns and infants relies on behavioral observation for such clues as vocalizations (crying and fussing), facial expressions, body movements (flailing of limbs and pulling legs in), withdrawal, and change in eating and sleeping habits.[26] Preschool children experiencing pain might become clingy, lose motor and verbal skills, and start to deny pain because treatment might be linked to discomfort or punishment. School-aged children might exhibit aggressiveness, nightmares, anxiety, and withdrawal when in pain; adolescents might respond to pain with oppositional behavior and depression.

Elderly Most of the previously discussed pain scales can be used in older persons who are cognitively intact or with mild dementia. The pain thermometer and FACES of pain have been studied in older persons. In persons with moderate-to-severe dementia or those who are nonverbal, observation of pain behaviors, such as guarding or grimacing, provides an alternative for pain assessment. The Pain Assessment in Advanced Dementia (PAINAD) tool might be used to quantify signs of pain and involves observing the older adult for 15 minutes for breathing, negative vocalizations, facial expression, body language, and consolability.[27] Regardless of which pain assessment tool is used, the practitioner should first determine if the patient understands the concept of the scale to ensure reliability of the instrument.

TREATMENT

Desired Outcomes

Prevention, reduction, and/or elimination of pain are important goals for the treatment of acute pain. With chronic pain, elimination of pain might not be possible, and goals might focus on improvement or maintenance of functional capacity and quality of life.

General Approach to Treatment

KEY CONCEPT Effective treatment involves an evaluation of the cause, duration, and intensity of the pain and selection of an appropriate treatment modality for the pain situation. Depending on the type of pain, treatment might involve pharmacologic and nonpharmacologic therapy or both. General principles for the pharmacologic management of pain are listed in the section "Patient Care Process." Two common approaches to the selection of treatment are based on severity of pain and the mechanism responsible for the pain (Figure 35–2). Clinical practice guidelines for pain management are available from the American Pain Society (APS), the Agency for Healthcare Research and Quality (AHRQ), the American Geriatrics Society (AGS), and the American Society of Anesthesiologists (ASA).

▶ *Selection of Agent Based on Severity of Pain*

KEY CONCEPT Whenever possible, the least potent oral analgesic should be selected. Guidelines for the selection of therapeutic agents based on pain intensity are derived from the World Health Organization (WHO) analgesic ladder for the management of cancer pain (Table 35–2).[28] Mild-to-moderate pain is generally treated with nonopioid analgesics. Combinations of medium-potency opioids and acetaminophen (APAP) or nonsteroidal anti-inflammatory drugs (NSAIDs) are often used for moderate pain. Potent opioids are recommended for severe pain. Throughout this progression, adjuvant medications are added, as needed, to manage side effects and to augment analgesia. While these guidelines can be useful for initial therapy, the clinical situation (type of pain), cost, pharmacokinetic profile of available drugs,

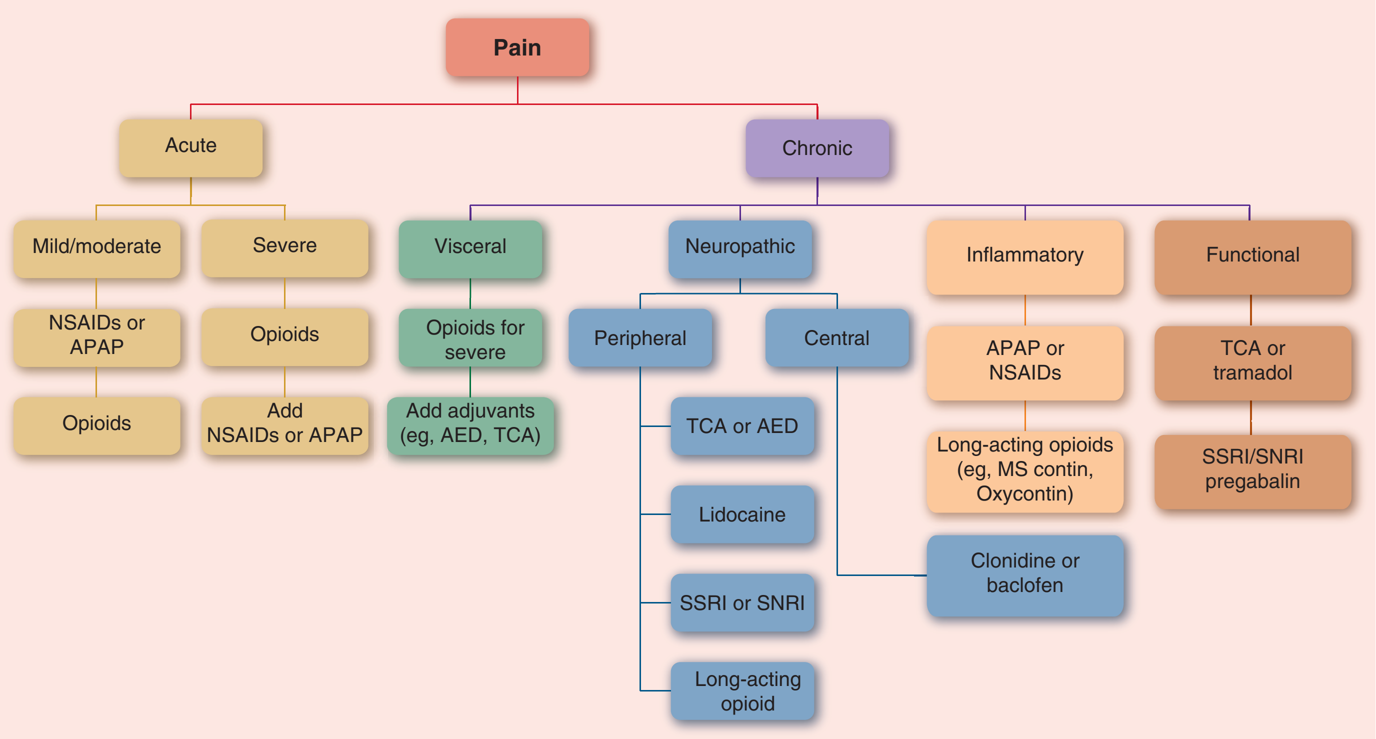

FIGURE 35–2. Pain algorithm. (AED, antiepileptic drugs; APAP, acetaminophen; MS, morphine sulfate; NSAIDs, nonsteroidal anti-inflammatory drugs; SNRI, serotonin norepinephrine reuptake inhibitors; SSRI, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants).

Table 35–2

Selection of Analgesics Based on Intensity of Pain[28,29,32]

Pain Intensity	Corresponding Numerical Rating	WHO Therapeutic Recommendations	Examples of Initial Therapy	Comments
Mild	1–3/10	Nonopioid analgesic; regular scheduled dosing	Acetaminophen 1000 mg every 6 hours; ibuprofen 600 mg every 6 hours	Consider adding an adjunct or using an alternate regimen if pain is not reduced in 1–2 days
Moderate	4–6/10	Add an opioid to the nonopioid for moderate pain; regular scheduled dosing	Acetaminophen 325 mg + codeine 60 mg every 4 hours; acetaminophen 325 mg + oxycodone 5 mg every 4 hours	Consider step-up therapy if pain is not relieved by two or more different drugs
Severe	7–10/10	Switch to a high-potency opioid; regular scheduled dosing	Morphine 10 mg every 4 hours; hydromorphone 4 mg every 4 hours	

and patient-specific factors (age, concomitant illnesses, previous response, and other medications) must also be considered. Pain medications might also be used in the absence of pain in anticipation of a painful event such as surgery to minimize peripheral and central sensitization.

▶ *Mechanistic Approach to Therapy*

Current analgesic therapy is aimed at controlling or blunting pain symptoms. However, diverse mechanisms contributing to various types of pain continue to be further elucidated. An understanding of these new mechanisms of pain transmission might lead to improvement in pain management as pharmacologic management of pain becomes more mechanism specific. Use of NSAIDs for inflammatory types of pain is an example of a mechanistic approach. Because several mechanisms of pain often coexist, a multimodal approach seems rational to target each mechanism.

Nonpharmacologic Therapy

Nonpharmacologic therapies (psychological interventions and physical therapy) might be used in both acute and chronic pain. Psychological interventions can reduce pain as well as the anxiety, depression, fear, and anger associated with pain. Psychological interventions helpful in management of acute pain are imagery (picturing oneself in a safe, peaceful place) and distraction (listening to music or focusing on breathing). Chronic pain patients might benefit from relaxation, biofeedback, cognitive behavioral therapy, psychotherapy, support groups, and spiritual counseling.

Physical therapy is an essential part of many types of pain situations. Treatment modalities include heat, cold, water, ultrasound therapy, TENS, massage, and therapeutic exercise. Heat and cold therapy are utilized in a variety of musculoskeletal conditions (muscle spasms, low back pain, fibromyalgia, sprains, and strains).

Pharmacologic Therapy

▶ *Nonopioid Analgesics*

Acetaminophen APAP, an analgesic and antipyretic, is often selected as initial therapy for mild-to-moderate pain and considered first line in several pain situations such as low back pain and osteoarthritis.[29] Mechanistically, APAP is believed to inhibit prostaglandin synthesis in the CNS and block pain impulses in the periphery. APAP is well tolerated at usual doses and has few clinically significant drug interactions except causing increased hypoprothrombinemic response to warfarin in patients receiving APAP doses of more than 2000 mg/day.[30] The maximum recommended dose for patients with normal renal and hepatic function is 4000 mg/day. Hepatotoxicity has been reported with excessive use and overdose, and the risk of this adverse effect increases in those with hepatitis or chronic alcohol use, as well as those who binge drink or are in a fasting state. Due to concerns of unintentional overuse and hepatoxicity, the FDA requires warning labels on over-the-counter (OTC) APAP products and limited the APAP component of narcotic analgesic combination to 325 mg per dosing unit. For these reasons, the maximum dose should be reduced by 50% to 75% in patients with renal dysfunction or hepatic disease and in those who engage in excessive alcohol use.

Aspirin and Other Salicylates Aspirin, nonacetylated salicylates, and other NSAIDs have analgesic, antipyretic, and anti-inflammatory actions. These agents inhibit cyclooxygenase (COX-1 and COX-2) enzymes, thereby preventing prostaglandin synthesis, which results in reduced nociceptor sensitization and an increased pain threshold.

Aspirin is effective for mild-to-moderate pain; however, the risk of gastrointestinal (GI) irritation and bleeding limits frequent use of this drug for pain management. Direct effects of aspirin on the GI mucosa and irreversible platelet inhibition contribute to this risk, which can occur even at low doses. Hypersensitivity reactions are also possible and might occur in 25% of patients with coexisting asthma, nasal polyps, or chronic urticaria. Of additional concern is the potential for cross-sensitivity of other NSAIDs in this group of patients. Nonacetylated salicylates (choline magnesium salicylate and sodium salicylate) have reduced risk of GI effects and platelet inhibition and might be used in aspirin-sensitive patients.

Nonsteroidal Anti-inflammatory Drugs NSAIDs are the preferred agents for mild-to-moderate pain in conditions that are mediated by prostaglandins (rheumatoid arthritis, menstrual cramps, and postsurgical pain) and in the management of pain from bony metastasis, but they are of minimal use in neuropathic pain. NSAIDs provide analgesia equal to or better than that of aspirin or APAP combined with codeine, and they are very effective for inflammatory pain and pain associated with bone metastasis.[10] These agents are classified by their chemical structures (fenamates, acetic acids, propionic acids, pyranocarboxylic acids, pyrrolizine carboxylic acids, and COX-2 inhibitors). Although only some members of this class have approval for treatment of pain, it is likely that all of them have similar analgesic effects. All members of this class appear to be equally effective, but there is great intrapatient variability in response. After an adequate trial of 2 to 3 weeks with a particular oral agent, it is reasonable to switch to another member of the class. Ketorolac and ibuprofen are available in parenteral and oral dosage forms; unlike other NSAIDs, ketorolac's duration of use is limited to 5 days due to risk of serious GI side effects. NSAIDs demonstrate a flat-dose response curve, with higher doses producing no greater efficacy than moderate doses but resulting in an increased incidence of adverse effects (GI irritation, hepatic dysfunction, renal insufficiency, platelet inhibition, sodium retention, and CNS dysfunction).

Patients at increased risk of NSAID-induced GI adverse effects (eg, dyspepsia, peptic ulcer formation, and bleeding) include the elderly, those with peptic ulcer disease, coagulopathy, and patients receiving high doses of concurrent corticosteroids. Nephrotoxicity is more common in the elderly, patients with creatinine clearance values less than 50 mL/min (0.83 mL/s), and those with volume depletion or on diuretic therapy. NSAIDs should be used with caution in patients with reduced cardiac output due to sodium retention and in patients receiving antihypertensives, warfarin, and lithium.

NSAIDs are classified as nonselective (they inhibit COX-1 and COX-2) or selective (inhibit only COX-2) based on degree of COX inhibition. COX-2 inhibition is responsible for anti-inflammatory effects, whereas COX-1 inhibition contributes to increase GI and renal toxicity associated with nonselective agents. Because the antiplatelet effect of nonselective NSAIDs is reversible, concurrent use might reduce the cardioprotective effect of aspirin due to competitive inhibition of COX-1. A boxed warning highlighting the potential for increased risk of cardiovascular events and GI bleeding is now required for all prescription nonselective NSAIDs and celecoxib. Stronger warnings about these adverse events are also required on nonprescription NSAIDs. When an NSAID is needed in a patient with cardiovascular risk, the benefits of therapy must outweigh the risks, and the lowest effective dose of the NSAID is recommended.[31]

▶ *Opioid Analgesics*

Opioids are considered the agents of choice for the treatment of severe acute pain and moderate-to-severe pain associated with cancer.[32] Opioids are classified by their activity at the receptor site, usual pain intensity treated, and duration of action (short acting versus long acting).

Selection and Dosing The opioids exert their analgesic efficacy by stimulating opioid receptors (μ, κ, and δ) in the CNS. There is a wide variety of potencies among the opioids, with some used for moderate pain (codeine, hydrocodone, tramadol, and partial agonists) and others reserved for severe pain (morphine and hydromorphone). Pure agonists (morphine) bind to μ-receptors to produce analgesia that increases with dose without a ceiling effect. Pure agonists are divided into three chemical classes: phenanthrenes or morphine-like, phenyl piperidine or meperidine-like, and diphenyl heptane or methadone-like. Partial agonists at the μ-receptor (ie, buprenorphine, butorphanol, and tramadol) cause less conformational change and receptor activation than full agonists. At low doses, both full and partial agonists may provide similar effects to their full agonist agents. However, when the dose of partial agonists increases, the analgesic activity will plateau, and further increases in doses will not provide additional relief but may increase the adverse effects. Mixed agonists/antagonists (ie, buprenorphine, butorphanol, nalbuphine, and pentazocine.) demonstrate varying activity depending on the opioid receptor but also varying on the dose. Partial agonists at the μ-receptor may cause reduced side effects but may precipitate withdrawal in patients who are dependent on pure agonists. Agents with high affinity for κ-receptors (pentazocine, nalbuphine, and butorphanol) are more likely to cause psychomimetic effects. Buprenorphine, a partial μ-agonist and κ antagonist, is indicated at high doses for opioid-use disorder while generally at lower doses to treat moderate-to-severe pain. Selection of the agent and route depend on individual patient-related factors including severity of pain, individual perceptions, weight, age, opioid tolerance, and concomitant disease (renal or hepatic dysfunction). Because pure agonists are pharmacologically similar, choice of agent might be also guided by pharmacokinetic parameters and other drug characteristics. Hepatic impairment can decrease the metabolism of most opioids, particularly methadone, meperidine, and pentazocine. Furthermore, the clearance of meperidine and morphine and their metabolites is reduced in renal dysfunction.

Table 35–3 provides a summary of opiate options, but several drugs warrant further discussion. Normeperidine, the active metabolite of meperidine, can produce tremors, myoclonus, delirium, and seizures. Due to the potential for accumulation of normeperidine, meperidine should not be used in the elderly, those with renal impairment, in patients using patient-controlled analgesia (PCA) devices, or for more than 1 to 2 days of intermittent dosing. Methadone is unique among the opioids because it has several mechanisms (μ-agonist, NMDA-receptor antagonist, and inhibition of reuptake of serotonin and norepinephrine). The long half-life of methadone (30 hours) permits extended dosing intervals; however, the potential for accumulation with repeated dosing often results in challenging dose conversion and concerns for respiratory depression. Another safety concern with methadone involves the risk of arrhythmia secondary to QT prolongation. Tramadol is a synthetic opioid with a dual mechanism of action (μ-agonist and inhibition of serotonin and norepinephrine reuptake) and efficacy and safety similar to that of codeine plus APAP. Tramadol has been evaluated in several types of neuropathic pain and might have a role in the treatment of chronic pain. Tramadol is associated with an increased risk of seizures in patients with a seizure disorder, those at risk for seizures, and

Table 35–3

Equianalgesic Doses of Selected Opioids[17,32,35,36]

	Dose Equianalgesic to 10 mg of Parenteral Morphine (mg)	
Opioid (Brand Name)	**Parenteral (mg)**	**Oral (mg)**
Mild-to-Moderate Pain		
Codeine (generic, various)	120	200
Hydrocodone (Vicodin, Lorcet)	N/A	30
Oxycodone (OxyContin, OxyFAST, Oxy IR)	N/A	20
Meperidine (Demerol)	100	400
Moderate-to-Severe Pain		
Morphine (Roxanol, MS Contin, Kadian, Avinza)	10	30
Hydromorphone (Dilaudid)	1.5	7.5
Oxymorphone (Opana, Opana SR, Numorphan)	1	N/A
Levorphanol (Levo-Dromoran)	2	4
Fentanyl (Duragesic)	0.1–0.2	N/A[a]
Methadone (Dolophine)	10[b]	3–5[b]

[a] Transdermal: 100 mcg/hour = 2–4 mg/hour of IV morphine.

[b] Dosage calculations when converting from morphine to methadone are not linear. The equianalgesic dose of methadone will decrease progressively as the morphine equivalents increase (Table 35–4).

IR, immediate release, MS, morphine sulfate, SR, sustained release.

those taking medications that can lower the seizure threshold. The use of tramadol with other serotonergic drugs (eg, selective serotonin reuptake inhibitors [SSRIs]) might precipitate serotonin syndrome. Although originally thought not to be habit forming, dependence can occur with tramadol.

About 70% of individuals will experience significant analgesia from 10 mg/70 kg of body weight of intravenous (IV) morphine or its equivalent.[10] For severe pain in opiate-naive patients, a usual starting dose is 5 to 10 mg of IV morphine every 4 hours. In the initial stages of severe pain, medications should be given around the clock. Rescue doses should be made available for breakthrough pain in doses equivalent to 10% to 20% of the total daily opioid requirement and administered every 2 to 6 hours if needed. Alternatively, one-sixth of the total daily dose or one-third of the 12-hourly dose might be used. Scheduled doses should be titrated based on the degree of pain. One method involves adjustment of the maintenance dose based on the total 24-hour rescue dose requirement. Alternatively, utilizing dose escalation, doses could be increased by 50% to 100% or 30% to 50% of the current dose, for those in severe and moderate pain, respectively. Once pain relief is achieved, and if treatment is necessary for more than a few days for cancer-related pain, conversion to a controlled-release or long-acting opioid may be made with an equal amount of agent. Several sustained-release products are available containing morphine, oxycodone, and fentanyl. Some clinicians will reduce the total daily dose of the long-acting dosage form by 25% when initiating a sustained-release product to reduce the likelihood of oversedation. The dose of a pure agonist is limited only by tolerability to side effects. Tolerance might develop to analgesic effects, necessitating increasing doses to achieve the same level of pain relief. Physical dependence will occur with the long-term use of opioids.[33]

Opioids are not first-line therapy for chronic pain. In response to the increase in opioid use and adverse events associated with such use, guidelines for the use of opioids in chronic pain have been recommended by the CDC.[8] The guidelines are not intended for patients receiving opioids for cancer treatment, palliative care, or in end-of-life. Table 35–4 provides a summary of these guidelines. In addition to these guidelines, the use of informed consent for chronic opioid therapy, medication management agreements, or pain contracts might be appropriate to monitor the use (prescribing and dispensing) of controlled substances.

Opioids are administered by a variety of routes, including oral (tablet and liquid), sublingual, rectal, transdermal, transmucosal, IV, subcutaneous (SC), and intraspinal. Although the oral and transdermal routes are most common, the method of administration is based on patient needs (severity of pain) and characteristics (swallowing difficulty and preference). Oral opioids have an onset of effect of 45 minutes, so IV or SC administration might be preferred if more rapid relief is desired. Intramuscular (IM)

Table 35–4

CDC Guidelines for Prescribing Opioids for Chronic Pain[8]

1. Nonpharmacologic therapy and nonopioid pharmacologic therapy are preferred for chronic pain. Clinicians should consider opioid therapy only if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, they should be combined with nonpharmacologic therapy and nonopioid pharmacologic therapy, as appropriate.
2. Before starting opioid therapy for chronic pain, clinicians should establish treatment goals with all patients, including realistic goals for pain and function, and should consider how opioid therapy will be discontinued if benefits do not outweigh risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.
3. Before starting and periodically during opioid therapy, clinicians should discuss with patients known risks and realistic benefits of opioid therapy and patient and clinician responsibilities for managing therapy.
4. When starting opioid therapy for chronic pain, clinicians should prescribe immediate-release opioids instead of extended-release/long-acting (ER/LA) opioids.
5. When opioids are started, clinicians should prescribe the lowest effective dosage. Clinicians should use caution when prescribing opioids at any dosage, should carefully reassess evidence of individual benefits and risks when considering increasing dosage to ≥ 50 morphine milligram equivalents (MME)/day, and should avoid increasing dosage to ≥ 90 MME/day or carefully justify a decision to titrate dosage to ≥ 90 MME/day.
6. Long-term opioid use often begins with treatment of acute pain. When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. 3 days or less will often be sufficient; more than 7 days will rarely be needed.
7. Clinicians should evaluate benefits and harms with patients within 1–4 weeks of starting opioid therapy for chronic pain or of dose escalation. Clinicians should evaluate benefits and harms of continued therapy with patients every 3 months or more frequently. If benefits do not outweigh harms of continued opioid therapy, clinicians should optimize other therapies and work with patients to taper opioids to lower dosages or to taper and discontinue opioids.
8. Before starting and periodically during continuation of opioid therapy, clinicians should evaluate risk factors for opioid-related harms. Clinicians should incorporate into the management plan strategies to mitigate risk, including considering offering naloxone when factors that increase risk for opioid overdose, such as history of overdose, history of substance use disorder, higher opioid dosages (≥ 50 MME/day), or concurrent benzodiazepine use, are present.
9. Clinicians should review the patient's history of controlled substance prescriptions using state prescription drug monitoring program (PDMP) data to determine whether the patient is receiving opioid dosages or dangerous combinations that put him or her at high risk for overdose. Clinicians should review PDMP data when starting opioid therapy for chronic pain and periodically during opioid therapy for chronic pain, ranging from every prescription to every 3 months.
10. When prescribing opioids for chronic pain, clinicians should use urine drug testing before starting opioid therapy and consider urine drug testing at least annually to assess for prescribed medications as well as other controlled prescription drugs and illicit drugs.
11. Clinicians should avoid prescribing opioid pain medication and benzodiazepines concurrently whenever possible.
12. Clinicians should offer or arrange evidence-based treatment (usually medication-assisted treatment with buprenorphine or methadone in combination with behavioral therapies) for patients with opioid use disorder.

ER, extended release; LA, long acting; MME, milligram morphine equivalent; PDMP, prescription drug monitoring program.

injections are not recommended because of pain at the injection site and wide fluctuations in drug absorption and peak plasma concentrations achieved. More invasive routes of administration such as PCA and intraspinal (epidural and intrathecal) are primarily used postoperatively but might also be used in refractory chronic pain situations. PCA delivers a self-administered dose via an infusion pump with a preprogrammed dose, minimum dosing interval, and a maximum hourly dose. Morphine, fentanyl, and hydromorphone are commonly administered via PCA pumps by the IV route but less frequently by the SC or epidural route.

Epidural analgesia is frequently used for lower extremity procedures and pain (eg, knee surgery, labor pain, and some abdominal procedures). Intermittent bolus or continuous infusion of preservative-free opioids (morphine, hydromorphone, or fentanyl) and local anesthetics (bupivacaine) might be used for epidural analgesia. Opiates given by this route might cause pruritus that is relieved by naloxone. Adverse effects including respiratory depression, hypotension, and urinary retention might occur. When epidural routes are used in narcotic-dependent patients, systemic analgesics must also be used to prevent withdrawal because the opioid is not absorbed and remains in the epidural space. Doses of opioids used in epidural analgesia are 10 times less than IV doses, and intrathecal doses are 10 times less than epidural doses (ie, 10 mg of IV morphine is equivalent to 1-mg epidural morphine and 0.1 mg of intrathecally administered morphine).[31]

Combination Analgesics Combinations of opioids and nonopioids often result in enhanced analgesia and lower dose of each. Combination analgesics are frequently used in moderate pain. However, in severe pain, the nonopioid component reaches maximum dosage, and thus, the usefulness of nonopioids in this situation is limited. Additionally, the combination products are short acting and often not suitable for chronic therapy. Single agents offer greater dosing flexibility than combination products.

Opioid Allergy True opioid allergies are rare and should not be confused with pruritus associated with opioid use. Cross-sensitivity between morphine-like, meperidine-like, and methadone-like agents is unlikely. Therefore, when an individual is allergic to one drug in a chemical class of opioids, it is reasonable to select an agent in another chemical class. For the purpose of drug selection in patients with allergies, mixed agonists/antagonists should be treated as morphine-like agents.

Tapering of Opioids Tapering of opioids should be considered in the following situations: painful situation has resolved; in those with prolonged opioid use; upon requests for dosage reduction; lack of clinically meaningful improvement in pain and function (eg, at least 30% improvement on the three-item PEG scale) dosages greater than 50 morphine milligram equivalents (MME)/day without benefit or opioids are combined with benzodiazepines; signs of substance use disorder (eg, work or family, problems related to opioid use, difficulty controlling use); overdose or other serious adverse event; or shows early warning signs for overdose risk such as confusion, sedation, or slurred speech. In these situations, the dose should be reduced by 10% per week to avoid withdrawal symptoms.

Managing Opioid Side Effects and Drug Interactions Side effects common to all opioids include sedation, hallucinations, constipation, nausea and vomiting, urinary retention, myoclonus, and respiratory depression. Table 35–5 shows management strategies for side effects. The most frequent side effects are sedation, nausea, and constipation. Sedation and nausea are common when initiating therapy and when increasing doses. Tolerance to respiratory depression develops rapidly with repeated doses, and respiratory depression is rarely a clinically significant problem in pain patients even those with respiratory impairment. Constipation is a significant adverse effect to which tolerance does not develop, and prophylaxis with stimulant laxatives (eg, senna or bisacodyl) and stool softeners such as docusate are recommended.

Codeine, hydrocodone, morphine, methadone, and oxycodone are substrates of the cytochrome P450 (CYP) enzyme, 2D6.[34] Inhibition of CYP2D6 results in decreased analgesia of codeine and hydrocodone due to decreased conversion to the active metabolites (eg, morphine and hydromorphone, respectively) and increased effects of morphine, methadone, and oxycodone. Methadone is a substrate of CYP3A4 and its metabolism is increased by phenytoin and decreased by cimetidine. CNS depressants might potentiate the sedative effects of opiates.

Patients with CYP450 pharmacogenetic variations may respond differently to opioids, ranging from drug unresponsiveness to toxicity with elevated serum levels.

Opioid Rotation Opioid rotation is the switch from one opioid to another to achieve a better balance between analgesia and treatment-limiting adverse effects. This practice is often used when escalating doses (> 1 g morphine/day) become ineffective.

Table 35–5

Managing Opioid Side Effects[18,32,35]

Adverse Effects	Drug Treatment/Management
Excessive sedation	Reduce dose by 25% or increase dosing interval
Constipation	Casanthranol-docusate one capsule at bedtime or twice daily; senna one to two tablets at bedtime or twice daily; bisacodyl 5–10 mg daily plus docusate 100 mg twice daily; polyethylene glycol 3350 17 g daily; methylnaltrexone 0.15 mg/kg SQ every other day; naloxegol 12.5–25 mg daily
Nausea and vomiting	Prevention: Hydroxyzine 25–100 mg (PO/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (PO/IM) every 6 hours as needed; ondansetron 4 mg IV or 16 mg PO Treatment: Prochlorperazine 5–10 mg (PO/IM) every 3–4 hours as needed or 25 mg PR twice daily; ondansetron 4–8 mg IV every 8 hours as needed
Gastroparesis	Metoclopramide 10 mg (PO/IV) every 6–8 hours (Caution: duration < 3 months)
Vertigo	Meclizine 12.5–25 mg PO every 6 hours as needed
Urticaria/ itching	Hydroxyzine 25–100 mg (PO/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (PO/IM) every 6 hours as needed
Respiratory depression	Mild: Reduce dose by 25% Moderate-to-severe: Naloxone 0.4–2 mg IV every 2–3 minutes (up to 10 mg) for complete reversal; 0.1–0.2 mg IV every 2–3 minutes until desired reversal for partial reversal; may need to repeat in 1–2 hours depending on narcotic half-life
CNS irritability	Discontinue opioid; treat with benzodiazepine

IM, intramuscular; IV, intravenous; PO, orally; PR, per rectum; SQ, subcutaneous, CNS, central nervous system.

In some settings, opioid rotation is used routinely to prevent the development of analgesic tolerance.[35]

Equianalgesic Dosing of Opioid Analgesics Conversion from one dosage form to another or from one opioid to another might be necessary in situations such as ineffective pain control, emergence of side effects, change in patient status, and in formulary restrictions. KEY CONCEPT Equianalgesic doses should be used when converting from one opioid to another. Clinicians should be familiar with the equianalgesic dosing and conversion strategies to avoid analgesic failure. Opioid potency is compared using a reference standard of 10-mg parenteral morphine. Switching from one dosage form to another of the same opioid (ie, IV to oral) is relatively simple. The current total daily dose is calculated and the total of the new dosage form is determined using a ratio of the equianalgesic doses. This result is then adjusted based on the usual dosing frequency of the new form. When converting to a sustained-release form of the same opioid, the oral dosage may be reduced by 25% to avoid initial sedation; however, the specific product literature should also be consulted.

The first step in an opioid conversion is to calculate the patient's total daily dose of opioid based on the regularly scheduled dose and the total amount of rescue dose needed in 24 hours. This total is then converted to morphine-dosing equivalents using equianalgesic doses (see Table 35–3). The total daily morphine dose is then used to calculate the daily dose of the new opioid using dosing equivalents from an equianalgesic table. Because cross-tolerance may not be complete between opioids, some references suggest that the calculated equianalgesic dose be reduced by 25% to 50%.[32] If the opioid switch is due to uncontrolled pain, a dosage reduction may not be needed. The calculated equianalgesic dose may need to be reduced more in the medically frail and when converting to methadone.[36,37] Methadone appears to be much more potent than once believed, and morphine-to-methadone ratios vary according to the total dose of morphine taken at the time of making the conversion to methadone (Table 35–6).[38,39] Conversion to methadone is a complex process, and several different strategies have been proposed including a switch of the entire dose in 1 day or a gradual conversion over 3 days.

Table 35–6

Methadone Dose Conversions[39]

Total Daily Dose of Oral Morphine	Morphine:Methadone Factor
< 100 mg	3:1 3-mg morphine:1-mg methadone
101–300 mg	5:1
301–600 mg	10:1
601–800 mg	12:1
801–1000 mg	15:1
> 1000 mg	20:1

Patient Encounter, Part 2

Following surgery, she was placed on morphine patient-controlled analgesia (PCA). She has been using 27 mg of morphine/24 hours with adequate pain control; however, she has developed redness and itching on her neck that is believed to be due to the morphine.

Current Meds: Morphine PCA; metoprolol succinate ER 50 mg daily; rivaroxaban 20 mg daily; levothyroxine 150 mcg daily; polyethylene glycol 3350 17 g daily; lisinopril 2.5 mg daily; amiodarone 200 mg daily; sertraline 50 mg daily. She will be discharged to a skilled nursing facility for rehabilitation therapy.

The physician would like to convert her to a combination preparation of hydrocodone and APAP.

What dosing regimen would you suggest?

Recommend a monitoring plan for this patient.

How would you assess pain response?

The patient is concerned about the redness and itching she developed while on morphine. What other interventions or education may be necessary at this time?

▶ *Adjuvant Agents for Chronic Pain*

The role of NSAIDs and opioids in chronic nonmalignant pain has been discussed; however, a review of adjuvant agents for chronic pain, particularly neuropathic pain, is warranted. Adjuvant analgesics are drugs that have indications other than pain but are useful as monotherapy or in combination with nonopioids and opioids. Common adjuvants include antiepileptic drugs (AEDs), antidepressants, antiarrhythmic drugs, local anesthetics, topical agents (eg, capsaicin), and a variety of other drugs (eg, NMDA antagonists, clonidine, and muscle relaxants).

Published guidelines have been suggested for the general management of neuropathic pain.[40] Suggestions for first-line therapy include gabapentin or pregabalin, transdermal lidocaine, or tricyclic antidepressants (TCAs) (Table 35–7).[40–43] Antidepressants, such as the SSRIs, have fewer side effects but appear to be less effective than the TCAs for neuropathic pain. However, serotonin-norepinephrine reuptake inhibitors (SNRIs) (eg, duloxetine and venlafaxine) have been used successfully for painful diabetic peripheral neuropathy (DPN). A stepwise approach is suggested

Patient Encounter, Part 3

She was discharged to a skilled nursing facility and is receiving physical therapy and occupational therapy 6 days each week.

Current Meds: Metoprolol succinate ER 50 mg daily; rivaroxaban 20 mg daily; levothyroxine 150 mcg daily; polyethylene glycol 3350 17 g daily; lisinopril 2.5 mg daily; amiodarone 200 mg daily; sertraline 50 mg daily, hydrocodone/acetaminophen 10/325 mg every 6 hours as needed for pain.

Pain Assessment: Patient reports pain of 7 out of 10; worse with movement. She complains of pain "everywhere, but my shoulder is really bothering me."

Physical therapy notes indicate patient is unable to complete therapy goals due to complaints of pain in her shoulder.

Based on this information, what would you recommend to optimize pain control?

Table 35–7

Selected Adjuvant Analgesics and Suggested Dosing[40–43]

Agent	Dosing Guidelines	FDA-Approved Indication
Amitriptyline (Elavil)	10–25 mg at bedtime with weekly increments to a target dose of 25–150 mg of amitriptyline or an equivalent dose of another TCA	
Duloxetine (Cymbalta)	DPN: 60 mg daily Fibromyalgia: 30 mg daily, may be increased to a target dose of 60 mg/day	DPN, fibromyalgia
Gabapentin (Neurontin)	Initially, 300 mg three times a day up to a maximum of 3600 mg daily, in divided doses[a]	PHN
Pregabalin (Lyrica)	DPN: Initially, 50 mg three times a day; may be increased to 100 mg three times a day within 1 week based on efficacy and tolerability[a] PHN: Initially 75 mg twice a day or 50 mg three times a day; may be increased to 100 mg three times a day within 1 week based on efficacy and tolerability[a] Fibromyalgia: Initially 75 mg twice a day, increase after 1 week to 300 mg to 450 mg/day (in divided doses every 12 hours)	DPN, PHN, and fibromyalgia
Lidocaine 5% (Lidoderm patch)	Up to three patches may be applied directly over the painful site once daily; patches are applied using a regimen of 12 hours on and 12 hours off	PHN

[a] Dosing for creatinine clearance of ≥ 60 mL/min (1.0 mL/s).

DPN, diabetic peripheral neuropathy; PHN, postherpetic neuralgia; TCA, tricyclic antidepressant.

for managing the patient with neuropathic pain beginning with the least invasive, effective therapeutic choice and proceeding to the rational use of multiple drug regimens (see Figure 35–2). Choice of agent might also depend on dosing frequency and comorbidities. Data on combination therapy are lacking, and the use of combined treatment is empirical based on the additive therapeutic benefit. Scheduled medication regimens instead of "as-needed" dosing should be used when treating chronic pain, and the effectiveness of therapy should be reassessed regularly. If patients are managed on a multiple drug regimen and changes are indicated, changing only one drug at a time is suggested. Topical agents (eg, capsaicin) might be added to a regimen to reduce the oral medication load, particularly if adverse effects are a problem or if pain is not relieved.

▶ *Complementary and Alternative Medicine*

Complementary and alternative medicine (CAM) is a term used to encompass a variety of therapies (eg, acupuncture, chiropractic, botanical and nonbotanical dietary supplements, and homeopathy). Painful conditions are among the most common reasons individuals seek relief from CAM. A variety of dietary supplements have been suggested for painful conditions such as S-adenosylmethionine (SAM-e), ginger, fish oil, feverfew, γ-linoleic acid, glucosamine, and chondroitin. Of these, glucosamine and chondroitin are the most popular and have the most evidence supporting their efficacy. Glucosamine in doses of 1500 mg/day has been shown to be effective in reducing the pain of osteoarthritis by fostering repair of cartilage, and it is recommended by the Osteoarthritis Research Society International (OARSI).[29]

Patient Encounter, Part 4

The patient has been at the skilled nursing facility for 2 weeks and is making progress toward rehabilitation goals; however, during a follow-up appointment to her surgeon, she learned that she has metastatic ovarian cancer.

She states that she has not been sleeping well and has lost 7 lb (3.2 kg) since admission. She also states that she hates waiting for her pain pills and requests something longer acting.

Pain Assessment: 8 out of 10

Current Meds: Metoprolol succinate ER 50 mg daily; rivaroxaban 20 mg daily; levothyroxine 150 mcg daily; polyethylene glycol 3350 17 g daily; lisinopril 2.5 mg daily; amiodarone 200 mg daily; sertraline 50 mg daily; diclofenac transdermal gel 1% to neck and left shoulder four times daily; hydrocodone/acetaminophen 10/325 mg every 4 hours as needed for pain (uses 6 doses per day).

What additional recommendations would you have at this time regarding pain management?

Are there any other therapeutic issues that should be addressed?

Patient Encounter, Part 5

The patient was discharged to her home, but 3 months after discharge was admitted to hospice service. She is no longer able to swallow her tablets and requires them to be crushed. The hospice nurse requests your advice on an equivalent regimen using transdermal fentanyl and oxycodone for breakthrough pain.

Pain Assessment: 8 out of 10

Current Meds: Metoprolol succinate ER 50 mg daily; rivaroxaban 20 mg daily; levothyroxine 150 mcg daily; polyethylene glycol 3350 17 g daily; lisinopril 2.5 mg daily; amiodarone 200 mg daily; diclofenac transdermal gel 1% to neck and left shoulder four times daily; morphine sulfate ER 30 mg twice daily; mirtazapine 15 mg at bedtime.

What additional recommendations would you have at this time regarding pain management?

Are there any other therapeutic issues that should be addressed?

Patient Care Process

Collect Information:

- Identify the source of pain.
- Assess the level of pain using a pain intensity scale.
- Review the medical and medication history.
- Determine if patient has insurance coverage for prescription medications.

Assess the Information:

- Determine if the patient is a candidate for pharmacotherapy.
- If patient is already receiving drug therapy, assess efficacy, side effects, adherence, and drug interactions.

Develop a Care Plan:

- Base the initial choice of analgesic on the severity and type of pain, as well as on the patient's medical condition and concurrent medications.
- Select the least potent oral analgesic that provides adequate pain relief and causes the fewest side effects.
- Avoid excessive sedation.
- Adjust the route of administration if the patient is unable to take oral medications.
- Use equianalgesic doses as a guide when switching opioids.
- Use a dosing schedule versus as-needed dosing.

Implement the Care Plan:

- Communicate the recommendations to the prescriber and members of the team.
- Communicate expectations of the therapy to the patient.

Follow-up: Monitor and Evaluate:

- Assess the patient for analgesic effectiveness and for side effects at each visit or more frequently, depending on the acuity of the patient's condition.
- Titrate the dose to one that achieves an adequate level of pain control.

OUTCOME EVALUATION

Routine pain assessment is essential for evaluating outcomes of therapy. For example, pain goals for acute pain might include "pain scale less than 3" or 30% reduction in PEG scale. Functional goals such as "be able to play a game with grandchildren," or "be able to knit again" may be appropriate for chronic pain. Assess patients periodically, depending on the method of analgesia and pain condition, for achievement of pain goals. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.

Abbreviations Introduced in This Chapter

AED	Antiepileptic drug
AGS	American Geriatrics Society
AHRQ	Agency for Healthcare Research and Quality
ASIPP	American Society of Interventional Pain Physicians
AIDS	Acquired immunodeficiency syndrome
AMPA	α-Amino-3-hydroxy-5-methylisoxazole-4-propionic acid
APAP	Acetaminophen
APS	American Pain Society
ASA	American Society of Anesthesiologists
CAM	Complementary and alternative medicine
CDC	Centers for Disease Control and Prevention
CNS	Central nervous system
COX	Cyclooxygenase
CRPS	Complex regional pain syndrome
CYP	Cytochrome P450 enzyme
DPN	Diabetic peripheral neuropathy
GABA	γ-Aminobutyric acid
GI	Gastrointestinal
HIV	Human immunodeficiency virus
IASP	International Association for the Study of Pain
IM	Intramuscular
IV	Intravenous
MME	Morphine milligram equivalents
NMDA	*N*-methyl-D-aspartate
NSAID	Nonsteroidal anti-inflammatory drug
OARSI	Osteoarthritis Research Society International
PAINAD	Pain Assessment in Advanced Dementia (tool)
PEG	Pain intensity, Enjoyment of life, General activity Assessment Tool
PCA	Patient-controlled analgesia
PHN	Postherpetic neuralgia
PQRST	Palliative/precipitating, Quality, Radiation, Severity, and Time
SAM-e	*S*-adenosylmethionine
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant
TENS	Transcutaneous electrical nerve stimulation
VAS	Visual analog scale
WHO	World Health Organization

Headache

Laurie W. Fleming, Leigh Ann Ross, and
Brendan S. Ross

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Differentiate types of headache syndromes based on clinical features.
2. Recommend nonpharmacologic measures for headache treatment and prevention.
3. Determine when the pharmacologic treatment of headache is indicated.
4. Construct individualized treatment regimens for the acute and chronic management of headache syndromes.
5. Monitor headache treatment to ensure its safety, tolerability, and efficacy.

INTRODUCTION

Headache is a common medical complaint with approximately 50% of the adult population experiencing at least one headache per year.[1] KEY CONCEPT Headaches can be considered primary or secondary conditions. Primary headaches, even when persistent or recurrent, are usually a benign condition. Secondary headaches are caused by an underlying medical disorder and may need medical emergencies. Primary headache syndromes are the focus of this chapter. KEY CONCEPT The International Headache Society (IHS) classifies primary headaches as migraine, tension-type, or cluster and other trigeminal autonomic cephalalgias.[2] Patients may seek headache care from multiple providers; so all clinicians should be familiar with the various types of headache; clinical indicators suggest the need for urgent medical attention or specialist referral, and nonpharmacologic and pharmacologic options for treatment.

EPIDEMIOLOGY OF HEADACHE DISORDERS

Migraine Headache

Migraine is a primary headache disorder with an estimated 3-month prevalence rate in the United States of 14.2% in adults over 18 years. Prevalence is higher in females at 19.1% compared to males at 9%. The highest prevalence is in women 18 to 44 years of age at 23.5%.[3] In pediatric patients, there is also a higher incidence in girls after the age of 10.[4] The difference in gender distribution is thought to be due to hormonal differences.

Tension-Type Headache

KEY CONCEPT Tension-type headache (TTH) is the most common primary headache disorder and can be further divided into episodic or chronic.[2] The term *TTH* is used to describe all headache syndromes in which sensitization to pericranial nociception, known as noxious stimuli, is the most significant factor in the pathogenesis of pain.[5] Overall reported prevalence of TTH is approximately 86%, and incidence is more common in women than men. Episodic TTH is the most common type, followed by frequent episodic TTH and chronic TTH. Incidence of TTH increases until approximately age 40, then incidence begins to slowly decline.[6] Environmental factors, as opposed to genetic predisposition, play a central role in the development of TTH. The mean frequency of attacks is 3 days per month in episodic disorders; episodic is defined as less than 15 attacks in a 1-month period with no pattern, and chronic TTH is defined as 15 or more attacks in a 1-month period for at least 6 months.[2]

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache disorders are severe primary headache syndromes and uncommon.[2] The lifetime prevalence is estimated to be 124 per 100,000.[7] Unlike migraine and TTH, cluster headaches are more frequently found in men. Onset most commonly occurs between 20 and 40 years.[2] A genetic predisposition is apparent, although affected individuals often present with additional risk factors, such as history of tobacco use, caffeine intake, and alcohol abuse.[7] Attacks consist of debilitating, unilateral head pains that occur in series lasting up to months at a time but may abate for extended periods, defined as remission, resulting in months or years between occurrences. In rare instances, cluster headache can be a chronic disorder without remission.[2]

ETIOLOGY AND PATHOPHYSIOLOGY OF HEADACHE DISORDERS

Migraine Headache

The exact mechanism by which migraines occur remains obscure, but the belief that only vascular changes are responsible for the pain is no longer accepted.[8] The vascular hypothesis suggested that intracerebral vasoconstriction has led to neural ischemia, which was followed by reflex extracranial vasodilation and pain. Negative neuroimaging evidence for such vascular changes, as well as the effectiveness of medications with no vascular properties, make this contention untenable.[5] A neuronal etiology has emerged as the leading mechanism for the development of migraine pain.[9] It is believed that depressed neuronal electrical activity spreads across the brain, producing transitory neural dysfunction.[8] Bioamine pathways projecting from the brain stem regulate activity within the trigeminovascular system. The pathogenesis of migraine is most likely due to an imbalance in the modulation of nociception and blood vessel tone by serotonergic and noradrenergic neurons.[9] Headache is likely due to compensatory overactivity in the trigeminovascular system of the brain. Activation of trigeminal sensory nerves leads to the release of vasoactive neuropeptides (eg, calcitonin gene–related peptide [CGRP], neurokinin A, substance P) that produce a sterile inflammatory response, which is triggered by a physical, chemical, or metabolic noxious stimuli around vascular structures in the brain, provoking the sensation of pain.[9] Continued sensitization of central nervous system (CNS) sensory neurons can potentiate and intensify headache as an attack progresses.[8]

Tension-Type Headache

The pathophysiologic mechanisms producing TTHs are not clearly understood and are likely multifactorial. However, central sensitization to peripheral nociceptive input arising from the pericranial myofascia is the leading hypothesis. The belief that sustained muscle contraction is solely responsible for generating the pain cannot be supported. Muscle tenderness is prominent in this syndrome, but it only reflects a heightened sensitivity to pain. TTH pain is believed to arise by disturbances in the muscles and tissues of the head being misinterpreted due to disordered CNS pain processing.[10]

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache is one of a group of disorders referred to as trigeminal autonomic cephalalgias.[11] This autonomic nervous system dysfunction is characterized by sympathetic underactivity coupled with parasympathetic activation. Similar to migraine, the pain of a cluster headache is believed to be the result of vasoactive neuropeptide release and neurogenic inflammation. The exact cause of trigeminal activation in this intermittently manifest syndrome is unclear.[11] One hypothesis is that hypothalamic dysfunction, occasioned by diurnal or seasonal changes in neurohormonal balance, is responsible for headache periodicity.[5] Serotonin affects neuronal activity in the hypothalamus and trigeminal system and may play a role in the pathophysiology of cluster headache. The precipitation of cluster headache by high-altitude exposure also implicates hypoxemia in the pathogenesis of trigeminal autonomic cephalalgias.[8]

CLINICAL PRESENTATION AND DIAGNOSIS OF HEADACHES

Migraine Headache

Migraine presents as a recurrent headache that is severe enough to interfere with daily functioning. KEY CONCEPT Migraine headaches are classified as migraine with aura and migraine without aura.[2] Aura is defined as a transient, focal neurologic symptom that can occur prior to or during an attack. These typically present as wavy lines or spots within the field of vision but can also present as a scotoma.[2] The IHS outlines diagnostic criteria that differentiate migraine with and without aura. Migraines can be triggered by changes in behavior, environment, diet, and hormone levels. Dietary intake of tyramine, aspartame, monosodium glutamate, and nitrites are known migraine triggers.[8] Migraines occurring 15 or more days per month for a 3-month period or longer, without the overuse of analgesic medications, are classified as chronic migraines.[2] Severe and debilitating migraine pain lasting more than 72 hours is termed status migrainosus.[2]

Clinical Presentation and Diagnosis of Migraine Without Aura

Patients experiencing "migraine without aura" may display the following headache symptoms and characteristics:

Two or more of the following are present:

1. Pain interrupts or worsens with physical activity
2. Unilateral pain
3. Pulsating pain
4. Moderate-to-severe pain intensity

One or more of the following are present during headache:

1. Nausea/vomiting
2. Photophobia and phonophobia

Duration: 4 to 72 hours (treated or not treated)

Criteria for diagnosis: Five or more attacks fulfilling above criteria are necessary

Laboratory assessments that may be helpful in excluding medical comorbidities: Complete blood count (CBC), complete chemistry panel, including liver function tests (LFTs), thyroid function tests (TFTs), and erythrocyte sedimentation rate (ESR)

Tension-Type Headache

TTH pain differs from migraine pain in that it is usually reported to be mild to moderate in severity, nonpulsating, and bilateral.[6] The pain is described by sufferers as a band-like tightness or pressure around the head. No transient neurologic deficits are noted, and systemic symptoms are rare.

Clinical Presentation and Diagnosis of Migraine with Aura

Patients experiencing "migraine with aura" may display the following headache symptoms and characteristics:

One or more of the following present with no motor weakness:

1. Visual (eg, flashes of light, blind spots)
2. Sensory (eg, sensitivity to light, sound, smell)
3. Speech and/or language (eg, speech or language difficulty)
4. Motor (eg, heaviness of limbs)
5. Brain stem (eg, vertigo, tinnitus)
6. Retinal (eg, change in vision or vision loss)

Two or more of the following:

1. At least one aura symptom that spreads gradually over at least 5 minutes
2. Individual aura symptoms lasting 5 to 60 minutes
3. At least one aura symptom is unilateral
4. The aura is accompanied or followed by a headache within 60 minutes

Criteria for diagnosis: Two or more attacks fulfilling above criteria are necessary

Clinical Presentation and Diagnosis of Tension-Type Headache

Patients experiencing TTH may display the following headache symptoms and characteristics:

Two or more of the following are present and are not aggravated by routine physical activity:

1. Bilateral pain
2. Nonpulsating pain
3. Mild or moderate pain intensity

Both of the following:

1. No nausea or vomiting (anorexia possible)
2. Either photophobia or phonophobia (not both)

Duration: 30 minutes to 7 days

Criteria for diagnosis: 10 or more attacks fulfilling above criteria occurring on average less than 1 day per month are necessary

TTHs occurring more than 15 days per month for more than 3 months, without evidence of medication overuse, would be classified as chronic TTH.[2]

Cluster Headache

Pain associated with cluster headache differs from migraine and TTH in that it is severe, intermittent, and short in duration.[5] Headaches typically occur at night, but attacks may occur multiple times per day.[11] The pain is usually unilateral, but, unlike migraine, it is not described as pulsatile.[5] Aura is not a feature, and pain intensity peaks early after onset, although it may persist for hours.[5] The headache is described as explosive, excruciating, and referred to as a "suicide headache." A constellation of features, ascribed to parasympathetic overactivity, can be seen, such as ipsilateral conjunctival injection as well as lacrimation, rhinorrhea, and sweating. Cluster headache patients tend to become excited and restless during attacks, rather than seeking quiet and solitude as in migraine.[11]

Clinical Presentation and Diagnosis of Cluster Headache

Patients experiencing cluster headaches may display the following headache symptoms and characteristics:

At least one or more of the following symptoms:

1. Lacrimation
2. Nasal congestion and/or rhinorrhea
3. Eyelid edema
4. Forehead or facial sweating/flushing
5. Sensation of fullness in the ear
6. Miosis and/or ptosis
7. Sense of restlessness or agitation

- Duration of pain: 15 to 180 minutes (untreated)
  - Frequency of attacks: One every other day and/or up to 8 per day for more than half the time the disorder is active (may have long periods when headaches are inactive)
  - Criteria for diagnosis: Five or more attacks fulfilling the above criteria

Patient Encounter, Part 1

A 29-year-old woman describes having mild-to-moderate headache that is bilateral and nonpulsating in nature. She denies nausea, vomiting, photophobia, and phonophobia. Her headaches typically last for 1 hour and occur three times per month. She reports using OTC pain relievers to help ease the pain, but she has not had any success thus far.

What type of headache is the patient most likely experiencing?

What characteristics of the headache support this diagnosis?

What are possible causes or triggers of headache in this patient?

What additional information is needed to formulate a treatment plan?

TREATMENT OF HEADACHE DISORDERS

Desired Outcomes

KEY CONCEPT The short-term treatment goal of migraine is to achieve rapid pain relief to allow the patient to resume normal activities. The long-term goal of therapy is to prevent headache recurrences and diminish headache severity.[12] Similarly, the goal of TTH care is to lessen headache, whereas the long-term goal is to avoid analgesic overuse and dependence.[8,13] The short-term therapeutic goal of cluster headache is to achieve rapid pain relief. Prophylactic therapy may be necessary to obtain the intermediate-term outcome of reducing the frequency and severity of headaches within a periodic cluster series as well as to achieve the long-term goal of delaying or eliminating recurrent periods.[14]

General Approach to Treatment

KEY CONCEPT Pharmacologic treatment of acute headache should be started early to abort the intensification of pain and improve response to therapy. First-line pharmacologic agents include nonsteroidal and opiate analgesics, as well as serotonin-receptor agonists (triptans).[12] The long-term management of headache syndromes focuses on lifestyle modification and other nonpharmacologic therapeutic options; if headaches are severe and frequent, prophylactic pharmacologic therapy is needed.[12] Nonpharmacologic therapies, which are important in the acute as well as preventive setting, include the following cognitive and behavioral treatment recommendations: relaxation timing, thermal biofeedback, acupuncture, cognitive behavioral therapy, and electrical nerve stimulation.[12] KEY CONCEPT Several clinical markers, so-called red flags, have been identified that warrant urgent physician referral and further diagnostic evaluation (Table 36–1).[15]

Nonpharmacologic Therapy

The successful management of headache disorders depends on comprehensive patient education. Recording headache frequency, duration, severity, possible triggers, and medication response in a "headache diary" provides beneficial information for the patient regarding headache precipitants and useful insights for

Table 36–1

Headache “Red Flags” Indicating Need for Urgent Medical Evaluation[8,15]

New-onset sudden and/or severe pain
Stereotyped pain pattern worsens
Systemic signs (eg, fever, weight loss, or accelerated hypertension)
Focal neurologic symptoms (ie, other than typical visual or sensory aura)
Papilledema
Cough-, exertion-, or Valsalva-triggered headache
Pregnancy or postpartum state
Patients with cancer, human immunodeficiency virus (HIV), and other infectious and immunodeficiency disorders
Seizures

the clinician selecting appropriate management strategies.[12] To prevent future occurrences, exposure to headache triggers (Table 36–2) should be limited.[14] In the acute setting, environmental control can lessen the severity of an attack, so patients may benefit from resting in a dark, quiet area. Behavioral interventions, such as biofeedback, relaxation therapy, and cognitive behavioral training, are effective and can be recommended for headache prevention. Headache sufferers may also benefit from stress management training.[8] Acupuncture has yielded inconsistent benefits in clinical trials.[16] Although the response is variable, headache patients should be advised to moderate alcohol use and curtail tobacco abuse.[14] All nonpharmacologic therapies may be useful in augmenting pharmacologic response.

Table 36–2

Migraine Triggers[8,44]

Behavioral

Emotional let down
Fatigue
Sleep excess or deficit
Stress
Vigorous physical activity

Environmental

Flickering lights
High altitude
Loud noises
Strong smells such as perfumes
Tobacco smoke
Weather changes

Food

Alcohol
Caffeine intake or withdrawal
Chocolate
Citrus fruits, bananas, figs, raisins, avocados
Dairy products
Fermented pickled products
Missing meals
Foods containing monosodium glutamate (MSG), Asian food, seasoned salt, nitrites (processed meats), saccharin/aspartame, diet soda or diet food, sulfites (shrimp), tyramine (cheese, wine, organ meats, yeast breads)

Medications

Cimetidine
Estrogen or oral contraceptives
Indomethacin
Nifedipine
Nitrates
Reserpine
Theophylline
Withdrawal due to the overuse of analgesics, benzodiazepines, decongestants, or ergotamines

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Normal childhood illnesses

FH: Father living, age 59 years: hypertension, diabetes mellitus; mother living, age 56 years: tension-type headaches; two sisters and one brother in good health

SH: Full-time pet groomer at a loud and strong-smelling veterinary clinic; two to three cups of coffee per day; enjoys two glasses of wine each night; has never smoked, but is married to a heavy smoker

Meds: Excedrin Extra Strength (acetaminophen 500 mg, aspirin 250 mg, caffeine 65 mg) two tablets orally every 6 hours as needed for headache

ROS: Headache, mild-moderate intensity, no sensitivity to light; no dizziness; no chest pain or palpitations; no shortness of breath with exertion; no weakness or joint discomfort

VS: BP 126/84, P 88, RR 19, T 37.0°C (98.6°F) oral

HEENT: No papilledema, neck tender without stiffness

CV: Regular rate and rhythm (RRR), normal S1, S2, S4 gallop, no murmur, rub

Chest: Clear to auscultation (CTA)

Abd: Benign, bowel sounds positive

Neuro: Nonfocal

Labs: CBC and complete chemistry panel within normal limits

What is your assessment of this patient’s condition?

What medical comorbidities or drug therapies may be contributing to her distress?

Identify treatment goals for this patient.

What nonpharmacologic options are needed at present, and what options are appropriate in the long term?

What pharmacologic therapy would you recommend in the acute setting?

Does this patient require long-term pharmacologic prophylaxis against recurrent headaches?

Pharmacologic Therapy

► *Migraine*

Analgesics, such as aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, and combination products containing caffeine, with or without an opioid, are the initial pharmacologic option for the acute management of migraine headache, especially when severity is mild to moderate. Clinical trial evidence supports many NSAID medications in the acute treatment of migraines with and without aura. Acetaminophen alone or in proprietary combinations with aspirin, opioids, caffeine, or butalbital is also effective.[17] If these analgesics prove to be ineffective, and when headaches are severe, then migraine-specific medications, such as triptans, are administered. Early abortive treatment should be the rule. Larger doses of oral medications may be necessary for pain relief, due to the enteric stasis and poor drug absorption accompanying migraine attacks. Intranasal, parenteral, and rectal administration can circumvent this complication.[12]

Ergotamine derivatives produce salutary effects on serotonin receptors similar to triptans. They also impact adrenergic and dopaminergic receptors. This receptor binding can potentially lead to additional adverse effects. Ergotamine tartrate and dihydroergotamine (DHE) are the most commonly used agents.[12] Analgesic onset is within 4 hours, although additional dosing is required if an acceptable response is not achieved. When dosed parenterally, these drugs are usually provided with an antiemetic due to their potential to worsen nausea associated with migraine. The outpatient use of subcutaneous ergotamines is limited by the lack of a prefilled syringe form; the exception is intranasal DHE that can be self-administered to abort an attack.[12] The same cautions associated with triptan use are also applicable to ergot use in patients at risk for vascular events.

Triptans inhibit neurotransmission in the trigeminal complex and activate serotonin 1B/1D pathways in the brain stem, which modulate nociception. They also decrease the release of vasoactive neuropeptides leading to vascular reactivity and pain.[18] The triptans are available in intranasal, subcutaneous, and oral dosage forms, including tablets or orally dissolving tablets. The available agents differ in their dosing and pharmacokinetic properties, but all help in effective treatments to abort or diminish migraine headache (Table 36–3).[8,19–28] Patient responses can be variable; if a patient does not respond to one agent, another is selected before a patient is prematurely labeled as triptan unresponsive. The severity of headache correlates with symptomatic response; thus, administration should be prompt. Relief is usually experienced within 2 to 4 hours. Treatment delay may lead to decreased analgesia through the development of refractory central pain sensitization. Efficacy tends to be dose-related; however, adverse effects do not appear to increase in relation to dose. These medications are well tolerated; the most common side effects are dizziness, a sensation of warmth, chest fullness, nausea, and paresthesia. Rarely, ischemic vascular events may be precipitated by the potential vasoconstrictive nature of these drugs. An initial dose under direct practitioner supervision is indicated for patients at increased cardiovascular risk. Triptans are avoided in patients with migraine associated with neurologic focality, a history of previous stroke, poorly controlled HTN, or unstable angina. Triptans are relatively contraindicated for routine use in pregnancy.[29] Triptans should not be used with concurrent ergotamine administration with the wait time of at least 24 hours between use.[8]

The small molecule CGRP antagonists selectively block the receptor binding of this protein, a potent vasodilator and pain-signaling neurotransmitter, which is known to be increased during a migraine. Two products in this class have been FDA

Table 36–3

Comparison of Serotonin-Receptor Agonists (Triptans)[8,20–28]

Medication (Brand Name)	Dosage Forms	Strength (mg)	Usual Dosage (mg)	May Repeat (hours)	Hepatic and Renal Dosing Considerations (mg)	Potential Drug Interactions
Almotriptan (Axert)	Oral tablets	6.25 12.5	6.25–12.5	2	HI and severe RI: 6.25 starting dose and ≤ 12.5	Ergot derivatives substrate: CYP 3A4, CYP 2D6
Eletriptan (Relpax)	Oral tablets	20 40	20–40	2	Severe HI: not recommended	Ergot derivatives substrate: CYP 3A4, CYP 2D6
Frovatriptan (Frova)	Oral tablets	2.5	2.5	2	Severe HI: use caution	Ergot derivatives substrate: CYP 1A2
Naratriptan (Amerge)	Oral tablets	1 2.5	2.5	4	Mild–mod RI or HI: do not exceed 2.5; severe RI (< 15 mL/min [0.25 mL/s]): do not administer	Ergot derivatives substrate: CYP (various)
Rizatriptan (Maxalt and Maxalt MLT)	Oral tablets Disintegrating tablets	5 10	5–10	2	None identified	Ergot derivatives MAO-A inhibitors
Sumatriptan (Imitrex)	Oral tablets Subcutaneous injection	25, 50, 100 4,6	50 6	2 1	Mild–mod HI: oral dose not to exceed 50; severe HI: contraindicated	Ergot derivatives MAO-A inhibitors
Sumatriptan (Onzetra Xsail)	Nasal spray Nasal powder	5, 20/spray 11 mg/spray	5–20 22–44	2 2		
Sumatriptan/naproxen sodium (Treximet)	Oral tablets	85/500	85/500	2	RI (CrCl < 30 mL/min [0.50 mL/s]): not recommended; mild-to-severe HI: contraindicated	Ergot derivatives MAO-A inhibitors
Zolmitriptan (Zomig and Zomig-ZMT)	Oral tablets Disintegrating tablets Nasal spray	2.5, 5 2.5, 5 2.5, 5/spray	2.5 1.25–2.5 2.5	2 2 2	CrCl 5–25 mL/min (0.08–0.42 mL/s): clearance reduced by 25%, use caution; mod–severe HI: not recommended	Ergot derivatives MAO-A inhibitors substrate: CYP 1A2

CrCl, creatinine clearance; CYP, cytochrome P450 enzyme; HI, hepatic impairment; MAO-A, monoamine oxidase type A; RI, renal impairment.

approved for the acute treatment of migraine, ubrogepant in 2019 and rimegepant in 2020. Ubrogepant is available in tablet form and rimegepant is available as an oral-disintegrating tablet that can be taken upon symptom onset for migraines with or without aura. While CGRP antagonists are relatively well tolerated, with nausea as the most common side effect, there may be cost limitations of their use.[30]

The choice of initial therapy for acute migraine attacks is a subject of debate among specialists. Some believe that nonspecific analgesics should be used first line, whereas others believe migraine-specific drugs should be the choice for patients with severe pain or a history of significant disability. A stepped-care approach within attacks from less to more specific drugs is usually recommended. Once a history of headache refractory to common analgesics is established, triptans should be used as initial therapy.[12] Selection of initial headache treatment is important in reducing the incidence of medication overuse headache (MOH). This occurs when patients use ergotamines, triptans, opioids, or other combinations for more than 10 days per month. This can also be considered in patients who are using nonspecific analgesics for more than 15 days per month.[13] Status migrainosus is an especially severe and long-lasting form of migraine, lasting longer than 72 hours even with treatment. In patients who present to the hospital with intractable pain, IV metoclopramide supplemented with DHE may be needed. Intravenous valproic acid may be another option for therapy in these patients. Oral medications in this setting are not used because nausea and vomiting limit their bioavailability.[12] Migraine patients with frequent and severe attacks are candidates for prophylactic treatment.[31]

▶ *Tension-Type Headache*

Most individuals who experience episodic TTHs will not seek medical attention.[2] Instead, they will find relief with the use of widely available OTC analgesics. Acetaminophen products and NSAIDs are commonly utilized. An individual patient may benefit from topical analgesics (eg, ice packs) or physical manipulation (eg, massage) during an acute attack, but the evidence supporting nonpharmacologic therapies is inconsistent.[5] Relaxation techniques can often reduce headache frequency and severity. When pain is unrelieved, prescription-strength NSAID use is required, or the combination of acetaminophen with an opioid analgesic may be necessary. The frequent use of these more potent analgesics should be limited, so that the development of dependency is prevented. As described above, MOH can occur with the frequent use of analgesics for TTH. For patients experiencing frequent TTH, prophylactic treatment should be considered.[13]

▶ *Cluster Headache*

Cluster headaches respond to many of the treatment modalities used in acute migraine; however, a therapy specific to cluster headaches is the administration of high-flow-rate oxygen: 100% at 12 to 15 L/min by nonrebreather face mask for approximately 15 minutes.[32] If the pain is not aborted, retreatment is indicated. No long-term side effects are seen with short-term oxygen use. Initial prophylactic therapy is required to limit the frequency of recurrent headaches within a periodic series. If oxygen therapy is not wholly effective, drugs are useful adjunctive therapy. Drug therapy is also used when supplemental oxygen is not readily available. The triptan class is safe and effective. Intranasal or subcutaneous sumatriptan as well as intranasal zolmitriptan has demonstrated efficacy in decreasing cluster headache.[33] Oral triptans are also effective, but their delayed onset of action may limit their applicability in acute cluster headache treatment.[18] Cluster headache is rapid in onset and achieves peak intensity quickly, but it can be of short duration. Oral agents may have utility in limiting the recurrence of cluster attacks. Intranasal, intramuscular, or IV ergotamine agents are alternatives to triptan use.[5] Repeated dosing may break a cluster series. For those patients in whom triptans and ergotamine derivatives are contraindicated due to ischemic vascular disease, octreotide may be helpful to relieve pain.[34] Octreotide is a somatostatin analogue that has a short half-life and may be administered subcutaneously. Unlike the other abortive agents, it has no vasoconstrictive effects; the most prominent treatment emergent adverse effect is gastrointestinal (GI) upset. Glucocorticoids, provided IV and later tapered orally, are effective when cluster headache attacks are not satisfactorily controlled.[12]

Pharmacologic Therapy for Headache Prophylaxis

KEY CONCEPT Prophylaxis for headache disorders is indicated if headaches are frequent or severe, significant disability occurs, pain-relieving medications are used frequently, or adverse events occur with acute therapies.[12,31]

▶ *Migraine Prophylaxis*

Migraine headaches that are severe, frequent, or lead to significant disability require long-term medication therapy. Prophylactic therapy is also recommended for migraines associated with neurologic focality because it may prevent permanent disability.[12] Although multiple medication classes have garnered US Food and Drug Administration (FDA) labeling for migraine prevention, there is no consensus on the best initial therapy (Table 36–4).[31] **KEY CONCEPT** The choice of pharmacologic agent is individually tailored to patient tolerability and medical comorbidities.

The β-blockers have long been a mainstay in migraine prevention, and many have been proven to be effective in improving patient symptoms. Cautious dosage titration is advised for those patients who do not have other indications for β-blocker

Table 36–4

Oral Medications for Prophylaxis of Migraines[12,17]

Medication (Brand Name)	Usual Dosage (mg/day)	Main Adverse Effects
Antiepileptics		
Topiramate (Topamax)[a]	25–200	Paresthesias, dizziness, fatigue, nausea
Valproic acid (Depakene)[a]	500–1500	
Divalproex sodium (Depakote)[a]	500–1500	
β-Blockers		
Atenolol (Tenormin)[b]	25–200	
Metoprolol (Lopressor)[a]	50–200	Fatigue, exercise intolerance
Nadolol (Corgard)[b]	20–160	
Propranolol (Inderal)[a]	80–240	
Timolol (Blocadren)[a]	10–30	
Antidepressants		
Amitriptyline (Elavil)[a]	10–150	Weight gain, dry mouth, sedation
Venlafaxine (Effexor)[a]	37.5–150	

[a] Level A: Established efficacy.

[b] Level B: Probably effective.

use. Comorbid reactive airway disease is a relative contraindication to β-blocker prophylaxis, and patients with cardiac conduction disturbances should be closely monitored.[17] Patients should also be advised to take only 5 mg of rizatriptan (max 15 mg/day) when they are prescribed propranolol because propranolol may increase levels of rizatriptan significantly.[24] Calcium channel antagonists are often used when patients cannot tolerate β-blockers. None of the calcium channel blockers carry an FDA indication, and their efficacies are considered to be variable. Angiotensin receptor blockers (ARBs) and angiotensin-converting enzyme inhibitors (ACEIs) have been evaluated for migraine prevention, but only two, lisinopril and candesartan, have shown possible efficacy.[17]

Low-dose amitriptyline or other tricyclic antidepressants (TCAs) have proven efficacy in migraine prevention.[17] Due to sedation, these medications are commonly administered at night. Secondary TCAs (eg, nortriptyline) or heterocyclic compounds (eg, trazodone) have fewer dose-limiting adverse effects than TCAs, especially anticholinergic effects (eg, dry mouth, constipation, and urinary retention), but efficacy has been variable with these agents. Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have been evaluated for migraine prevention, but thus far, only venlafaxine has demonstrated probable efficacy. The FDA has issued a controversial warning about using serotonergic antidepressants along with triptans due to the rare occurrence of serotonin syndrome.[35]

The antiseizure medications (ASM) valproic acid and topiramate are approved for migraine prophylaxis. In patients whose migraine headaches are believed to be related to trigeminal neuralgia, carbamazepine is used as prevention for both disorders.[17] Divalproex sodium doses are gradually titrated to 1000 mg/day; topiramate is titrated to a maximum of 100 mg twice per day. At these doses, serum drug level monitoring is infrequently needed.[17] Topiramate is especially useful in patients who have metabolic syndrome, diabetes, and dyslipidemia because it is unlikely to cause weight gain often seen with valproic acid. Topiramate has the potential for side effects such as paresthesia, fatigue, anorexia, nausea, and cognitive impairment. These side effects can be mitigated by a slow dosage titration and maintaining adequate hydration.[36]

Three injectable monoclonal antibodies targeting the CGRP were approved by the FDA for migraine prevention in 2018 and include erenumab-aooe, galcanezumab-gnlm, and fremanezumab-vfrm. They are all dosed as monthly injections with the exception of fremanezumab-vfrm that has an additional quarterly injection dosing option.[37–39] Later in 2020, Eptinezumab-jjmr was FDA approved as an intravenous infusion given over 30 minutes.[40] The most common side effects include injection site reactions and constipation. Further studies regarding long-term effectiveness and side effects are needed.

Methysergide is an ergotamine derivative that impacts central serotonin balance. Inflammatory fibrosis is a rare but serious adverse reaction associated with the prolonged use of methysergide. Retroperitoneal fibrosis, pulmonary fibrosis, or fibrosis in cardiac tissue can occur. These conditions may resolve upon drug withdrawal, but cardiac valvular damage can be irreversible. Some experts believe it is the best choice for refractory migraine with frequent attacks, but due to its significant adverse effect profile, it is not marketed in the United States.[41]

Given that migraines can be triggered by changes in hormonal balance, it is not surprising that some women have migraines around the time of menstruation. Often, these migraines can be prevented by starting NSAIDs prior to the beginning of menstruation. Triptans can be tried in patients unresponsive to NSAIDs. Three triptans have been shown to be effective in preventing menstrual migraines. Frovatriptan, naratriptan, and zolmitriptan can be considered and should be started 2 to 3 days prior to the beginning of menstruation.[31]

OnabotulinumtoxinA has received FDA approval for the treatment of chronic migraine, but the evidence supporting its use is conflicting. In 2008, the American Academy of Neurology conducted an evidence review and concluded that OnabotulinumtoxinA was probably ineffective for the prevention of migraines.[42] In the PREEMPT 1 and PREEMPT 2 trials, there was a statistically significant reduction in the number of headache days per month when compared to placebo, but the absolute difference between the two groups was only 1.8 days.[43,44]

While evidence is limited, some complementary alternative therapies can be considered for migraine prophylaxis. Petasites (butterbur) has been associated with a potential 60% reduction in the number of headaches experienced over a 1-month period when compared to placebo; however, the risk of liver toxicity associated primarily with the plant's root and allergic reactions in patients with asthma may limit its use. Studies for riboflavin have been mixed, with some older studies supporting its use for migraine prevention, but some newer studies have failed to show efficacy. Finally, MIG-99 (feverfew) has also shown possible efficacy with very limited trial evidence.[45]

▶ *Tension-Type Headache Prophylaxis*

The prevention of chronic TTHs uses the same pharmacologic strategies as for migraine prophylaxis. TCAs are the mainstay of chronic therapy. The efficacy of serotonergic agonists remains in question. Although there is a little need for muscle relaxants (eg, methocarbamol) in the treatment of acute TTH, they are often provided as a preventive intervention. Combination prophylactic therapies may be needed to wean patients from daily analgesic abuse. Stress reduction techniques may be particularly effective in this setting.[5]

▶ *Cluster Headache Prophylaxis*

The calcium channel blocker verapamil is the mainstay of cluster attack prevention and chronic prophylaxis.[5] It is dosed 240 to 360 mg/day within an attack period and may be dosed 120 to 240 mg/day for prevention during remission. Higher doses may be necessary to stave off recurrent cluster periods. Beneficial effects may be appreciated after 1 week of treatment, but 4 to 6 weeks is usually needed. Adverse effects include smooth muscle relaxation with the subsequent exacerbation of gastroesophageal reflux and the development of constipation. Caution should be exercised in patients with myocardial disease because verapamil is an inotropic and chronotropic cardiac suppressant.[5] Pharmacokinetic drug–drug interactions must be considered, as verapamil is a moderate inhibitor of oxidative metabolism through cytochrome P450 (CYP) enzyme 3A4. Eletriptan, a CYP 3A4 substrate, should be avoided concurrently with verapamil.[5,21] Lithium is another effective therapy to reduce headache frequency in a cluster series and limit recurrences.[12] The dose administered should be individualized to achieve a low serum concentration (0.4–0.8 mEq/L [mmol/L]). Dose adjustments in the setting of renal disease or congestive heart failure are required.[5] Lithium is contraindicated in patients concurrently prescribed thiazide diuretics, NSAIDs, ACEIs, or ARBs. Patient persistence with long-term lithium therapy may be hindered by the emergence of tremor, GI distress, and lethargy. Verapamil and lithium doses can be lowered when used in combination with ergotamine. If possible,

Patient Encounter Part 3: Creating a Care Plan

Based on the information presented, create a care plan for the acute and chronic management of this patient's headache. Your plan should include the following:

A statement of the drug-related needs and/or problems.

The goals of therapy.

A detailed, patient-specific therapeutic plan.

A monitoring plan to determine whether the goals have been achieved and adverse effects are avoided.

bedtime dosing is recommended, given the nocturnal predilection of cluster headache attacks.[11]

SPECIAL POPULATIONS

Migraine Headache in Children and Adolescents

Migraine headaches are common in children, and their prevalence increases in the adolescent years.[4] The diagnosis and evaluation of headaches are especially difficult in children, given their decreased ability to articulate symptoms. Treatment presents another challenge because medications used for headache management in adults have not been fully evaluated for efficacy and safety in children. Consensus panel recommendations identify ibuprofen as effective and acetaminophen as probably effective in the acute treatment of headache in patients older than 6 years.[41] Aspirin use is avoided due to the risk of precipitating Reye syndrome. The use of triptans in children and adolescents has not been shown to be more effective than placebo. Only rizatriptan is FDA approved for children over 6 and almotriptan for children over 12. The rest are approved for greater than 18 years of age.[20,24,45] Medication prophylaxis for migraines in children and adolescents is understudied with conflicting data.[46,47] Nonpharmacologic interventions and trigger identification and avoidance are advised.

Pregnancy

Headaches are common in pregnancy and are likely related to hormonal shifts. TTHs predominate; migraine attacks may increase in frequency, but more often, frequency decreases during pregnancy.[48] Recommendations for headache care during pregnancy are based on limited evidence and are largely anecdotal. Because headaches are not associated with fetal harm, reflexive pharmacologic therapy should be avoided and drug treatment choices carefully considered. Standard nonpharmacologic therapies are often sufficient. Acetaminophen is safe for the pregnant woman and her fetus.[49] NSAIDs are avoided late in the third trimester to prevent detrimental prostaglandin alterations leading to premature ductus arteriosus closure. Opioids are second-line agents and should not be used chronically. Opioids can lead to dependence in the mother and acute withdrawal in the infant after birth.[48] Centrally acting antiemetic agents are safe and may

Patient Care Process

KEY CONCEPT Individualized treatment regimens for headache disorders are based on headache type, pattern of occurrence, response to therapy, medication tolerability, and comorbid medical conditions.

Collect Information:

- Obtain a complete medical and social history to identify any potential drug–disease interaction or social factor that may influence treatment choices.
- Obtain a family medical history, focusing on headache or mental health disorders in first-degree relatives.
- Perform medication history, including prescription and nonprescription medications along with dietary supplements. Identify medication allergies.
- Complete a review of systems and physical examination to identify causes or complications of headache.
- Review medical records, including any laboratory assessment and radiographic finding.

Assess the Information:

- Based on information obtained for reviewing the patient's medical history, patient interview, review of systems, and physical examination, identify the type of headache.
- Determine if there are triggers for the patient's headaches.
- Assess laboratory assessments to determine renal function and liver function as these may affect medication choice.
- Based on patient history and family history, evaluate the patient's cardiovascular health especially if considering a triptan.
- If patient is already receiving pharmacotherapy, assess for appropriateness and efficacy.

Develop a Care Plan:

- Recommend appropriate pharmacologic therapy to abort headache based on type, patient characteristics, current medication profile, and comorbid conditions.
- When selecting new agents for acute management or prophylaxis, ensure that the medication is financially accessible.

Implement the Care Plan:

- Educate the patient on the administration, maximum dosage, and anticipated adverse effects of the prescribed medication and advise the patient when to seek emergency medical attention.
- Instruct the patient to keep a headache diary to assess therapeutic response.
- Educate on the potential for medication overuse headache.

Follow up: Monitor and Evaluate:

- Follow-up should be scheduled within 4 weeks of starting any new medication for headache to assess efficacy. As patient becomes more aware of headache symptoms and appropriate agents are on board for prevention and treatment of headache, follow-up can become less frequent (ie, 3–6 months).

be useful as adjunctive agents. Corticosteroids may be needed for intractable headache relief. Prednisone and methylprednisolone are preferred, as they are metabolized in the placenta and do not expose the fetus. In pregnant women with migraine headache, vasoconstrictive agents such as triptans are relatively contraindicated, even though maternal registry data reveal little teratogenicity. If triptans are considered for acute migraine treatment, sumatriptan, naratriptan, and rizatriptan have the greatest evidence of safety during pregnancy.[48] Ergot compounds are strictly avoided because they may precipitate uterine contractions and placental ischemia leading to hypoxemia in the fetus. Migraine prophylaxis is considered cautiously because β-blockers and calcium channel antagonists may lead to maternal hypotension and diminished placental blood flow or fetal bradycardia.[48] Use of antiseizure medications in this setting has not been sufficiently studied to allow definitive recommendations.

Outcome Evaluation

To ensure optimal headache management, in acute treatment and prophylactic therapy, monitor regimens both for therapeutic outcomes and adverse events, which may impact quality of life and medication adherence. In acute management, monitor patients for pain improvement within 2 hours of treatment initiation.[49] If pain control has not been achieved, additional therapy may be needed. With chronic management for headache prevention, patients are encouraged to track progress in a headache diary, and clinicians monitor overall headache status every several weeks to months for a 50% or greater reduction in headaches. A slow decrease in headache frequency is anticipated during this time. Monitoring for adverse effects is central to successful treatment. For acute management, monitor for GI effects from analgesics such as NSAIDs or octreotide, vasoconstrictive symptoms from triptans, and nausea and vascular problems from ergotamine derivatives. Monitor those taking β-blockers for reactive airway disease and cardiac conduction disturbances. Monitor those taking TCAs for sedation and anticholinergic effects such as dry mouth, constipation, and urinary retention. Monitor patients taking calcium channel blockers for gastroesophageal reflux symptoms and constipation, and monitor those taking lithium for tremor, GI distress, and lethargy.

Acknowledgments

The authors and editors wish to acknowledge and thank Dr. Joshua Fleming, the first author of this chapter in the third through fifth editions of this book.

Abbreviations Introduced in This Chapter

ACEI	Angiotensin-converting enzyme inhibitor
ARB	Angiotensin receptor blocker
CBC	Complete blood count
CGRP	Calcitonin gene–related peptide
CNS	Central nervous system
CV	Cardiovascular
CYP	Cytochrome P450
DHE	Dihydroergotamine
ESR	Erythrocyte sedimentation rate
FDA	Food and Drug Administration
GABA	γ-Aminobutyric acid
GI	Gastrointestinal
HI	Hepatic impairment
HIV	Human immunodeficiency virus
IHS	International Headache Society
MAO-A	Monoamine oxidase type A
MOH	Medication overuse headache
NSAID	Nonsteroidal anti-inflammatory drug
OTC	Over-the-counter
RI	Renal impairment
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant
TFT	Thyroid function test
TTH	Tension-type headache

Substance-Related Disorders

Chris Paxos and Christian J. Teter

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify the prevalence of use for alcohol, opioids, central nervous system (CNS) stimulants, cannabinoids, and tobacco in the US population.
2. Explain the commonalities of action of substances on the reward system in the brain.
3. Determine when a patient meets criteria for substance use disorder.
4. Identify the typical signs and symptoms of intoxication and withdrawal associated with the use of alcohol, opioids, CNS stimulants, cannabinoids, and tobacco.
5. Determine the appropriate treatment measures to produce a desired outcome after episodes of intoxication and withdrawal.
6. Choose specific pharmacotherapeutic options based on patient-specific factors.
7. Recommend a comprehensive medication treatment and monitoring program to help maintain recovery and prevent relapse to substance use.

INTRODUCTION

Substance use disorders (SUDs) are highly prevalent worldwide. In the United States, patterns of substance use have been cyclical. For example, cocaine was first isolated from coca leaves in 1860. Its use was advocated by many in the medical establishment until the mid-1890s when it became evident that chronic use might be addictive in some individuals and could have deleterious physiologic effects. Its use decreased after prescribing and dispensing restrictions in the early 20th century. In the 1980s, a smokeable formulation (ie, crack) became available, and cocaine use again became epidemic. This historically cyclic nature of substance use is common to many substances with abuse potential.

KEY CONCEPT Pharmacotherapy has a role in treatment of some substance-related disorders, including intoxication, withdrawal, and/or long-term relapse prevention. These substances include alcohol, opioids, central nervous system (CNS) stimulants, cannabinoids, and tobacco. This chapter focuses on pharmacotherapy for these common substance-related disorders. Although other substances can be misused (eg, benzodiazepines), they are not the focus of this chapter.

EPIDEMIOLOGY AND ETIOLOGY

The National Survey on Drug Use and Health (NSDUH) uses a representative sample of individuals 12 years or older to determine the annual prevalence of licit and illicit substance use.[1] In 2018, 164.8 million Americans (60.2% of the population) used a substance, including alcohol, tobacco, or illicit substances in the past month. More than half (51.1%; 139.8 million) of Americans reported current (ie, past month) alcohol use. Nearly one in four Americans (24.5%; 67.1 million) reported binge drinking (ie, five or more drinks for men and four or more drinks for women), and 6.1% (16.6 million) reported heavy drinking (ie, binge drinking on five or more occasions) over the past month. Approximately one-fifth (21.5%; 58.8 million) of Americans reported current tobacco use. During the time frame of 2002 to 2018, cigarette use declined overall; however, this may be due in part to electronic cigarettes. Regarding illicit drug use, one in five Americans (19.4%; 53.2 million) reported past year use, with cannabis and prescription pain relievers being most common (Figure 37–1).[1] The NSDUH findings indicate that substance use is wide ranging and continues to be a major public health concern.

Reward Pathway

KEY CONCEPT Virtually all substances of abuse appear to activate the same brain reward pathway, which is highlighted by dopaminergic neurotransmission arising in the ventral tegmental area (VTA) and projecting to the nucleus accumbens (NA) and prefrontal cortex (PFC). This pathway is also responsible for reinforcement of behaviors, focus, and learning.

Figure 37–2 depicts the mesocorticolimbic dopamine (DA) pathway. Key components are DA projections from the VTA to the NA and PFC.[2,3] Many studies support mesolimbic DA system involvement in natural rewards and reinforcement; however, there is also evidence that reinforcement exists independently of DA.[4,5] The initial pleasurable experiences secondary to substance use appear to be primarily attributable to activation of primary reward circuits in the brain. These same reward circuits operate under normal circumstances to reinforce activities that promote survival, such as food and water consumption, social affiliation, or sexual activity. In SUDs, these systems become disrupted, especially after repeated substance use in susceptible individuals. Therefore, SUDs may be viewed as a disease of disrupted reinforcement, where seeking and use of substances often supersedes natural rewards.

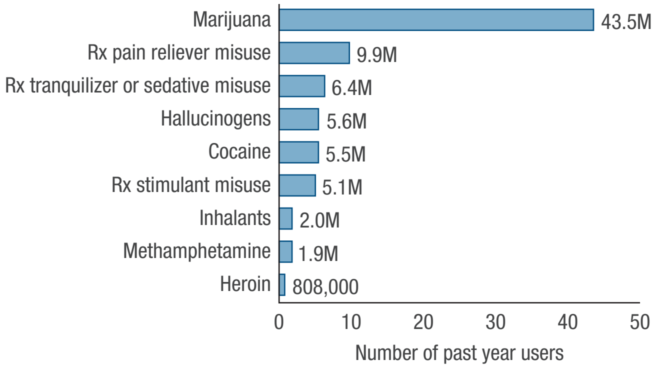

FIGURE 37–1. Past-year illicit drug use in the United States among individuals 12 years and older in 2018. (Data and figure in the public domain from Substance Abuse and Mental Health Services Administration. Key Substance Use and Mental Health Indicators in the United States: Results from the 2018 National Survey on Drug Use and Health. Rockville, MD: Center for Behavioral Health Statistics and Quality, Substance Abuse and Mental Health Services Administration, 2019.)

Although most individuals experience pleasant effects, most persons that misuse these substances do not develop a disorder. Why some individuals develop SUDs while others do not relates to complex genetic, environmental, and cultural factors.

PATHOPHYSIOLOGY

Neuronal Adaptation

KEY CONCEPT Although activation of reward pathways explains the pleasurable sensations associated with acute substance use, chronic use (which may result in substance-related disorders) may be related to neuroadaptive effects within the brain.

While diagnostic criteria use SUD and related terminology, the term addiction continues to appear in the literature. Addiction is often described as a repeating cycle with three phases: binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation (ie, craving).[5] The binge/intoxication phase is characterized by using a substance with abuse potential and experiencing its pleasurable or rewarding effects. Chronic use leads to neuroadaptations in the brain, including a generalized decrease in DA neurotransmission and increase in corticotropin-releasing factor (CRF). After a period of chronic use, an individual may experience the withdrawal/negative affect phase in the absence of the substance. Withdrawal symptoms can include negative emotions and physical symptoms. The preoccupation/anticipation phase, characterized by an individual craving the substance, may involve other neurotransmitters (ie, beyond DA). For example, elevated CRF, norepinephrine (NE), and glutamate may exist in the “extended amygdala” during prolonged abstinence. Perhaps these changes lead to a long-term need to use substances to relieve unpleasant symptoms, such as stress.[5] Multiple factors are associated with an increased risk of relapse, including substance availability, psychological stressors, and triggers such as seeing a white powder or returning to a location where substances were previously obtained. These factors may trigger residual adaptive changes (eg, elevated glutamatergic activity) that occurred during the period of addiction.

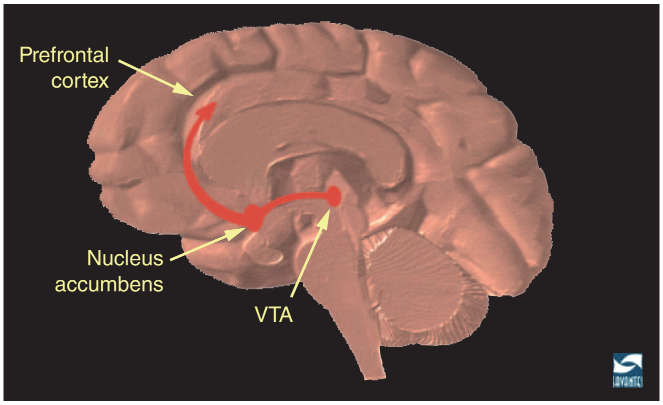

FIGURE 37–2. The mesocorticolimbic dopaminergic (ie, “reward”) pathway. (VTA, ventral tegmental area.) (Data available in the public domain from The National Institute on Drug Abuse [Internet]. https://www.drugabuse.gov/publications/teaching-addiction-science/understanding-drug-abuse-addiction-what-science-says.)

Patient Encounter 1

A 46-year-old man is admitted to inpatient psychiatry unit secondary to depressive symptoms. Past medical history includes major depressive disorder and alcohol use disorder, specifically, heavy episodic alcohol consumption. Home medications include sertraline and acamprosate, both of which he takes regularly. On examination, the patient reports that he does not drink consistently, but when he does consume alcohol, he tends to “overdo it” and that a typical drinking episode may “easily” involve 6 to 10 drinks. The patient appears to possess insight that his drinking is excessive and likely harmful to his health and well-being. The patient would like to reduce the number of drinks he consumes on a given occasion and “lessen the damage” he might be doing to himself.

What are the most immediate actions to be taken regarding this patient’s treatment?

What pharmacotherapy can help the patient maintain abstinence from alcohol?

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT Assess individuals for behaviors indicative of a substance use disorder, such as impaired control over substance use, risky use, and social impairment, as described in the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5).[6] Diagnostic criteria from the *DSM-5* are listed in Table 37–1. Consistent with the *DSM-5*, the remainder of this chapter is organized by pharmacologic class and discusses intoxication, withdrawal, and SUDs for each class (except tobacco, which does not have *DSM-5* intoxication criteria).

A variety of standardized instruments are available to screen for and assess the various stages of substance use and its consequences, such as withdrawal symptoms and functional impairment (Table 37–2).[7,8] The Addiction Severity Index (ASI) is the gold-standard instrument that assesses seven problem areas associated with substance use, such as medical and psychiatric status, in addition to measures of alcohol and drug use.[7] Many SUD instruments can be freely obtained from the Substance Abuse and Mental Health Services Administration (SAMHSA).

Table 37–1

***DSM-5* Criteria for Diagnosis of Substance Use Disorders**[6]

A problematic pattern of substance use leading to clinically significant impairment or distress; manifested by ≥ 2 of the following, occurring within a 12-month period:

1. Substance often taken in larger amounts or over longer period than intended.
2. Persistent desire or unsuccessful efforts to cut down or control substance use.
3. Great deal of time spent in activities necessary to obtain substance, use substance, or recover from its effects.
4. Craving, or a strong desire or urge to use the substance.
5. Recurrent substance use resulting in failure to fulfill major role obligations at work, school, or home.
6. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance.
7. Important social, occupational, or recreational activities are given up or reduced because of substance use.
8. Recurrent substance use in situations in which it is physically hazardous.
9. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem likely to have been caused or exacerbated by substance.
10. Tolerance, as defined by either of the following:
    a. Need for markedly increased amounts of substance to achieve intoxication or desired effect.
    b. Markedly diminished effect with continued use of same amount of substance.
11. Withdrawal, as manifested by either of the following:
    a. Characteristic withdrawal syndrome for the substance (refer to Criteria A and B of the *DSM-5* criteria set for substance withdrawal).
    b. Substance (or closely related substance) is taken to relieve or avoid withdrawal symptoms.

Specify[a] current severity:
Mild: Presence of 2 to 3 symptoms.
Moderate: Presence of 4 to 5 symptoms.
Severe: Presence of ≥ 6 symptoms.

[a] Additional specifiers (eg, early vs sustained remission) and substance-specific notes (eg, taking opioid under medical supervision) are included in the *DSM-5*.

Intoxication Signs and Symptoms

Intoxication caused by most substances is described in the *DSM-5* as clinically significant, problematic behavioral or psychological changes to the individual, which are caused by the physiologic effects of the substance. These changes are observed during or shortly after use of the substance. Euphoria or experiencing a pleasurable sensation are initial effects of most substances with abuse potential.[9] Other signs and symptoms are specific to the particular substance or medication class involved. Table 37–3 lists the effects of intoxication from select substances.[6,10-13]

Withdrawal Signs and Symptoms

Although most substances with abuse potential can cause some degree of physical dependence, the severity of withdrawal varies considerably among them. Table 37–4 lists common withdrawal symptoms that emerge upon abstinence from substance use.[6,10-14] Typically, withdrawal symptoms are the opposite of the acute effects of the substance. For example, although alcohol is a CNS depressant, signs and symptoms of withdrawal encompass a hyperalert physiologic response.

Patient Encounter 2

A 27-year-old man reports the intention to quit his long-term cannabinoid use. Upon further discussion, it becomes clear that each time the patient attempts to quit cannabinoids, which he takes in many different forms, such as edibles and via his vaporizer, his anxiety becomes intolerable. This, in turn, also makes it very difficult for him to sleep through the night.

Are there medications that can be recommended to help the patient quit cannabinoid use?

Are there any limitations to these recommendations that should be disclosed?

TREATMENT OF SUBSTANCE USE DISORDER

Patients with SUDs require more than pharmacotherapy to achieve sustained remission. However, medications can sometimes alleviate the effects of intoxication, attenuate withdrawal symptoms, or somewhat decrease craving and likelihood of relapse. For example, pleasurable and intoxicating effects of opioids appear to be caused by their action as μ-opioid receptor agonists. Competitive μ-opioid receptor antagonists, such as naloxone, acutely reverse many opioid effects, including symptoms of intoxication. To date, specific antagonists for most other substances are unavailable. Similarly, reversal of withdrawal syndromes caused by substances with abuse potential is not always possible. Benzodiazepines are used for alcohol withdrawal because of cross tolerance with alcohol. For long-term medication management, patients with opioid use disorder can be maintained on a regimen of medically managed, US Food and Drug Administration (FDA)-approved opioid medications. Regardless of the pharmacotherapy chosen, medications should always be used as adjuncts to a comprehensive psychosocial approach.[10]

TREATMENT OF INTOXICATION SYNDROMES

KEY CONCEPT Treatment goals for acute intoxication of alcohol, opioids, CNS stimulants, and cannabinoids include (a) management of psychological/psychiatric manifestations of intoxication, such as aggression, hostility, and psychosis and (b) management of medical manifestations of intoxication, such as respiratory depression, hyperthermia, hypertension, cardiac arrhythmias, stroke, and seizures. In all cases of intoxication that require medical intervention, referral to and participation in treatment programs are desirable.

Alcohol Intoxication

Desired outcomes are appropriate management of medical problems, prevention of harmful behaviors, and stabilization of mood. Most cases of mild-to-moderate alcohol intoxication, including cases with blood alcohol concentrations (BACs) at lower limits of legal intoxication, do not require medical treatment. Providing a safe environment and reassurance until alcohol effects have dissipated is sufficient in most cases. Initially, BACs may continue to rise if gastrointestinal (GI) absorption is still occurring. Otherwise, BACs generally decrease at a rate of 15 to 20 mg/dL (0.015%–0.02% or 3.3–4.3 mmol/L) per hour. Table 37–3 lists the physiologic effects of alcohol at various BACs; however, individuals with tolerance to alcohol may not show the same level of symptoms at a given BAC as individuals without tolerance.

At more severe levels of intoxication, confusion, stupor, coma, and death may occur. Clinicians must rule out other causes of

Table 37–2

Commonly Used Instruments for Assessing Patients With Substance Use Disorders[7,8]

Instrument	Purpose	Values and Interpretation
Addiction Severity Index (ASI)	Assessment tool Semi-structured interview that addresses seven problem areas: medical status, employment and support, alcohol use, drug use, legal status, family and social status, and psychiatric status Questions include frequency, duration, and severity of problems in the past 30 days or lifetime for various substances Clinician- or technician-administered	200 items Patient and interviewer ratings included Interviewer severity ratings of "need for additional treatment" and composite scores to measure severity Composite score normative data from nationally representative sample of treatment programs is available for those seeking to compare a patient's ASI data with national data (www.tresearch.org); otherwise, comparisons with previous (eg, baseline) composite scores are useful
Alcohol Use Disorders Identification Test (AUDIT)	Screening tool Evaluates quantity and frequency of drinking, physiologic dependence on alcohol, and harmful use	10 items; maximum score = 40 Score of ≥ 8 identifies heavy drinking and those with possible alcohol use disorders
Alcohol Use Disorders Identification Test—Concise (AUDIT-C)	Clinician- or self-administered	AUDIT-C is an abbreviated 3-item version
CAGE Questionnaire	Screening tool Used to identify the presence of problematic drinking Clinician- or self-administered	4 items; maximum score = 4 Score of ≥ 2 is positive and suggests problem drinking Positive screen prompts the need for further assessment
Clinical Institute Withdrawal Assessment–Alcohol, Revised (CIWA-Ar)	Assessment tool Gold-standard alcohol withdrawal assessment; used as part of a symptom-triggered approach Clinician-administered	10 items; maximum score = 67 < 10: mild withdrawal 10–18: moderate withdrawal > 18: severe withdrawal Monitor scores over time; ≥ 8–10 (depending on institutional protocols or co-occurring conditions) indicates need for medication
Clinical Opiate Withdrawal Scale (COWS)	Assessment tool Used to follow the course of opioid withdrawal symptoms and effectiveness of medication regimens Clinician-administered	11 items Score of 0 (asymptomatic) to 4 or 5 (severely symptomatic) for each item based on intensity of signs and symptoms 5–12: mild withdrawal 13–24: moderate withdrawal 25–36: moderately severe withdrawal > 36: severe withdrawal Monitor scores over time; higher scores may indicate need for medication; no standard cut-off exists
Fagerström Test for Nicotine Dependence	Assesses extent of nicotine tolerance, dependence, and craving	6 items Higher scores may predict greater difficulty quitting 0–2: very low 3–4: low 5: moderate 6–7: high 8–10: very high

these serious adverse events because patients may combine alcohol with other substances, sustain head or other injuries, or have vitamin deficiencies and electrolyte abnormalities. If consciousness is impaired, give thiamine by the intravenous (IV) or intramuscular (IM) route at 100 mg/day for at least 3 days. If hypoglycemia is suspected, administer thiamine before glucose-containing fluids to prevent precipitation of acute Wernicke syndrome (see Alcohol Withdrawal section). Interactions between alcohol and medications may also occur. Table 37–5 details drug–drug interactions associated with medications used to treat SUDs.[15]

Behaviorally, patients may insist on driving, become aggressive and agitated, or otherwise be a danger to themselves or others. Indeed, most suicidal behaviors among those misusing alcohol occur during intoxication. Antipsychotics lower the seizure threshold and are best avoided. However, in some instances, agitation may require antipsychotic treatment. Haloperidol has been proposed as a potential option for agitation in the presence of alcohol intoxication.[16] Sedation with benzodiazepines has been used but, in the presence of alcohol, respiratory depression can be dangerous or even fatal.

Opioid Intoxication

The word *opioid* refers to medications and substances that exert their action through the opioid system. Opioids encompass a wide range of substances, including naturally occurring (eg, morphine) and synthetic (eg, oxycodone).

Patients with acute intoxication usually present with miosis, euphoria, slow breathing, slow heart rate, and low blood pressure. Seizures may occur with certain agents, such as meperidine.

Table 37–3

Signs and Symptoms of Drug Intoxication for Select Substances[6,10-13]

Drug	Behavioral Effects	Physiologic Effects
Alcohol	Disinhibition, euphoria, dysphoria, inappropriate aggressive or sexual behavior, impaired judgment; possibly progressing to somnolence and coma as the blood level increases	Blood levels 0.02%–0.1% (20–100 mg/dL or 4.3–21.7 mmol/L): Slight impairment (eg, reaction time) Blood levels 0.1%–0.2% (100–200 mg/dL or 21.7–43.4 mmol/L): Significant impairment (eg, balance, speech, vision) Blood levels 0.2%–0.3% (200–300 mg/dL or 43.4–65.1 mmol/L): Marked ataxia, mental confusion, nausea, vomiting Blood levels 0.3%–0.4% (300–400 mg/dL or 65.1–86.8 mmol/L): Severe dysarthria, amnesia, hypothermia Blood levels > 0.4% (400 mg/dL or 86.8 mmol/L): Coma, decreased respiration or respiratory arrest, aspiration of gastric contents, airway obstruction by flaccid tongue, drop in blood pressure and body temperature
Opioids	Drowsiness, sedation, slurred speech, impaired memory and attention, psychomotor retardation	Nausea, vomiting, respiratory depression (dose-related), stupor, coma, itching, miosis, hypothermia, bradycardia
CNS stimulants	Elated mood, anxiety, panic, impaired judgment, violent behavior, paranoia, delusions, hallucinations (tactile or auditory, rarely visual), increased motor activity, compulsive or stereotyped behavior (eg, skin picking)	Neurologic/neuromuscular: mydriasis, headache, tremor, hyperreflexia, muscle twitching, flushing, hyperthermia or cold sweats, rhabdomyolysis (possibly resulting in renal failure), dyskinesias, seizures, coma Cardiovascular: tachycardia, hypertension, vasoconstriction, arrhythmias, myocardial infarction, cerebral hemorrhage GI: nausea, vomiting, weight loss
Cannabinoids	Anxiety, euphoria, paranoia, impaired judgment, social withdrawal	Impaired motor coordination, tachycardia, xerostomia, conjunctival injection, increased appetite

CNS, central nervous system; GI, gastrointestinal.

Monitor patients carefully to avoid cardiac and respiratory depression and death from overdose. One strategy is to reverse intoxication using naloxone 0.4 to 2 mg IV every 2 to 3 minutes up to 10 mg; the IM, subcutaneous, or intranasal (IN) route may be used if IV access is unavailable. Naloxone is shorter-acting than many opioids and may require readministration at periodic intervals; otherwise, patients could lapse into cardiopulmonary arrest after a symptom-free interval of reversed intoxication. In addition, naloxone can induce withdrawal symptoms in patients with physical dependence to opioids, so patients may awaken feeling distressed and agitated. Buprenorphine intoxication may be more difficult to reverse.[17]

Table 37–4

Signs and Symptoms of Drug Withdrawal for Select Substances[6,10-14]

Drug	Timeline	Symptoms
Alcohol	As levels decrease:	
	Early symptoms	Tremor, nausea, vomiting, tachycardia (> 110 beats/min), hypertension (> 140/90 mm Hg), headache, insomnia
	Peak (24 hours)	Seizure activity (usually 1 or 2 generalized tonic-clonic seizures, but can be numerous and possibly fatal)
	72–96 hours	Delirium tremens
	Onset at any time	Hallucinations (usually visual)
Opioids	For shorter-acting opioids (eg, heroin, morphine) withdrawal may begin 6–24 hours after last dose and last for about 1 week; with longer-acting opioids (eg, methadone) may take up to 2–4 days for withdrawal to emerge and will last longer	EENT: lacrimation, mydriasis, rhinorrhea GI: nausea, vomiting, diarrhea Cardiovascular: increased heart rate and blood pressure CNS: irritability, restlessness, yawning Musculoskeletal: increased body temperature, piloerection
CNS stimulants	Stage 1: immediately following binge	Craving, intense dysphoria, depression, anxiety, agitation
	Stage 2: within 1–4 hours	Dysphoria, desire for sleep
	Stage 3: 3–4 days	Hypersomnia, increased appetite, craving may dissipate but return later
Cannabinoids	Withdrawal symptom onset typically within 24–72 hours; peaks within 1 week	Severity reflects degree and duration of cannabinoid use; symptoms include irritability, anxiety, sleep abnormalities, depressed mood, headache, tremors, sweating, chills
Tobacco	Begins within 24 hours of cessation; peaks within 1–2 weeks; may persist for months	Severity reflects degree and duration of nicotine use; symptoms include irritability, anxiety, frustration, craving, difficulty concentrating, decreased heart rate, increased appetite

CNS, central nervous system; EENT, ears, eyes, nose, and throat; GI, gastrointestinal.

Table 37–5

Clinically Relevant Drug Interactions With Substances or Medications Used to Treat Substance Use Disorders[15]

Drug	Interacting Drug	Type of Interaction
Amphetamines	MAOIs	Combination of amphetamines and MAOIs may result in hypertensive reactions; AVOID combination
	Sodium bicarbonate	Sodium bicarbonate increases renal tubular reabsorption of amphetamine, resulting in prolonged amphetamine elimination half-life; closely monitor
Buprenorphine	Atazanavir	Combination of buprenorphine and atazanavir (without ritonavir) results in both lower atazanavir levels and higher buprenorphine levels; AVOID combination
	CYP3A4 inhibitors	May raise buprenorphine levels; monitor for greater than expected effects
Bupropion	MAOIs	Combination of bupropion and MAOIs may result in hypertensive reactions; AVOID combination
	Substances that lower seizure threshold	Use caution when initiating other medications that lower the seizure threshold; AVOID bupropion in patients at risk for experiencing alcohol withdrawal
Cigarette smoking	CYP1A2 substrates	Cigarette smoking (but not NRT) induces CYP1A2, increasing metabolism of CYP1A2 substrates (eg, theophylline, olanzapine, clozapine); may need to increase substrate dose when patient begins to smoke or decrease substrate dose if smoking is stopped
Disulfiram	Alcohol-containing solutions	Disulfiram reaction; AVOID combination
	Metronidazole	Combination has led to CNS effects (eg, psychosis); AVOID combination
	Benzodiazepines	Disulfiram (weakly) inhibits CYP1A2, 2C9, and 3A4; many benzodiazepines are metabolized via these pathways and doses may need to be lowered; lorazepam and oxazepam undergo conjugation and are alternatives
	Cocaine	Disulfiram decreases clearance of cocaine; may have increased or prolonged cocaine effects with combination
	Phenytoin	Disulfiram decreases metabolism of phenytoin, resulting in higher phenytoin levels; phenytoin dose may need to be reduced; because phenytoin undergoes nonlinear metabolism, it is difficult to predict magnitude of increase in blood levels; AVOID combination if possible
Alcohol	Acetaminophen	Chronic alcohol use increases hepatotoxicity risk when acetaminophen is used in high doses
	Bupropion	Abrupt discontinuation of alcohol with bupropion use may lower seizure threshold; AVOID bupropion in patients at risk for experiencing alcohol withdrawal
	Cefotetan or metronidazole	Disulfiram-type reaction may occur when these anti-infectives are combined with alcohol; AVOID combination
	CNS depressants	Alcohol may potentiate the effects of CNS depressant medications; advise patients to AVOID combination
	Methotrexate	Risk of hepatotoxicity may be increased in those who chronically drink large amounts of alcohol; AVOID methotrexate in this population if possible; otherwise, monitor LFTs
	MAOIs	Alcohol DOES NOT interact with MAOIs; however, tyramine may be a component of aged alcoholic drinks, such as red wines or tap beers
	Tapentadol	Alcohol may result in higher maximum serum levels of extended-release tapentadol; AVOID combination
Methadone	CYP3A4 inducers	Methadone is primarily metabolized via CYP3A4; if used together, may need to increase methadone dose to avoid withdrawal
	CYP3A4 inhibitors	May result in higher methadone levels; methadone dose adjustment should be based on clinical judgment, but a dose decrease may be necessary
	Didanosine	Methadone decreases oral absorption of didanosine; monitor the therapeutic effects of didanosine as a dose increase may be necessary
	Efavirenz	Efavirenz is a CYP3A4 inducer; efavirenz decreases methadone levels and has precipitated methadone withdrawal; may need to increase methadone dose
	MAOIs	Potential serotonin syndrome when MAOIs are combined with methadone; AVOID combination
	Nevirapine	Nevirapine is a CYP3A4 inducer and may decrease methadone levels, resulting in withdrawal complaints; may need to increase methadone dose
	QTc-prolonging medications	Medications that prolong the QT interval (eg, ziprasidone) should be AVOIDED with methadone when possible due to additive QT-prolonging effects
	Zidovudine	Methadone increases zidovudine levels, likely via methadone inhibition of both metabolic and renal clearance of zidovudine; may need to decrease zidovudine dose to avoid toxicity

CNS, central nervous system; CYP, cytochrome P450; LFT, liver function test; MAOI, monoamine oxidase inhibitor; NRT, nicotine replacement therapy.

Secure the airway and ensure breathing in cases of opioid overdose. In some cases, intubation and manual or mechanical ventilation may be required to avoid oxygen desaturation leading to brain hypoxia or anoxia and brain damage or death.

New opportunities for "take-home" naloxone have emerged in an effort to prevent overdose deaths. Many states allow naloxone distribution to family members or friends who can administer it if a patient is experiencing opioid intoxication. The FDA has approved a naloxone autoinjector and IN naloxone for this purpose.[15,17] The IN naloxone is commonly used in nonmedical settings due to ease of use. Educate patients and caregivers on naloxone, including when to use, how to assemble, proper administration, and notifying emergency services.[8]

Stimulant (Cocaine and Amphetamines) Intoxication

Desired outcomes of stimulant intoxication treatment are appropriate management of medical and psychiatric complications. Medical problems include hyperthermia, hypertension, arrhythmias, chest pain, stroke, seizures, and rhabdomyolysis. Some problems are related to route of administration, such as nosebleeds or infections with IN or IV administration, respectively. Psychiatric effects include anxiety, aggression, and psychosis.[13]

Pharmacotherapy for stimulant intoxication in acute settings may include benzodiazepines, aspirin, nitroglycerin, nitroprusside, and phentolamine.[13] The American Heart Association guidelines indicate that acute use of β-blockers is not recommended and may worsen cocaine-related chest pain and hypertension secondary to unopposed α-receptor–mediated vasoconstriction.[18] Rhabdomyolysis management includes administration of IV fluids to enhance renal perfusion.[13]

Cocaine is short-acting, and a single benzodiazepine may provide sufficient treatment for anxiety reactions. Depending on benzodiazepine half-life, multiple doses may be required for longer-acting amphetamine intoxication. Antipsychotics can manage psychosis, and psychotic symptoms usually respond rapidly in the absence of other co-occurring psychiatric disorders.[13]

Cannabinoid Intoxication

No established treatment recommendations exist for cannabinoid intoxication. Symptoms may include tachycardia, anxiety, and paranoia. Symptomatic treatment is commonly used. Synthetic cannabinoids are more likely than cannabis to produce serious psychiatric disturbances and may require aggressive benzodiazepine treatment for intense symptoms of anxiety or psychosis. These intense psychiatric symptoms are theorized to result from potent full-agonist activity and the lack of cannabidiol in synthetic products.[13] Cannabidiol has been associated with diminishing anxious and psychotic symptoms and behaviors.[19]

TREATMENT OF WITHDRAWAL SYNDROMES

KEY CONCEPT Treatment goals for withdrawal from alcohol, opioids, CNS stimulants, and cannabinoids include (a) a determination if pharmacologic treatment of withdrawal symptoms is necessary, (b) management of other medical manifestations, and (c) referral to the appropriate program for long-term treatment. Desired outcomes in the treatment of withdrawal syndromes are to ensure patient safety, comfort, and successful transition to longer-term maintenance treatment. Referral to specialized SUD treatment is strongly recommended after treatment of withdrawal. Rapid referral can introduce patients to the concept of recovery while they still vividly recall the negative consequences from using substances. Achieving a drug-free state by detoxification and then rehabilitation with a focus on total abstinence, or a reduction in substance use for some individuals, is the ideal outcome.

Alcohol Withdrawal

Alcohol withdrawal is characterized as either uncomplicated or complicated. Each differs in terms of pharmacologic treatment.

▶ *Uncomplicated Alcohol Withdrawal*

Uncomplicated alcohol withdrawal is the more commonly observed syndrome and is not complicated by seizures, **delirium tremens** (DTs), or hallucinosis. Symptoms are typically rated using a validated scale, such as the Clinical Institute Withdrawal Assessment–Alcohol, Revised (CIWA-Ar) (Table 37–2). There is some evidence for "kindling" during successive episodes of alcohol withdrawal, such that symptom severity and complications increase with additional withdrawal episodes.[11,20,21]

Benzodiazepines are the treatment of choice for uncomplicated alcohol withdrawal.[10] Anticonvulsants, such as carbamazepine, sodium valproate, and gabapentin, have also been evaluated. Commonly used benzodiazepines include lorazepam, diazepam, and chlordiazepoxide. They differ by routes of administration and by pharmacokinetic properties, such as the rapidity of onset due to the rate of GI absorption and the rate of crossing the blood–brain barrier. Benzodiazepines are given using a symptom-triggered approach or loading dose strategy. Adjunctive "as needed" medications are typically used, as well.[11]

Benzodiazepines can be administered for signs and symptoms of alcohol withdrawal using a symptom-triggered approach with the CIWA-Ar scale.[22] The recommended CIWA-Ar threshold score for treating uncomplicated alcohol withdrawal with medications is 8. When the CIWA-Ar score is 8 or greater, this "triggers" benzodiazepine administration. For example, lorazepam is given at a dose of 1 to 2 mg. The CIWA-Ar is then repeated hourly after each administration during the first 24 hours until the patient's withdrawal symptoms are minimized. Risks of not treating patients with high CIWA-Ar scores with medication are seizures and DTs, and those with a prior history of seizures or DTs have an increased risk for subsequent episodes.

An alternative to the symptom-triggered approach is the loading dose strategy. Longer-acting agents, such as diazepam and chlordiazepoxide, are given in large doses initially, then followed by a 3- to 5-day taper. Their long half-lives and active metabolites usually provide a natural taper without further medication administration. Diazepam may be preferred to chlordiazepoxide secondary to its faster onset (ie, quicker GI absorption and rapid CNS entry due to high lipophilicity). However, a faster onset of action may be associated with euphoria and is a treatment disadvantage. This approach may be accompanied by "as needed" short-acting benzodiazepine doses for breakthrough alcohol withdrawal symptoms.

Special Dosing Considerations Unlike chlordiazepoxide and diazepam, lorazepam is not metabolized into active compounds. It is excreted by the kidneys after glucuronidation. This is important because many patients with alcohol use disorder have compromised liver function. Therefore, when treatment is initiated before results of liver function tests (LFTs) are known, lorazepam may be preferred. Patients with liver disease may still be treated with diazepam or chlordiazepoxide at lower doses.[11]

American Psychiatric Association (APA) guidelines recommend thiamine for patients being treated for moderate-to-severe alcohol use disorders to prevent or treat adverse neurologic symptoms.[10] However, there are inadequate data with regard to the most efficacious thiamine dose, frequency, and route of administration to prevent or treat Wernicke syndrome associated with alcohol use disorders.[23] The APA guidelines recommend thiamine 50 to 100 mg/day given IV or IM, although other guidelines recommend higher doses (eg, thiamine 300 mg/day).[10,24] Administration of thiamine, essential for proper energy utilization by the CNS, must precede glucose-containing IV fluid administration, which can help prevent an acute exacerbation of Wernicke syndrome.

▶ *Complicated Alcohol Withdrawal*

Alcohol Withdrawal Seizures Alcohol withdrawal seizures, a medical emergency, should be treated in an inpatient setting. Withdrawal seizures are usually generalized tonic-clonic convulsions. Although binge drinking and alcohol withdrawal can lead to status epilepticus, the occurrence of focal seizures or status epilepticus may also suggest another etiology. Management consists of keeping the airway open and preventing self-injury during convulsions. Benzodiazepines are the treatment of choice. Give diazepam 5 to 10 mg IV to terminate a seizure if IV access is available. Repeat dose in 5 minutes if seizures persist. Alternatively, lorazepam 4 mg IM may be given, followed by insertion of an IV line after convulsive movements subside. In the event of a recurrent seizure, lorazepam 2 mg IV may be administered if the patient received IM lorazepam. Avoid IM diazepam or chlordiazepoxide because of erratic absorption that complicates the timing of subsequent doses and can result in delayed oversedation. Intravenous benzodiazepines may depress respiration; therefore, administer only if advanced cardiopulmonary support is available. When the patient can take oral medications, treatment may continue using either the symptom-triggered or loading dose strategy. Electrolyte imbalances can contribute to seizures and should be corrected.[21,25] Avoid phenytoin for preventing or treating alcohol-related seizures.[20] Alcohol withdrawal seizures result from γ-aminobutyric acid (GABA) and glutamate abnormalities secondary to chronic alcohol intake. Phenytoin affects sodium channels rather than directly affecting GABA or glutamate and is ineffective for alcohol-related seizures.

Alcohol Withdrawal Delirium (DTs) DTs is a medical emergency necessitating hospitalization. Signs and symptoms include hallucinations, delirium, severe agitation, fever, increased blood pressure and heart rate, and possible cardiac arrhythmias. Benzodiazepines are the treatment of choice.[22] Reserve haloperidol for severe agitation unresponsive to benzodiazepines. Evidence does not support antipsychotic monotherapy; in addition, antipsychotics may prolong the QT interval and lower the seizure threshold.[25] Administer thiamine according to the previously described guidelines.

Opioid Withdrawal

Withdrawal from opioids is extremely uncomfortable. Opioid withdrawal is commonly described as feeling “sick,” because it resembles a bad case of the flu. Symptoms include muscle, bone, and joint pain, nausea, vomiting, diarrhea, anxiety, headaches, mydriasis, rhinorrhea, lacrimation, piloerection, yawning, fever, increased heart rate, and hypertension.[12] Following initial withdrawal symptoms, patients can experience protracted withdrawal symptoms of dysphoria, craving, and hyperalgesia that can remain for weeks or months.[8] Therefore, the general approach is to manage acute symptoms, stabilize medical issues, and facilitate entry into an opioid use disorder treatment program.[10]

Clinical withdrawal scales (Table 37–2), such as the Clinical Opiate Withdrawal Scale (COWS), provide interrater reliability and clinical utility given their objective measurement of withdrawal severity. The baseline score assists in deciding whether to treat pharmacologically or to observe. As COWS scores increase (eg, 5 or greater), treatment of symptoms is indicated. In severe withdrawal, either buprenorphine (ie, partial μ-opioid receptor agonist) or methadone (ie, full μ-opioid receptor agonist) are recommended for medically supervised withdrawal (detoxification). Methadone is the gold standard for treating opioid use disorders but, under current US law, medically supervised withdrawal with methadone requires referral to a federally approved program. Pharmacotherapy for opioid withdrawal treatment in regular clinical settings is with a symptoms-based approach or buprenorphine.[26]

▶ *Medically Supervised Withdrawal*

Medically supervised withdrawal entails using μ-opioid receptor agonists (buprenorphine or methadone) in tapering doses to manage opioid withdrawal symptoms and assist patients in discontinuing opioids. On its own, short-term medically supervised withdrawal is associated with high rates of patients returning to illicit opioid use; therefore, consider transitioning to maintenance treatment with methadone, buprenorphine, or naltrexone.[8] As methadone is only available for use in federally approved opioid treatment programs (OTPs), this chapter will focus on buprenorphine. Refer to Chapter 35 for additional information on methadone.

Buprenorphine is a partial μ-opioid receptor agonist and is available in multiple formulations with varying pharmacokinetic profiles. For example, buprenorphine in combination with naloxone is available as a sublingual tablet, sublingual film, and buccal film.[15] Certain formulations (eg, sublingual film) may have greater buprenorphine bioavailability, and hence lower dosage requirements than other formulations (eg, sublingual tablets). Naloxone is poorly absorbed via the sublingual and buccal routes but is added to buprenorphine formulations to block opioid receptors if the medication is injected. Thus, naloxone has negligible effects when used appropriately while discouraging inappropriate IV use. Therefore, buprenorphine plus naloxone is the recommended formulation (vs buprenorphine alone) unless the patient is pregnant or hypersensitive to naloxone. Opioid antagonists, such as naloxone, have been associated with severe negative outcomes among pregnant women (eg, spontaneous abortion) and should be avoided.[26]

To initiate buprenorphine, a patient with physical dependence to opioids should be displaying signs of opioid withdrawal. Otherwise, buprenorphine will likely induce withdrawal because it has high affinity for μ-opioid receptors, displacing other full μ-opioid agonists, and is a partial rather than full agonist. Table 37–6 provides an example protocol for initiating buprenorphine.[8] Once the final dose is established, it is tapered and discontinued within 1 to 2 weeks (eg, 25% reduction per day as a general rule of thumb) or continued as a maintenance dose.

▶ *Symptoms-Based Treatment*

Symptomatic treatment focuses on minimizing withdrawal symptoms to increase patient comfort. Examples of symptom-specific medications are listed in Table 37–7.

▶ *General Patient Guidelines for Outpatient Opioid Detoxification*

Patient safety is the highest priority. The first step is to educate patients about the course of withdrawal. Symptoms generally peak at 5 to 7 days and may last up to 2 weeks, depending on the

Table 37–6

Sample Regimen[a] for Buprenorphine Induction Treatment of Opioid Withdrawal and Long-Term Relapse Prevention[8]

Day	Buprenorphine Sublingual/Buccal Dosage
1	2–4 mg every 2 hours (maximum, 8 mg on first day)
2	Start with total day 1 dose; additional 2–4 mg every 2 hours (maximum, 16 mg)
3	Start with total day 2 dose; additional 2–4 mg every 2 hours (maximum, 32 mg)
4–5	Maintain on dose required to alleviate withdrawal symptoms[b]

[a] For withdrawal from any opioid.

[b] Patient will likely be transitioned to long-term maintenance dose indefinitely.

half-life of the opioid used. Educate patients on the side effects of medications used for medically supervised withdrawal. Balance the risk of adverse events with the potential benefits. Buprenorphine side effects include constipation, sedation, and headaches. Potential for serious overdose exists when buprenorphine is combined with benzodiazepines or other sedative–hypnotics.

Risk of developing physiologic tolerance to buprenorphine is high if used for prolonged periods. In this case, buprenorphine requires a slow taper to discontinuation. Withdrawal from buprenorphine is generally easier and less severe than withdrawal from a full agonist, such as methadone.[8] However, there is concern regarding a subset of patients who have difficulty discontinuing buprenorphine. The duration of buprenorphine treatment is specific to each patient's needs and resources, and difficulty in tapering the medication to discontinuation complicates this decision further.

Following medically supervised withdrawal, rehabilitation and acquiring recovery skills are tied to positive outcomes. This goal can be accomplished by either achieving medically supervised withdrawal on-site during rehabilitation or by quick and seamless transition from detoxification to a rehabilitation program. The more time that elapses between the two modalities, the greater the likelihood of treatment failure and relapse.

Stimulant (Cocaine, Amphetamines) Withdrawal

Cocaine and amphetamine withdrawal are grouped together because their symptom profiles as described in *DSM-5* are similar, and the physiologic basis of their withdrawal syndromes involves the DA neurotransmitter system.[6,13] This group of stimulants includes methylphenidate, but not nicotine and caffeine, which have different neurophysiologic mechanisms of action. Major adverse complications of stimulant withdrawal are profound depression with suicidal thoughts, and the primary treatment goal is suicide prevention. Therefore, unless suicidality warrants hospitalization, stimulant withdrawal can be treated in outpatient setting with psychological support and reassurance with an emphasis on patient safety. Medications have been studied to alleviate withdrawal symptoms and cravings, but inconsistent results preclude any recommendations for their routine use. Refer patients with stimulant use disorder for treatment because of the high risk for continued use either during or immediately following stimulant withdrawal.

Table 37–7

Symptoms-Based Treatment Approach for Opioid Withdrawal[8,10,27]

The following are examples of medications for withdrawal symptoms that cause distress:

1. Insomnia: trazodone 75–200 mg at bedtime
2. Headache, muscle aches, or pain: acetaminophen 500–1000 mg every 6 hours
3. Noradrenergic hyperactivity: clonidine 0.1–0.2 mg every 6–8 hours (not to exceed 1.2 mg in 24 hours) lofexidine 0.54–0.72 mg every 6 hours (not to exceed 2.88 mg in 24 hours)
4. Abdominal cramps: dicyclomine 10–20 mg every 6 hours
5. Diarrhea: loperamide 2 mg every 6 hours

Cannabinoid Withdrawal

Symptoms of cannabinoid withdrawal are primarily behavioral. For example, significant anxiety may accompany cannabinoid withdrawal, which can lead many individuals to resume substance use. This is particularly problematic following heavy and prolonged use. Pharmacotherapy aimed at improving anxiety or sleep difficulties (eg, buspirone, gabapentin) shows promise for the management of cannabinoid withdrawal.[28] Currently, no medications are FDA approved to specifically target cannabinoid withdrawal.

GENERAL APPROACH TO THE TREATMENT OF SUBSTANCE USE DISORDERS

KEY CONCEPT A multimodal and comprehensive approach is preferred when treating patients with SUDs given the heterogeneous nature of addiction. Pharmacologic treatment is always adjunctive to psychosocial therapy. Steps to be taken in the management of SUDs are similar for all substances and are highlighted in the Patient Care Process.[10]

Address comorbid psychiatric conditions such as anxiety, depression, insomnia, and pain. These conditions increase risk of relapse to substance use. Although complete abstinence may be desirable, harm reduction may be sufficient in certain cases. **Harm reduction** involves strategies that seek to reduce negative consequences associated with substance use. Examples include **medication-assisted treatment**, naloxone deregulation, needle syringe programs, and medically supervised injection sites.[29]

Nonpharmacologic Therapy

Although pharmacologic agents may help prevent relapse, psychotherapy is the core therapeutic intervention. Psychotherapy typically addresses one or more of the following:

- Motivation enhancement to stop or reduce substance use
- Coping skills education
- Providing alternative reinforcement
- Managing painful affect (eg, dysphoria)
- Enhancing social support and interpersonal functioning

A thorough review of psychosocial approaches is beyond the scope of this chapter and are available elsewhere.[10] However, a few of the commonly used techniques are cognitive-behavioral therapy, motivational-enhancement therapy, and other behavioral therapies (eg, community reinforcement).

Pharmacologic Therapy

▶ *Maintenance Treatment*

KEY CONCEPT Certain pharmacologic agents are helpful for long-term maintenance in patients with SUDs. Typically, these medications exert their effects by one of the following theorized mechanisms: (a) substitution therapy with an agonist, (b) blocking effects with an antagonist, and (c) miscellaneous relapse prevention medications with indirect mechanisms of action. Medications from each of these categories are discussed in greater detail for alcohol, opioid, cannabinoid, stimulant, and tobacco use disorders.

▶ *Alcohol Use Disorder*

The FDA-approved medications for alcohol use disorder are naltrexone (oral and depot), acamprosate, and disulfiram. Practice guidelines recommend naltrexone and acamprosate as first-line agents.[24,30] However, in motivated patients or with supervised administration to ensure adherence, disulfiram is another option.[31] More recently, APA guidelines have strengthened their recommendations for the use of topiramate or gabapentin as potential medication management options. The following sections discuss FDA-approved medications; however, novel approaches, such as gabapentin and topiramate, may also be considered for alcohol use disorder.

Naltrexone Is a competitive opioid receptor antagonist that decreases alcohol intake, craving for alcohol, and alcohol-induced euphoria (ie, reduces positive reinforcement of drinking).[3] Naltrexone is more efficacious than placebo for a variety of drinking measures.[30] According to a meta-analysis, it significantly improves abstinence rates, decreases relapse rates, and has a safety profile similar to placebo.[32] Predictors of naltrexone efficacy may include family history of alcohol use disorder and a specific μ-opioid receptor gene polymorphism.[33] In the landmark COMBINE study, which assessed the efficacy of behavioral intervention, medical management, medications, and their combinations for treatment of alcohol use disorder, naltrexone with medical management was associated with a higher percent of days abstinent than other interventions.[34] An oversimplified interpretation of this complex study suggests that naltrexone is effective (eg, higher percent of days abstinent), but acamprosate offers no discernable advantage.[34]

Naltrexone is available as a tablet and long-acting IM injection. Naltrexone is dosed 50 mg once daily, with a range from 25 to 100 mg. A 25-mg test dose can be given, then increased to 50 mg/day as tolerated. While specific dosage adjustments are not provided in the package insert, caution is warranted in patients with severe hepatic or renal impairment.[15] Adherence to naltrexone strongly affects drinking outcomes; therefore, a long-acting IM formulation is available. Administered as 380 mg once monthly, it results in significantly greater reductions in heavy drinking days compared with placebo injection.[35]

Common side effects include nausea, headache, insomnia, and nervousness. Injectable naltrexone is associated with injection site reactions. Because naltrexone can precipitate withdrawal in patients with physical dependence to opioids, withhold the first dose for 7 to 10 days after last opioid use (10–14 days for long-acting opioids) and give only when the urine drug screen for opioids is negative. Naltrexone can be hepatotoxic, albeit typically not at oral doses less than 250 mg/day or at the recommended injectable dose. Baseline and periodic LFTs are recommended.[15]

Naltrexone can block effects of opioid receptor agonists, rendering them therapeutically ineffective. Given that opioid agonists are a mainstay of pain management, alternatives to opioids may be required in patients requiring pain relief.

Educate patients taking naltrexone to carry a pocket warning card or wear a medical bracelet. In the event that emergency pain management is needed, the patient will be insensitive to opioid analgesia unless potentially toxic doses are administered. Warn patients of the potential for opioid overdose under two conditions. First, dosing with opioids to reverse opioid insensitivity (ie, naltrexone's competitive blockade of opioid receptors) requires high doses of opioids that can cause respiratory depression and death. Second, following chronic opioid receptor antagonist therapy, patients are likely to have reduced tolerance to opioids, thereby increasing risk of respiratory depression and death when previously tolerated doses of opioids are taken.[15]

Acamprosate AR appears to be a glutamatergic *N*-methyl-D-aspartate receptor antagonist and may affect GABA.[3] Alcohol acutely inhibits glutamatergic function. During acute and post-acute alcohol withdrawal, increased activity of the glutamate system is caused by upregulation of receptors combined with absence of alcohol-related inhibition. Thus, acamprosate may correct glutamate/GABA imbalances that occur following chronic alcohol use (eg, reduce negative reinforcement associated with craving and withdrawal).[3,15]

Generally, trials assessing efficacy of acamprosate have shown mixed results. This may be partly attributable to differences in research methodologies, such as varying levels of abstinence required in trials before acamprosate initiation.[30] Notably, in the aforementioned COMBINE study, acamprosate appeared to offer no treatment advantage,[34] but more recent data suggest it is more efficacious than placebo.[36] A meta-analysis suggests that acamprosate may be more effective at maintaining abstinence, whereas naltrexone may more effectively reduce heavy drinking and craving.[37]

The dose of acamprosate is 666 mg orally three times daily. It is not metabolized by the liver and is excreted unchanged by the kidneys. Consequently, it is contraindicated in patients with severe renal impairment (creatinine clearance 30 mL/min [0.50 mL/s] or less), and dose reduction is necessary when creatinine clearance is between 30 and 50 mL/min (0.50 and 0.83 mL/s). Monitor renal function in older adult patients to ensure proper dosing. Common side effects are nausea, diarrhea, and CNS effects, including insomnia, anxiety, and depressive symptoms.[15]

Disulfiram Irreversibly blocks the enzyme aldehyde dehydrogenase, a step in the metabolism of alcohol.[15] This results in increased blood levels of the toxic metabolite, acetaldehyde. As acetaldehyde levels increase, patients experience the disulfiram reaction consisting of the following symptoms: decreased blood pressure, increased heart rate, chest pain, palpitations, dizziness, flushing, sweating, weakness, nausea, vomiting, shortness of breath, blurred vision, and syncope. Symptom severity increases with amount of alcohol consumed, and emergency treatment may be warranted. Psychologically, disulfiram works to deter drinking due to the knowledge that the disulfiram reaction occurs if alcohol is consumed.[31] Efficacy directly depends on medication adherence and can be effective when procedures for enhancing adherence are used.[31,38]

The usual starting dose of disulfiram is 250 mg once daily. It can be started at 500 mg once daily for the first 1 to 2 weeks, and the range is 125 to 500 mg/day.[15] Compared with 250 mg, the larger dose is recommended if a patient does not experience a disulfiram reaction after alcohol consumption. The smaller dose is given when intolerable side effects are experienced at higher doses or for older adult patients. Use disulfiram with caution in patients with renal or hepatic impairment. Dosing begins only after the BAC reaches zero (ie, 12–24 hours after the last drink) and after the patient is educated on the consequences of drinking with disulfiram.

Contraindications include cardiovascular or cerebrovascular disease, hypersensitivity to thiuram derivatives, and metronidazole. Common side effects are rash, drowsiness, and metallic or garlic-like taste. Less common, but concerning, adverse effects include neuropathies, psychosis, and hepatotoxicity.[15] Given the serious nature of these adverse events, baseline and periodic monitoring is recommended. If LFT values are greater than three times the upper limit of normal, withhold disulfiram and repeat testing every 1 to 2 weeks. When LFTs return to normal, they may be repeated every 1 to 6 months.[39] Although elevated LFTs may signal disulfiram-induced hepatotoxicity, it may also indicate the patient was not taking disulfiram and resumed alcohol consumption. Psychosis has been reported with doses exceeding 500 mg/day and may be related to disulfiram's inhibition of DA β-hydroxylase, resulting in increased DA activity. Nevertheless, patients with schizophrenia or other co-occurring psychiatric disorders have received disulfiram at usual doses without difficulties.[40]

The disulfiram–alcohol interaction serves as disulfiram's mechanism of action. Depending on the dose of disulfiram, sensitivity to disulfiram, amount of alcohol consumed, and metabolism, patients may be at risk for an adverse interaction with alcohol for 2 to 14 days after stopping disulfiram (5 days on average) and should be educated accordingly. Table 37–5 lists relevant disulfiram interactions.

Universally accepted treatment algorithms for alcohol use disorder treatment are lacking. Table 37–8 lists patient-specific factors that can guide medication selection.[39]

▶ *Opioid Use Disorder*

After conclusion of withdrawal, patients may not feel their usual selves for some time and could relapse to using opioids, just to "feel normal." Long-term use of opioids results in neuroadaptations, and the brain might not readily return to its prior homeostasis. The goal of treatment is to encourage stability, both in the body and in the patient's life. If an individual is not successful in quitting opioids (eg, because of withdrawal symptoms or postacute craving), then maintenance treatment should be considered.

Methadone, buprenorphine, and long-acting naltrexone are used for maintenance treatment, also called medication-assisted treatment, of opioid use disorder. Methadone is a full μ-opioid receptor agonist and widely used to treat women during pregnancy. Methadone maintenance treatment can only be provided in federally approved OTPs.[26] Naltrexone, an opioid receptor antagonist, is administered as a once-monthly IM injection. Administer naltrexone 7 to 10 days after last opioid use (10–14 days for long-acting opioids) to avoid precipitating withdrawal in a patient with physical dependence to opioids. The final medication for maintenance treatment, which will be the focus of this section, is buprenorphine.

The more widely available office-based opioid treatment (OBOT) exclusively uses buprenorphine, a partial μ-opioid receptor agonist, typically in oral formulations also containing naloxone.[8] Two long-acting buprenorphine formulations are also available: a subcutaneous injection and subdermal implants.[15] Under the Drug Addiction Treatment Act of 2000 and the Comprehensive Addiction and Recovery Act of 2016, clinicians may prescribe buprenorphine in the outpatient office-based setting once requirements (eg, training) are met. When these criteria are met, qualified providers obtain a separate "X" Drug Enforcement Administration number.[8]

Patients receiving buprenorphine maintenance should sign a treatment contract requiring full adherence, financial responsibility for treatment, adherence to office policies, and agreement to provide random urine samples for drug screens. Instruct patients to bring their prescribed medication for pill counts at every visit. In the event of OBOT failure, the alternative to buprenorphine maintenance is referral to an OTP for methadone administration. Methadone may offer an advantage over buprenorphine for select outcomes (eg, retention in treatment).[41] Therefore, there are circumstances under which referral to methadone maintenance remains the preferred treatment option.

Although there are no treatment algorithms to guide medication selection, there are protocols for some medications that assist with dosing and titration. The effective maintenance dose of buprenorphine (with or without naloxone) is usually between 8 and 24 mg/day.[15] Initiate buprenorphine at the low end of the

Table 37–8

Alcohol Use Disorder Medication Decision Grid[39]

Pretreatment Indicator	Acamprosate	Disulfiram	Oral Naltrexone	Injectable Naltrexone
Renal failure	X	A	A	A
Significant liver disease	A	C	C	C
Coronary artery disease	A	C	A	A
Chronic pain	A	A	C	C
Current opioid use	A	A	X	X
Psychosis	A	C	A	A
Unwilling or unable to sustain total abstinence	A	X	A	A
Risk factors for poor medication adherence	C	C	C	A
Diabetes	A	C	A	A
Obesity that precludes intramuscular injection	A	A	A	X
Family history of alcohol use disorders	A	A	+	+
Bleeding or other coagulation disorders	A	A	A	C
High level of craving	A	A	+	+
Opioid use disorder in remission	A	A	+	+
History of postacute withdrawal syndrome	+	A	A	A
Cognitive impairment	A	X	A	A

+, particularly appropriate; A, appropriate to use; C, use with caution; X, contraindicated.

Patient Encounter 3

A 42-year-old woman presents to the pharmacy to pick up a prescription. She is diagnosed with epilepsy and seasonal allergies and takes the following: levetiracetam 1000 mg twice daily and over-the-counter loratadine 10 mg once daily. While at the pharmacy counter, the patient expresses interest in tobacco cessation pharmacotherapies. The patient smokes approximately 1 pack of cigarettes per day and denies alcohol or illicit substance use.

Is the patient a candidate for all first-line tobacco cessation pharmacotherapies?

Can the patient take a combination of tobacco cessation pharmacotherapies?

dosing range for older adult patients. Reduce initial and titration doses for patients with hepatic impairment and monitor for signs of toxicity or overdose.[15] The subcutaneous injection is given as 300 mg once monthly for 2 months, then 100 mg once monthly thereafter. The dose can be increased to 300 mg once monthly if needed. In patients stabilized on 100 mg once monthly, a dose of 300 mg to cover a 2-month duration may be given in select circumstances (eg, extended travel). The subdermal implants deliver buprenorphine continuously for up to 6 months.

▶ *Stimulant Use Disorder*

There are no FDA-approved pharmacotherapies for treatment of stimulant use disorder. Combine medications with psychosocial approaches. The APA guidelines suggest three medications as possible treatment options: topiramate, disulfiram, and modafinil.[10,42] Disulfiram shows promise, possibly due to its inhibition of DA β-hydroxylase, which converts DA to NE. The resulting increase in DA may counter DA deficiency states that are believed to underlie cocaine withdrawal and craving.[42] Consistent with the APA guidelines, a more recent systematic review also cited the potential of topiramate for the treatment of stimulant use disorders. However, it should be noted that the authors considered the evidence for topiramate to be of "low strength," and therefore the findings must be interpreted with caution.[43]

▶ *Cannabinoid Use Disorder*

There are no proven pharmacotherapies for treatment of cannabinoid use disorder. As previously described for cannabinoid withdrawal, promising medication management approaches for cannabinoid use disorders target symptoms of anxiety or sleep difficulties that complicate cessation of cannabinoid use.[28] Pharmacotherapy trials have emerged in the literature, but universally accepted medication treatment strategies have yet to emerge.

▶ *Tobacco Cessation*

Nonpharmacologic Behavioral treatment increases abstinence rates. The five As model below can be used by all clinicians.[14]

- Ask about tobacco use.
- Advise to quit.
- Assess willingness to make a quit attempt.
- Assist in quit attempt.
- Arrange follow-up.

Provide tobacco cessation education to all patients who use tobacco, and assist those interested to achieve cessation. Screen for tobacco use, provide all patients who use tobacco with brief advice and assistance with appropriate medications to quit, and provide referral to specialized services when needed.[14]

Electronic cigarette use has grown considerably in recent years. Preliminary evidence suggests they may be useful for smoking cessation; however, long-term safety is unknown.[44-47] Studies are investigating the harmful constituents that individuals are exposed to with electronic cigarettes.[44] The FDA recently gained regulatory authority over electronic cigarettes, allowing them to restrict sales to minors and ensure products contain proper health warnings.

Pharmacologic According to practice guidelines, first-line medications for tobacco use disorder are nicotine replacement therapy (NRT), bupropion sustained-release (SR), and varenicline (Table 37–9).[14]

Maintenance treatment for tobacco use disorders is achieved with any single or combination of the currently available NRTs.[14] Similar to opioid receptor agonists, NRTs act as substitution therapy as safer alternatives to tobacco use. While NRTs are generally considered safe, their use in pregnancy is made on a case-by-case basis.[48] Given the various products available, choice of NRT formulation depends on various factors, including patient preference.[10]

Two non-NRT medications are FDA approved for the treatment of tobacco use disorders: bupropion SR and varenicline. Bupropion is an antidepressant that blocks reuptake of DA and NE; in addition, it appears that one of its metabolites is a nicotinic antagonist. These mechanisms may help explain how bupropion reduces nicotine reinforcement, withdrawal, and craving.[3] Bupropion is contraindicated in patients with seizure disorders, eating disorders, and patients withdrawing from alcohol or sedative–hypnotics.[15] Varenicline is an $\alpha_4\beta_2$ nicotinic acetylcholine receptor partial agonist. Varenicline decreases withdrawal and craving and prevents reinforcing effects of nicotine if the patient relapses.[3] Warnings include seizures and cardiovascular adverse events (eg, angina).[15] Both bupropion SR and varenicline have been associated with psychiatric disturbances (eg, depression, anxiety, psychosis) when used for smoking cessation.[15]

As shown in Table 37–10, various NRTs, bupropion SR, and varenicline increase abstinence rates at 6 months compared to placebo.[49] Combining NRTs (eg, nicotine patch and "as needed" gum) is common. A meta-analysis concluded that NRT, bupropion SR, and varenicline all improve smoking cessation rates. Varenicline was more effective than single NRT or bupropion SR, but varenicline and combination NRT were equally effective.[50]

OUTCOME EVALUATION

KEY CONCEPT A major component of successful SUD treatment is to monitor use of medications and identify a mechanism for long-term support of sobriety that might be appropriate for a specific patient such as Alcoholics Anonymous, Narcotics Anonymous, or recovery programs for healthcare professionals.

To determine immediate treatment outcomes for patients with intoxication and withdrawal syndromes, evaluate parameters such as blood pressure, heart rate, respirations, body temperature, and mental status. Select validated and standardized instruments to monitor the responsiveness of withdrawal syndromes to

Table 37–9

First-Line Medications for Treatment of Tobacco Use Disorder[14,15]

Medication	Dosing and Administration[a]	Adverse Effects, Warnings, and Precautions[b]
Nicotine patch (7, 14, and 21 mg)	Apply 1 patch/day to nonhairy area on the upper body; rotate application sites Use 21 mg for 4–6 weeks, 14 mg for 2 weeks, then 7 mg for 2 weeks if > 10 cigarettes/day Use 14 mg for 6 weeks, then 7 mg for 2 weeks if ≤ 10 cigarettes/day Duration: 8–12 weeks	Skin irritation, insomnia, vivid dreams Remove patch at bedtime if sleep disturbances occur and apply new patch in the morning
Nicotine gum (2 and 4 mg)	Chew slowly until gum tingles, then "park" in cheek until tingle is gone; repeat Avoid eating or drinking for 15 minutes before or during use Use 4 mg if first cigarette is smoked within 30 minutes of waking; otherwise, use 2-mg dose Use 1 piece every 1–2 hours for 1–6 weeks, then 1 piece every 2–4 hours for 7–9 weeks, then 1 piece every 4–8 hours for 10–12 weeks Maximum: 24 pieces of gum/day Duration: 12 weeks (or as needed)	Sore mouth, hiccups, dyspepsia, insomnia Limit swallowing excess saliva to avoid GI irritation
Nicotine lozenge (2 and 4 mg)	Avoid chewing; occasionally move lozenge around mouth until completely dissolved Avoid eating or drinking for 15 minutes before or during use Use 4 mg if first cigarette is smoked within 30 minutes of waking; otherwise, use 2-mg dose Use 1 piece every 1–2 hours for 1–6 weeks, then 1 piece every 2–4 hours for 7–9 weeks, and 1 piece every 4–8 hours for 10–12 weeks Maximum: 20 lozenges/day Duration: 3–6 months	Hiccups, cough, heartburn, nausea, insomnia Limit swallowing excess saliva to avoid GI irritation
Nicotine nasal spray (0.5 mg delivered to each nostril)	Do not inhale during administration 1 dose = 1 spray in each nostril Use 1–2 doses/hour Maximum: 5 doses/hour; 40 doses/day Duration: 3–6 months; taper	Nasal irritation or congestion, changes in smell Avoid in patients with reactive airway disease Dependence risk is higher than other formulations
Nicotine inhaler (4 mg in each cartridge)	Inhale ("puff") lightly 80 times/cartridge Cold temperature decreases nicotine delivery; store in warm area (eg, pocket) Avoid eating or drinking for 15 minutes before or during use Use 6–16 cartridges/day Maximum: 16 cartridges/day Duration: Up to 6 months; taper	Mouth and throat irritation (improves with use), cough, rhinitis, sneezing
Bupropion sustained-release	Dosing: 150 mg once daily for 3 days, then 150 mg twice daily Start 1–2 weeks before quit date	Neuropsychiatric events (eg, mood disturbances) when used for smoking cessation
Varenicline	Dosing: 0.5 mg once daily for 1–3 days, then 0.5 mg twice daily for 4–7 day, then 1 mg twice day on day 8 and after Renal dosing (CrCl < 30 mL/min [< 0.50 mL/s]): 0.5 mg once daily with a maximum of 0.5 mg twice daily Start 1 week before quit date	CNS: insomnia, abnormal dreams, neuropsychiatric events (eg, depression, suicidal thoughts) GI: dose-related nausea

[a] NRT dosage adjustments for renal or hepatic impairment are not established. Severe impairment may affect nicotine clearance.

[b] Avoid NRT in patients with recent myocardial infarction, arrhythmias, or unstable angina.

CNS, central nervous system; CrCl, creatinine clearance; GI, gastrointestinal; NRT, nicotine replacement therapy.

medical treatment. To determine the overall effectiveness of your health system for the treatment of substance-related disorders, monitor outcomes using sentinel events such as the rates of cardiopulmonary arrest, seizures, discharges against medical advice, patient violence, and use of physical restraints. The ultimate goal is to enable the transition of patients to formal substance use treatment when indicated.

Important outcome indicators to evaluate postintoxication and/or postwithdrawal treatment can be divided into three major groups: decreased consumption of substances, decreased problems associated with substance use, and improved psychosocial functioning. When complete abstinence has not been achieved, quantify the consumption of substances using quantity–frequency measures, rates of abstinence, and time to first relapse as determined by interviews, self-report, and biological markers such as urine and blood tests. The ASI (Table 37–2) assesses alcohol and substance-related problems in various domains and provides a more comprehensive picture of the patient's life.

KEY CONCEPT Clinicians must be familiar with "essential" resources, many of which are in the public domain. Table 37–11 provides a list of these resources that provide useful information for clinical management, research, teaching, and policy development purposes.

Table 37–10

Six-Month Postquit Smoking Abstinence Rates and Associated Odds Ratios[49]

Medication	Abstinence Rate (%)	Odds Ratio (95% CI)
Placebo	13.8	1.0
NRTs		
Nicotine gum (6–14 weeks)	19.0	1.5 (1.2–1.7)
Nicotine patch (6–14 weeks)	23.4	1.9 (1.7–2.2)
Nicotine gum (> 14 weeks)	26.1	2.2 (1.5–3.2)
Nicotine patch (> 14 weeks)	23.7	1.9 (1.7–2.3)
Non-NRTs		
Bupropion SR	24.2	2.0 (1.8–2.2)
Varenicline (1 mg/day)	25.4	2.1 (1.5–3.0)
Varenicline (2 mg/day)	33.2	3.1 (2.5–3.8)
Combination Strategies		
Nicotine patch (> 14 weeks) + ad lib gum or spray	36.5	3.6 (2.5–5.2)
Nicotine patch + bupropion SR	28.9	2.5 (1.9–3.4)

CI, confidence interval; NRT, nicotine replacement therapy; SR, sustained-release.

Patient Care Process

Collect Information:

- Conduct a medication history for prescription, nonprescription, herbal, and dietary supplement use. Identify medication allergies and associated reactions.
- Retrieve a state prescription drug-monitoring program report.
- Document medical history, family history (eg, SUDs, psychiatric disorders), social history (eg, alcohol, tobacco, and illicit substance use), physical assessment, and mental status examination findings.
- Document other factors (eg, transportation, employment) that may impact treatment.
- Determine the patient's preferences, beliefs, and functional goals.
- Consider the use of screening and assessment instruments (Table 37–2).
- Assess the patient's readiness to change.

Assess the Information:

- Assess medication appropriateness, efficacy, safety, and adherence.
- Review laboratory tests (eg, electrolytes, liver and renal function, drug screen, human immunodeficiency virus [HIV] test).
- Assess previous periods of abstinence and factors that worked to achieve this.

Develop a Care Plan:

- Substance *intoxication*: Management is typically supportive. The most important goal is to maintain cardiopulmonary function. If consciousness is impaired, obtain blood chemistries to help identify causative substance and rule out other etiologies. Observe patient until intoxication has resolved.
- Substance *withdrawal*: Select instrument to monitor withdrawal symptoms and guide medication use (Table 37–4). Severe symptoms (eg, seizures) require inpatient treatment.
- Medication management is an adjunct to psychosocial approaches for achieving recovery.
- Align treatment (eg, medically supervised withdrawal vs longer-term treatment) with patient goals.

Implement the Care Plan:

- Educate the patient and the patient's support system about SUDs, medications, adverse effects, and adverse effect management. Ensure the patient has access to medications.
- Discuss the importance of medication adherence and psychosocial treatment approaches.
- Provide referrals for the treatment of co-occurring medical conditions or complications.
- Reduce stress and risk factors for relapse and improve attitude toward wellness.

Follow-up: Monitor and Evaluate:

- Assess treatment effectiveness, safety, and adherence regularly. Make changes as needed.
- Evaluate progress toward treatment goals (eg, improved coping skills, functioning, and relapse prevention).
- Continuously monitor for triggers, cravings, substance use, and relapse. Provide support.

Abbreviations Introduced in This Chapter

APA	American Psychiatric Association
ASI	Addiction Severity Index
AUDIT	Alcohol Use Disorders Identification Test
BAC	Blood alcohol concentration
CAGE	Cut down, angry/annoyed, guilty, eye opener
CIWA-Ar	Clinical Institute Withdrawal Assessment–Alcohol, Revised
CNS	Central nervous system
COWS	Clinical Opiate Withdrawal Scale
CRF	Corticotropin-releasing factor
DA	Dopamine
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders*, 5th edition
DTs	Delirium tremens
FDA	US Food and Drug Administration
GABA	γ-Aminobutyric acid
GI	Gastrointestinal
IM	Intramuscular
IN	Intranasal
IV	Intravenous
LFT	Liver function test
NA	Nucleus accumbens
NE	Norepinephrine
NRT	Nicotine replacement therapy
NSDUH	National Survey on Drug Use and Health
OBOT	Office-based opioid treatment
OTP	Opioid treatment program
PFC	Prefrontal cortex
SAMHSA	Substance Abuse and Mental Health Services Administration
SR	Sustained-release
SUD	Substance use disorder
VTA	Ventral tegmental area

Schizophrenia

Deanna L. Kelly, Mary Borovicka, and
Heidi J. Wehring

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Recognize signs and symptoms of schizophrenia and be able to distinguish among positive, negative, and cognitive impairments associated with the illness.
2. Explain potential pathophysiologic mechanisms that are thought to underlie schizophrenia.
3. Identify treatment goals for a patient with schizophrenia.
4. Recommend appropriate antipsychotic medications based on patient-specific data.
5. Compare side effect profiles of individual antipsychotics.
6. Educate patients and families about schizophrenia, treatments, and the importance of adherence to antipsychotic treatment.
7. Describe components of a monitoring plan to assess the effectiveness and safety of antipsychotic medications.

INTRODUCTION

Schizophrenia is a challenging disorder often requiring lifelong treatment. The disorder may have many pathophysiologic pathways that ultimately manifest with psychotic symptoms, including positive symptoms such as hallucinations and delusions, as well as disordered thinking. Commonly, these symptoms are accompanied by cognitive impairment (abnormalities in thinking, reasoning, attention, memory, and perception), impaired insight and judgment, and negative symptoms including loss of motivation (**avolition**), loss of emotional range (restricted affect), and a decrease in spontaneous speech (poverty of speech). Cognitive impairments and negative symptoms account for much of the poor social and functional outcomes. Schizophrenia is the fourth leading cause of disability among adults and is associated with substantially lower rates of employment, marriage, and independent living compared with population norms. Persons with schizophrenia have a higher mortality rate as compared with the general population, likely due to numerous factors such as physical comorbidities, insufficient health services, poor diet, lack of exercise, substance use (including tobacco), stigma about mental illness, and low socioeconomic status. However, earlier diagnosis, treatment, advances in research, and newer treatment developments have led to better outcomes with the potential for remission and recovery.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 0.7% of the world population suffers from schizophrenia, with symptoms typically presenting in late adolescence or early adulthood.[1] Prevalence is equal in men and women, but symptoms appear earlier in men with first hospitalization typically occurring at 15 to 24 years compared to 25 to 34 years in women.

The etiology of schizophrenia remains unknown. A genetic basis is supported by the fact that first-degree relatives of patients with schizophrenia carry a 10% risk of developing the disorder, and when both parents have the diagnosis, the risk to their offspring is 40%. For monozygotic twins, the concordance rate is about 50%. Many genes have been weakly associated with the development of schizophrenia; however, there is probably no single "schizophrenia gene." Research continues to explore candidate genes, loci, and copy number variants, hoping to better understand the genetic contribution.[2] Possibly, when a genetic liability is present, environmental stimuli may trigger expression of the illness. These risk factors may include intrauterine exposure to significant stress, viral or bacterial infections. Also, emerging data suggest that certain drugs of abuse during childhood or adolescence, such as marijuana, may be one of those "triggers" in susceptible individuals. More research is needed on the role of these factors in the development of schizophrenia.

PATHOPHYSIOLOGY

The dopamine hypothesis, the oldest pathophysiologic theory, proposes that psychosis is caused by excessive dopamine in the brain. This hypothesis followed the discovery that chlorpromazine, the first antipsychotic medication, was a postsynaptic dopamine antagonist. Drugs that cause an increase in dopamine (eg, cocaine and amphetamines) worsen or cause psychotic symptoms, and medications that decrease dopamine (eg, antipsychotics) improve psychotic symptoms. However, data reveal a more complicated picture with both hyperdopaminergic and hypodopaminergic brain regions in schizophrenia. Hyperdopaminergic activity in the **mesolimbic pathway** contributes to positive symptoms of psychosis, while hypoactivity of the **mesocortical pathway** in the prefrontal cortex may contribute to negative symptoms. Thus, a more modern reworking of the dopamine hypothesis is the "dysregulation hypothesis," which takes these findings into account and also focuses primarily on presynaptic dopamine.[3] It is possible, however, that the hypothesized dopamine abnormalities may

Patient Encounter, Part 1

A 22-year-old woman was brought to the emergency department (ED) at a local hospital by the police after she was found wandering her neighborhood. The neighbors saw her peering in the windows and trying to open the doors of their homes and called the police. In the ED, her appearance was disheveled and her hair was long and tangled. She was easily distracted and irritable and when asked what she was doing wandering the neighborhood, she stated "I left my home because they are plotting to kill me there. It is dangerous there and I had to leave". During her interview with the psychiatry resident, she frequently looked over her shoulder, and her eyes darted around the room. Then she asked the resident, "Do you even understand me? I need to get out of here. It is not safe for me here and they are looking for me. There is nothing wrong with me. I am really hungry; do you have something for me to eat?"

Her attention seemed to be focused on something else and then she blurted out "my dad is my other half and he will protect me." When asked to explain, she said "I tell the voices my dad is my other half. They tell me I am terrible and that I should die." The patient's mother was called to the ED to see her daughter and provide more information.

She was admitted to the inpatient psychiatric unit for further evaluation.

What diagnoses are suggested by this presentation?

What additional information would clarify the diagnosis, and why?

Should the patient's mother be involved in her care?

represent changes occurring secondary to other pathophysiologic abnormalities. Other implicated neurotransmitter systems include a combined dysfunction of the dopamine and glutamate neurotransmitter systems. It is hypothesized that glutamate, possibly through malfunctioning *N*-methyl-D-aspartate (NMDA) receptors, impacts dopaminergic activity in the mesolimbic and mesocortical pathways. NMDA antagonists such as phencyclidine (PCP) and ketamine can elicit a state resembling schizophrenia, including positive and negative symptoms and cognitive impairments.[3] There is evidence for the serotonergic system in schizophrenia as evidenced by serotonin-induced hallucinations and serotonin modulation of second-generation antipsychotics (SGAs).[4] It is notable that, to date, antipsychotics without any primary or secondary dopamine-modulating properties have been ineffective for the treatment of positive symptoms of schizophrenia.

CLINICAL PRESENTATION AND DIAGNOSIS

In addition to the positive, negative, and cognitive symptoms of schizophrenia, people with schizophrenia may sometimes be uncooperative, suspicious, hostile, anxious, or aggressive. Psychotic and depressive symptoms may lead to poor hygiene and impaired self-care. Sleep and appetite disturbances may be present, and people with schizophrenia may have difficulty living independently, forming close relationships with others, and initiating or maintaining employment. Co-occurring medical and substance use disorders are common with cigarette smoking and illicit drug use about four to five times more prevalent than the general population.[5,6]

KEY CONCEPT A diagnosis of schizophrenia is made clinically because there are no psychological assessments, brain imaging, or laboratory examinations that confirm the diagnosis.

The diagnosis is made by ruling out other causes of psychotic symptoms and meeting specified diagnostic criteria. When present, a family history of mental illness supports the diagnosis. The commonly accepted diagnostic criteria for schizophrenia are from the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*)[7] (Table 38–1).

KEY CONCEPT Patients presenting with odd behaviors, illogical thought processes, fixed false beliefs, and hallucinations should be comprehensively assessed to rule out other diagnoses or contributing factors.[8]

At minimum, patients with psychotic symptoms should have a medical workup at the time of admission to rule out other diagnoses or contributing factors, such as medical illnesses, infections,

Table 38–1

Diagnostic Criteria for Schizophrenia

A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be 1, 2, or 3:
   1. Delusions
   2. Hallucinations
   3. Disorganized speech (eg, frequent derailment or incoherence)
   4. Grossly disorganized or catatonic behavior
   5. Negative symptoms (ie, diminished emotional expression or avolition)

B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved before onset (or when onset is in childhood or adolescence, there is a failure to achieve expected level of interpersonal, academic, or occupational functioning).

C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meets Criterion A (ie, active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (eg, odd beliefs, unusual perceptual experiences).

D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (a) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (b) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

E. The disturbance is not attributable to the physiologic effects of a substance (eg, drug of abuse or medication) or another medical condition.

F. If there is a history of autism spectrum disorder or communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

Reproduced with permission from the American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed. Washington, DC: American Psychiatric Association; 2013.

or other psychiatric or substance use disorders. Often, people with psychosis are poor historians and the gathering of collateral information about symptoms and medical history from family/friends is necessary. When considering delusional symptoms, cultural beliefs and norms should be explored. Co-occurring substance abuse, medical illnesses, and psychosocial stressors often confound the diagnosis.

COURSE AND PROGNOSIS

Treatment of schizophrenia has been associated with poor long-term outcomes in the past; however, with earlier treatment and better care, many people can achieve remission, and recovery is possible. Without early intervention, there are traditionally intermittent acute psychotic episodes with a downward decline in psychosocial functioning. Though many of the more dramatic and acute symptoms may fade with time, severe residual symptoms may persist. Involvement with law enforcement is common for vagrancy, loitering, and disturbing the peace. Life expectancy is shortened primarily because of suicide, cardiovascular disease, accidents, and compromised self-care. Lifetime risk of suicide for people with schizophrenia is 5% to 10%, and it is estimated that suicide risk in this population exceeds that in the general population more than eightfold.[9] Persistent adherence with a tolerable medication regimen improves prognosis, while relapse without antipsychotic medication exceeds 50% in the year following discontinuation of antipsychotic treatment.

The onset of schizophrenia can be rapid with acute psychosis presenting as the first symptom, or can be insidious with negative symptoms and social impairments predating psychosis by many years. Whether insidious or acute, the period around the diagnosis is difficult for patients, families, and clinicians. Patients may hide symptoms from family and friends and isolate themselves from social support networks. Gradual development of psychosis and the misunderstanding of symptoms can delay diagnosis and treatment. Recent data suggest that people treated early in their illness may have a better prognosis. Therefore, the first challenge of optimal therapy is to initiate treatment closer to the onset of psychosis.

Clinical Presentation of Schizophrenia

General

Schizophrenia is a chronic disorder of thought and affect, causing significantly impaired vocational and interpersonal function. Onset is usually preceded by gradual social withdrawal, diminished interests, changes in appearance and hygiene, changes in cognition, and bizarre or odd behaviors incongruent with cultural beliefs and norms. The clinical presentation of a person with schizophrenia is extremely varied.

Symptoms

Psychotic symptoms (positive symptoms):

- Hallucinations (distortions or exaggeration of perception).
  - Most frequently auditory, can also be visual, olfactory, gustatory, and tactile.
  - Can be voices or thoughts that feel distinct from the person's mind.
  - Voices may be threatening or commanding (eg, commanding the person to perform a particular action).
- Delusions (fixed false beliefs).
  - Beliefs despite invalidating evidence.
  - May be bizarre in nature.
  - Often paranoid in nature which may cause suspiciousness.
- Thought disorder (illogical thought and speech).
  - Loosening of associations.
  - **Tangentiality**.
  - **Thought blocking**.
  - **Concreteness**.
  - Circumstantiality.
  - Perseveration.
  - Thinking and speech may be incomprehensible and illogical.

Negative symptoms:

- Impoverished speech and thinking.
- Lack of social drive (avolition).
- Flatness of emotional expression.
- Apathy.
- May be primary or occur secondarily to medication side effects, mood disorder, environmental understimulation, or demoralization.
- The best strategy for differentiating primary from secondary negative symptoms is to observe for their persistence over time despite efforts at resolving the other causes.

Cognitive impairments (diminished function in the following):

- Attention.
- Processing speed.
- Verbal, visual memory, and working memory.
- Problem solving.
- Loss of, on average, one standard deviation of preillness IQ, with the average IQ between 80 and 84.

Laboratory and Other Diagnostic Assessments

An initial psychotic workup includes a thorough neurologic, medical, and laboratory evaluation to rule out other causes:

- Electrolytes.
- Blood urea nitrogen.
- Serum creatinine.
- Urinalysis.
- Liver and thyroid function profile.
- Syphilis serology.
- Serum pregnancy test.
- Urine toxicology.

If warranted, neuroimaging and/or electroencephalogram (EEG).

TREATMENT

Desired Outcomes

KEY CONCEPT The goals of treatment are to reduce symptomatology and psychotic relapses and to improve functional and social outcomes.[10] Patients should receive comprehensive treatment as early as possible, and earlier treatment can lead to better outcomes.[11] In the past, the primary treatment goal was to decrease positive symptoms and associated hostile and aggressive behaviors. Newer approaches also focus on functional and social outcomes. Though antipsychotic medications may improve combativeness, hostility, sleep, and appetite, other aspects of the illness are less responsive to treatment. Improvements in negative symptoms, cognitive functioning, social skills, and judgment generally require adjunctive treatments and a longer period to improve.

General Approach to Treatment

The concept of recovery has become an increasingly prominent treatment goal. Treatment planning increasingly includes providing recovery-oriented services to people with schizophrenia. A range of nonpharmacologic interventions are now part of the long-term strategy to improve functioning. Implementation of evidence-based practice and prescribing behaviors has led to the use of interventions that promote a remission or recovery attitude, and new data suggest that one in seven people with schizophrenia can achieve full recovery.[12,13] Moreover, recent attempts to improve and measure patient satisfaction and to include shared decision making have fostered patient empowerment and hope.

KEY CONCEPT The cornerstone of treatment is antipsychotic medication, and most patients with schizophrenia relapse when not medicated. Treatment with antipsychotic medications should begin as soon as psychotic symptoms are recognized. Many patients are on lifelong antipsychotic medication because nonadherence and discontinuation are associated with high relapse rates. Often, adjunctive medications may also be necessary for specific symptoms or comorbid diagnoses. If other symptoms are present, such as depression and anxiety, these symptoms should be aggressively treated. Nonpharmacologic and psychosocial treatments should also play an important role in treatment.

Nonpharmacologic Therapy

▶ *Psychosocial Treatment*

As previously discussed, antipsychotic medications are the cornerstone of schizophrenia treatment plans; however, KEY CONCEPT psychosocial support helps improve functional outcomes. Residual symptoms often persist such as avolition, isolation, and impaired social functioning, limiting participation in social, vocational, and educational endeavors. Psychosocial interventions, as adjuncts to pharmacotherapy, help people with

Patient Encounter, Part 2

PPH: This is her first admission to a psychiatric hospital. Her mother reports that her daughter changed during her first year away at college and did not return for her second year. She lived at home and became reclusive, no longer spending time with her family or friends. The family could often hear her talking loudly in her room, but she could not tell them who she was talking to. The patient stopped taking care of herself and would wear the same clothes several days in a row. She would wander away from home for days and then suddenly return but could not tell anyone where she had been. She was often found on the streets with dangerous people who exploited her. The patient occasionally was aggressive and threatening toward her mother.

PMH: She does not have any other medical illnesses including seizures or history of head trauma.

SH: The patient did well in grade school and graduated from high school. She was active in the band and theater. She attended her first year of college away from home, but after the first year, she did not return. The only job she has had was as a cashier at a local convenience store when she was 20, but she was let go after 3 months for wandering away during her shift.

FH: The patient grew up with her parents and one brother who is 2 years older than her. Her mother is an elementary school teacher, has a history of major depression, and has a good relationship with her daughter but does not understand why she is behaving this way. The patient's father recently passed away from cancer, and she had been very close to him. Her brother recently graduated from college with a degree in business as an accountant and accepted his first job out of town. There is no history of schizophrenia in the family. The patient's mother states that her mother (the patient's grandmother) had a psychiatric diagnosis and remembers her being hospitalized for periods of time but does not know what the diagnosis was.

Mental Status Examination

Appearance: Appears disheveled, dressed in dirty clothes, and hair is long, tangled, and looks like it has not been washed for several days. No abnormal movements. Poor eye contact. She is distracted and is looking around the room and over her shoulder.

Speech: Speech is loud, but normal rate.

Mood: Says she feels "normal but agitated." Denies feeling depressed.

Affect: Guarded with restricted range. She denies feeling sad, guilty, hopeless, or helpless.

Thought content: She is not a reliable historian and cannot explain where she goes when she leaves home or how she ends up on the street with strangers. She endorses hearing voices and states that they tell her she is terrible and should die. She has passing thoughts of suicide but no plan. She denies homicidal thoughts.

Thought processes: Irritable, vague, and paranoid.

Cognition: Grossly intact.

Insight and judgment: Insight and judgment are poor. She does not believe she has a mental illness.

Given this additional information, how has your differential diagnosis changed?

What medications would you consider to be first-line options, and why?

What are the goals of treatment for this patient?

schizophrenia cope with challenging aspects of their illness and set goals as medication alone is typically not sufficient for remission and recovery. In the United States, psychosocial treatments are less frequently used than in Europe, but their use is increasing, and current guidelines recommend nonpharmacologic strategies in conjunction with antipsychotic treatment. There are much data to support family education in decreasing relapse rates and vocational support to improve vocational outcomes. A few of the best-supported and most promising approaches to psychosocial rehabilitation are social skills training (SST), cognitive behavioral therapy for psychosis (CBTp), and cognitive remediation (CR). In addition, psychoeducation, supported employment, Assertive Community Treatment (ACT), and Medical Home care models have improved outcomes.[12,14]

Pharmacologic Therapy

▶ *Antipsychotic Treatment*

In the United States, we have two general classes of antipsychotic medications, the first-generation antipsychotics (FGAs; typical antipsychotics) and the second-generation antipsychotics (SGAs) (atypical antipsychotics). The SGAs include risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, paliperidone, iloperidone, asenapine, lurasidone, brexpiprazole, cariprazine, lumateperone, and clozapine. Clozapine, the prototype SGA, is the recommended treatment for treatment-resistant schizophrenia (TRS) as it has superior efficacy in this population. However, it has some additional monitoring and a unique side effect profile (see below). Antipsychotic medications share a common mechanism of dopamine antagonism, although there is significant variation in receptor binding among the agents as some also act as dopamine partial agonists. Dopaminergic antagonism is important in symptom treatment but also contributes to some medication-induced side effects. Of the four main dopaminergic pathways in the brain, positive symptoms are thought to be associated with hyperdopaminergic activity in the mesolimbic pathway, so blockade in this area is thought to reduce psychotic symptoms. However, blockade of dopamine activity in the other three main pathways may worsen some symptoms or lead to side effects. For example, hypodopaminergic activity in the mesocortical pathway may be associated with negative symptoms and cognitive impairments, and further reducing dopamine activity could exacerbate these issues. Blockade of dopaminergic activity in the **nigrostriatal** pathway can lead to motor-related side effects, and blockade of dopaminergic activity in the **tuberoinfundibular** pathway may lead to prolactin elevation and related side effects.[3] Differences in dopaminergic and nondopaminergic receptor antagonism and receptor affinity across the antipsychotic agents and classes lead to differing potential for dopamine-related side effects.

KEY CONCEPT Compared with the FGAs, the SGAs are associated with a lower risk of motor side effects (tremor, stiffness, restlessness, and dyskinesia).

With the introduction of SGAs in the 1990s, the use of FGAs has progressively decreased, and FGAs have less than 10% market share of the antipsychotics used for schizophrenia. This decline occurred because of the touted better side effect profile and other possible benefits of SGAs in nonpsychotic domains of the illness. However, a large landmark study (the Clinical Antipsychotics Trials of Intervention Effectiveness [CATIE trial]; $n > 1400$) examined the effectiveness of SGAs relative to a midpotency FGA, perphenazine. The study revealed that the FGA was equal to the SGAs for the primary endpoint of time to discontinuation of medication.[15] SGAs have historically been much more expensive than the FGAs; however, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, paliperidone, and clozapine are now available in generic formulations. When selecting an antipsychotic, the risk-to-benefit profile becomes fundamental and the varying side effect profiles must be considered.

Second-Generation (Atypical) Antipsychotics

FGAs exert most of their effects through dopamine receptor blockade at the dopamine$_2$ (D_2) receptor. SGAs may have different receptor binding profiles that contribute to their "atypicality." This possibly includes greater serotonin to dopamine antagonism, dopamine antagonism with rapid dissociation, partial dopamine antagonism and serotonin$_{1A}$ (5-HT$_{1A}$) partial agonism. Despite heterogeneous receptor binding, the efficacy for positive symptoms among the SGAs is similar.[15] Several long-acting injectable (LAI) formulations are now available and will be discussed below. However, due to differences in specific receptor binding affinity, side effect risks may vary between these agents. Additionally, recent data for SGAs and lower doses of FGAs document similar overall efficacy with an effect size for acute treatment of 0.30 to 0.60 for most antipsychotics.[16] These findings have led to a modest resurgence of FGA use. Only clozapine, however, has demonstrated superior efficacy in treatment-resistant patients. An important distinction of the SGAs is their lower propensity to cause acute as well as long-term **extrapyramidal symptoms** (EPSs) including **tardive dyskinesia** (TD). TD risk with SGAs is 1.5% annually in adults (< 54 years of age) compared to approximately a 5% annual risk with FGA treatment.[17] However, side effects such as weight gain, the potential for glucose dysregulation, and lipid abnormalities may be caused by treatment with these agents. Weight gain may be caused by a combination of lifestyle and medication interaction with neurotransmitter systems that may increase appetite and food intake (serotonergic, histaminergic, and dopaminergic), and, although all antipsychotics may be associated with weight gain, certain SGAs such as clozapine, olanzapine, quetiapine, and risperidone may offer greater risk. Similarly, risk of lipid abnormalities mirrors the risk for weight gain. Risk for glucose dysregulation or new-onset diabetes generally follows the risk of agents with most weight gain potential, although it is important to note that clozapine and olanzapine have been associated with diabetic ketoacidosis in the absence of significant weight gain in isolated cases. Sexual side effects as a result of prolactin elevation may occur due to dopamine antagonism at the tuberoinfundibular tract. SGAs have differing potentials to cause these side effects, which may include gynecomastia, galactorrhea, oligomenorrhea, or amenorrhea.

KEY CONCEPT The SGAs are heterogeneous with regard to side effect profiles. Many SGAs carry an increased risk for weight gain and for the development of glucose and lipid abnormalities; therefore, careful monitoring is essential. Dosing and comparative side effects of SGA are shown in Tables 38–2 and 38–3.

▶ *Risperidone*

Risperidone, a benzisoxazole derivative, was the initial first-line oral SGA to become available generically. It has high binding affinity to both serotonin 2$_A$ (5-HT$_{2A}$) and D_2 receptors and binds to α_1 and α_2 receptors, with very little blockade of cholinergic receptors.[18] At doses less than or equal to 6 mg/day, EPSs are low, although higher doses are associated with a greater incidence of EPS. Risperidone is often associated with elevated prolactin to a greater extent than most other SGAs and FGAs. Elevated prolactin levels can, but do not always, lead to amenorrhea, galactorrhea, gynecomastia, and sexual dysfunction. Mild-to-moderate

Table 38–2

Second-Generation (Atypical) Antipsychotics

Second-Generation Antipsychotic	Usual Oral Starting and Target Dose (mg/day) (Schizophrenia)	Maximum Oral Dose Likely to Be Beneficial (mg/day)	Available Dosage Forms
Aripiprazole (Abilify; Abilify MyCite; Aristada [aripiprazole lauroxil injection])	Initial: 10–15 Target: 15–30	30	• 2-, 5-, 10-, 15-, 20-, and 30-mg tablets • MyCite available as 2, 5, 10, 15, 20, and 30-mg tablets with Ingestible Event Marker (IEM) sensor to track drug ingestion (adults) • 1-mg/mL oral solution • 10- and 15-mg orally disintegrating tablets • Abilify Maintena extended-release 300- and 400-mg vial powder for suspension or prefilled syringe long-acting injection • Aristada extended-release 441, 662, 882, and 1064-mg prefilled syringes • Aristada Initio, including 675-mg long-acting injection and 30-mg oral dose
Asenapine (Saphris; Secuado [patch])	Initial: 5 twice daily Target: 10–20 total daily dose	10–20	• 2.5-, 5-, and 10-mg sublingual tablets • Secuado (asenapine) transdermal system for once-daily administration; 3.8 mg/24 hours initial dosing; available as 3.8 mg/24 hours, 5.7 mg/24 hours, and 7.6 mg/ 24 hours
Brexpiprazole (Rexulti)	Initial: 1 Target: 2–4	4	• 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets
Cariprazine (Vraylar)	Initial: 1.5 Target: 1.5–6	6	• 1.5-, 3-, 4.5-, and 6-mg capsules
Clozapine (Clozaril, FazaClo, Versacloz, also available generically)	Initial: 12.5–25 Target: 300–450	500–800	• 12.5-, 25-, 50-, 100-, and 200-mg tablets • FazaClo (orally disintegrating tablets) 12.5, 25, 100, 150, and 200 mg • Versacloz (oral suspension) 50 mg/mL
Iloperidone (Fanapt)	Initial: 1 twice daily Target: 12–24 total daily dose	24	• 1-, 2-, 4-, 6-, 8-, 10-, and 12-mg tablets
Lumateperone (Caplyta)	Initial and target: 42 mg daily with food	42	• 42-mg capsule
Lurasidone (Latuda)	Initial: 40 Target: 40–160	160	• 20-, 40-, 60-, 80-, and 120-mg tablets
Olanzapine (Zyprexa, also available generically)	Initial: 5–10 Target: 10–20	30–40[a]	• 2.5-, 5-, 7.5-, 10-, 15-, and 20-mg tablets • Orally disintegrating tablets: 5, 10, 15, and 20 mg • IM 10-mg vial (after reconstitution, ˜5 mg/mL) • Zyprexa Relprevv 210-, 300-, and 405-mg/vial powder for suspension long-acting injection
Paliperidone (Invega)	Initial: 6 Target: 3–12	12	• 1.5-, 3-, 6-, and 9-mg tablets • Invega Sustenna 39-, 78-, 117-, 156-, and 234-mg prefilled syringes for long-acting injection • Invega Trinza 273-, 410, 546-, or 819 mg for long-acting injection
Quetiapine (Seroquel, also available generically)	Regular release Initial: 25 twice daily Target: 300–750 Extended release Initial: 300 Target 400–800	800	• 25-, 50-, 100-, 200-, 300-, and 400-mg tablets • Seroquel XR (extended-release tablets) 50-, 150-, 200-, 300-, and 400-mg tablets
Risperidone (Risperdal, also available generically)	Initial: 1–2 Target: 4–6	6–8	• 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets • 1 mg/mL (30-mL) solution • Orally disintegrating tablets: 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets • Risperdal Consta long-acting injectable 12.5-, 25-, 37.5-, and 50-mg vial/kit • Perseris long-acting subcutaneous injection; 90- and 120-mg kits
Ziprasidone (Geodon, also available generically)	Initial: 20 twice daily Target: 120–160 total daily dose	160–240[a]	• 20-, 40-, 60-, and 80-mg capsules • IM 20 mg/mL

weight gain and mild elevations in serum lipids and glucose may occur.

▶ *Olanzapine*

Olanzapine has greater affinity for 5-HT$_{2A}$ than for D$_2$ receptors. It also has affinity at the binding sites of D$_4$, D$_3$, 5-HT$_3$, 5-HT$_6$, α_1-adrenergic, muscarinic$_{1-5}$ (M$_{1-5}$), and histamine$_1$ (H$_1$) receptors.[19] In the CATIE trial, olanzapine was associated with the longest time to treatment discontinuation,[15] suggesting it may differ from the other SGAs in effectiveness. Olanzapine has a low rate of EPS and causes slight, transient prolactin elevations. Olanzapine causes significant weight gain across the dosage range, similar to that seen with clozapine and greater than that observed with the other SGAs. Olanzapine is also associated with hypertriglyceridemia, increased fasting glucose, and new-onset type 2 diabetes (ie, metabolic syndrome). Among the first-line SGAs, it is associated with the greatest elevations in these metabolic parameters.[15]

▶ *Quetiapine*

Quetiapine, structurally related to clozapine and olanzapine, has high affinity for 5-HT$_{2A}$ receptors and lower affinity for D$_2$ and D$_1$ receptors. It has some affinity for α_1, α_2, and H$_1$ receptors but very little for muscarinic receptors. Quetiapine may be beneficial for anxiety and depression. Motor side effects and prolactin elevations are uncommon. Orthostasis occurred in 4% of subjects in clinical trials. Sedation is common, but generally transient. Quetiapine is sometimes used for insomnia, though this practice is off label and not considered an appropriate use. Weight gain and elevations in triglycerides can occur. Use of quetiapine with agents that can prolong the QTc interval or in patients with prolonged QTc should be avoided. Quetiapine has been associated with some dose-related decreases in thyroid hormones.

▶ *Ziprasidone*

Ziprasidone was developed to block D$_2$ receptors but also to bind with greater affinity to central 5-HT$_{2A}$ receptors. It has a binding affinity ratio of 11:1 for 5-HT$_{2A}$:D$_2$ receptors. It has a relatively high affinity for 5-HT$_{2C}$, 5-HT$_{1D}$, α_1-adrenergic, and D$_1$ receptors.[20] It should be taken with food (at least 500 calories [2100 J]), as this results in absorption levels twice that of fasting administration. Liability for EPS, weight gain, and lipid elevations is low but does occur. Ziprasidone causes some prolongation of the QTc interval in adults. However, overdose data and pharmacokinetic interaction data show little evidence that significant QTc prolongation occurs. Use of ziprasidone with agents that can prolong the QTc interval or in patients with existing diseases associated with prolonged QTc should be avoided. Drug reaction with eosinophilia and systemic symptoms (DRESS) has occurred rarely.

▶ *Aripiprazole*

Aripiprazole has both antagonist and partial agonist activity at the D$_2$ receptor. Aripiprazole is also a partial agonist at 5-HT$_{1A}$ receptors, an antagonist at 5-HT$_{2A}$ receptors, and has affinity for D$_3$ receptors. Additionally, it has moderate affinity for α_1 and H$_1$ receptors with no appreciable affinity for the M1 receptor.[21] In CYP2D6 poor metabolizers, start dosing with one-half the usual dose with adjustment to clinical efficacy. Sedation, nausea, and vomiting are the most often seen side effects. Elevations in weight, lipids, and glucose are generally negligible, and aripiprazole is not associated with elevations in serum prolactin. In fact, patients switched to aripiprazole from other antipsychotic agents may experience decreases in prolactin.

▶ *Paliperidone*

Paliperidone is the 9-hydroxy (9-OH) metabolite of risperidone. The efficacy of risperidone and paliperidone is similar. Receptor binding affinity is also similar between the two agents, with paliperidone having a greater affinity at 5-HT$_{2A}$ compared with D$_2$ receptors. Unlike many other antipsychotic medications, paliperidone is mostly excreted unchanged, a potential advantage in patients with liver impairment, although adjustment may need to be made in renal impairment. Patients should be told to expect to see the shell of the tablet in the stool because it may not dissolve in the digestive tract.[22] Side effects of paliperidone are expected to be similar to those of risperidone, including the potential for dose-related EPS and prolactin elevation.[22]

▶ Iloperidone

Iloperidone exhibits high affinity for 5-HT_{2A}, dopamine D_2, and D_3 receptors and acts as an antagonist at these, as well as at the 5-HT_{1A} and norepinephrine α_1/α_{2C} receptors. Doses must be titrated because of the risk of orthostatic hypotension, and dosing should be reduced by half in CYP2D6 poor metabolizers. Common adverse reactions include dizziness, dry mouth, fatigue, orthostatic hypotension, tachycardia, and weight gain. Dizziness, tachycardia, and weight gain were twice as common with higher dose (20–24 mg total daily dose) versus lower doses (10–16 mg total daily dose).[23] Use of iloperidone with agents that can prolong the QTc interval or in patients with diseases that are associated with prolonged QTc should be avoided.

▶ Asenapine

Asenapine's mechanism of action is thought to be its antagonistic activity at 5-HT_{2A} and D_2 receptors. It also exhibits a high affinity for other serotonergic and dopaminergic receptors, as well as α_1- and α_2-adrenergic receptors and H_1 receptors. Asenapine tablets must be placed under the tongue and allowed to dissolve completely; tablets should not be chewed or swallowed. Patients should not drink or eat for 10 minutes after administration. No added benefit was seen with doses above 10 mg twice daily, but adverse effects increase. Common adverse effects include somnolence, dizziness, and akathisia. It has shown little effect on metabolic parameters and weight change. Labeling for asenapine was modified to address rare occurrence of hypersensitivity reactions, including anaphylaxis and angioedema.[24] A transdermal formulation of asenapine has been marketed as a once-daily (every 24 hours) formulation.

▶ Lurasidone

Lurasidone antagonizes D_2 and 5-HT_{2A} receptors. It also has moderate affinity as an antagonist at α_{2C}, is a partial agonist at 5-HT_{1A}, and is an antagonist at α_{2A} receptors. Lurasidone should be taken with caloric intake of at least 350 calories (1500 J) for maximal absorption. Adverse reactions reported in at least 5% of patients (and at least twice the placebo rate) include somnolence, akathisia, nausea, parkinsonism, and agitation. Lurasidone has shown only a small effect on body weight and causes minimal changes in other metabolic parameters.[24]

▶ Brexpiprazole

Brexpiprazole is a partial agonist at 5-HT_{1A}, D_2 and D_3 receptors. It is also an antagonist of 5-HT_{2A}, 5-HT_{2B}, 5-HT7, α_{1A}, α_{1B}, α_{1D}, α_{2C}, and H_1 receptors. It has negligible affinity for muscarinic receptors. In CYP2D6 poor metabolizers, usual dosage should be reduced by one-half. This medication is slightly less stimulating and has less akathisia than aripiprazole. The most commonly occurring side effects are weight gain and akathisia.[25]

▶ Cariprazine

Cariprazine is a dopamine D_3-preferring D_2/D_3 receptor partial agonist. It also acts as a partial agonist of 5-HT_{1A} and as an antagonist of 5-HT_{2A} receptors. It is given once daily and has a long half-life; thus, side effects should be monitored for several weeks after initiation or a dose change. Most common side effects are akathisia, EPS, nausea, vomiting, somnolence, and restlessness. Those having a known hypersensitivity reaction to cariprazine should not be treated with the medication.[26]

▶ Lumateperone

Lumateperone is a 5-HT_{2A} and D_2 receptor antagonist with higher affinity for 5-HT_{2A} compared with D_2, and lower affinities for α_1 and H_1 receptors. It also works as a presynaptic dopamine partial agonist, serotonin reuptake inhibitor, and an indirect modulator of glutamatergic systems. Due to gastrointestinal adverse effects in clinical trials, it is recommended to administer lumateperone with food. Only one dose (42 mg) is currently approved due to lack of efficacy of varying doses. Dose titration or adjustment is not required. Use of lumateperone was not associated with increased EPS risk as compared with placebo in pooled safety analyses of three clinical studies. Sedation/somnolence and dry mouth were associated with occurrence greater than twice the rate of placebo or at least 5% of patients exposed to lumateperone. Rates of EPS-related side effects and mean change in weight were less for lumateperone and placebo compared with risperidone.[27]

First-Generation (Typical) Antipsychotics

The FGAs are high-affinity D_2 receptor antagonists. During chronic treatment, they block 65% to 80% of D_2 receptors in the striatum and other dopamine tracts in the brain.[25] Clinical

Patient Encounter, Part 3

The patient started treatment with haloperidol 5 mg/day in the hospital. After a couple of days, the dose of haloperidol was increased to 10 mg/day. Over several days, the patient started to feel less paranoid and the voices began to dissipate. She began participating in group activities on the unit and interacting with her peers. She was discharged from the hospital after 2 weeks. Her mother agreed to have her return home.

The patient had a follow-up appointment 2 weeks after discharge. At the appointment, she expressed feeling well enough to consider going back to school. During the interview, the physician noted that she had a pill-rolling tremor and masked facies. Upon examination, the patient also had cogwheel rigidity and a lack of arm swing when she walked.

After discussion with the patient and her mother, the decision was made to switch her from haloperidol to oral olanzapine 5 mg/day. The doctor called the patient a week later to discuss how she was doing on the new medication. The patient felt like some of her schizophrenia symptoms were returning, so he decided to increase the olanzapine dose to 10 mg/day. The doctor called the patient again a week later, and she stated her hallucinations and paranoia were improving as were the stiffness and rigidity she experienced on haloperidol, so the dose was maintained at 10 mg/day.

What symptom was the patient experiencing on haloperidol? What other treatments could have been considered besides switching agents?

Discuss the differences in the side effect profiles of haloperidol and olanzapine.

Table 38–4

First-Generation (Typical) Antipsychotics[a]

Class	Agent (Brand Name)	Dosage Range (mg/day)	Chlorpromazine Equivalents (mg)	Available Formulations
Butyrophenone	Haloperidol (Haldol)	5–30	2	T, LC, I
Dibenzoxazepine	Loxapine (Loxitane, Adasuve)	20–100	10	C, IP
Diphenylbutylpiperidine	Pimozide (Orap)[b]	1–10	1–2	T
Phenothiazines	Chlorpromazine (Thorazine)	300–800	100	T, I
	Fluphenazine (Prolixin)	2–40	2	T, L, LC, I
	Perphenazine (Trilafon)[c]	8–64	8–10	T
	Thioridazine (Mellaril)	300–800	100	T
	Trifluoperazine (Stelazine)	15–30	5	T
Thioxanthenes	Thiothixene (Navane)	5–60	4	C

[a] Low-potency antipsychotics include thioridazine, mesoridazine, and chlorpromazine. High-potency antipsychotics include haloperidol, fluphenazine, thiothixene, and pimozide.

[b] Poor CYP2D6 metabolizers, alternative dosing strategies; recommend 2D6 genotyping above certain doses.

[c] Poor 2D6 metabolizers may demonstrate higher plasma concentration.

C, capsule; I, injection; IP, inhalation powder; LC, liquid concentrate; L, liquid solution, elixir, or suspension; T, tablet.

response is generally associated with 60% D_2 receptor blockade, while 70% and 80% are associated with hyperprolactinemia and EPS, respectively. During the 1990s, SGAs began to replace FGAs as first-line therapy.

Doses for FGAs are frequently given as **chlorpromazine equivalents**, which are defined as the FGA equipotent dose with 100 mg of chlorpromazine. The target dose recommendation for acute psychosis is 400 to 600 chlorpromazine equivalents unless the patient's history indicates that dose may not be tolerated. Generally, maintenance therapy is 300 to 600 chlorpromazine equivalents daily. Dosing and available dosage forms are shown in Table 38–4. All FGAs are equally efficacious when studied in equipotent doses in groups of patients. Relative potency of FGA agents is related to side effect profile, with lower potency agents such as chlorpromazine demonstrating higher risk of anticholinergic and cardiovascular side effects and higher potency agents such as haloperidol displaying more potent EPS side effects. However, an individual patient may not respond equally to each antipsychotic. Selection of a particular antipsychotic is based on patient variables, such as the need to avoid certain side effects or drug–drug interactions or previous patient or family history of response. Long-acting formulations of FGA medications are shown in Table 38–5.

Side Effects of the First-Generation Antipsychotics

As previously mentioned, the low-potency FGA agents are less likely to cause EPS than the high-potency agents (see Table 38–4). Of note, high-potency and midpotency agents may cause less EPS than once believed and were similar to SGAs in the CATIE trial.[15]

The FGAs are commonly associated with early-onset EPS (including **akathisia** [motor or subjective restlessness], **dystonia** [muscle spasm], and pseudoparkinsonism [akinesia, tremor, and rigidity]) caused by dopamine antagonism in the nigrostriatal pathways. SGAs also may have these side effects. Akathisia, or the feeling of restlessness, occurs in 20% to 40% of FGA patients. Roughly half of the cases of akathisia present within 1 month of FGA initiation, though it may present within 5 to 10 days after the first dose or after an increase in dosage. Younger people and those taking high doses of high-potency antipsychotics are at greater risk for development of akathisia.

Acute dystonic reactions are abrupt in onset and are usually seen within 24 to 96 hours after a first dose or increase in dosage. Characteristic signs and symptoms include abnormal positioning or spasm of the muscles of the head, neck, limbs, or trunk. Dystonia may occur in 10% to 20% of patients. There is higher risk for dystonia in young male patients and those taking high-potency FGAs.

Pseudoparkinsonism may be present in 30% to 60% of people treated with FGAs. The onset of symptoms is usually within 1 to 2 weeks after dose initiation or dose increase. Clinical presentation may include cogwheel rigidity, pill-rolling hand movements, resting tremor, shuffling gait, stooped posture, and mask facies. Risk factors include older age, female gender, high doses, and possibly those with depressive symptoms. Anticholinergic medications are used for treatment of dystonic reactions and pseudoparkinsonism, while β-blocking agents are generally first line for akathisia.[28]

Tardive dyskinesia is a movement disorder characterized by abnormal choreiform (rapid, objectively purposeless, irregular, and spontaneous) and athetoid (slow and irregular) movements beginning late in relation to initiation of antipsychotic therapy. It usually develops over several months or after at least 3 months of cumulative exposure to antipsychotics. When antipsychotics are tapered or discontinued, there is typically a transient worsening of abnormal movements, and movements may be irreversible in some cases. Risk factors for TD include older age; longer duration of antipsychotic treatment; and presence of EPS, substance abuse, and mood disorders. SGAs have a lower risk of approximately 2% to 4% risk of TD than FGAs (5%–6%).[17] A variety of approaches have been used for treating TD including switching to clozapine, using high-dose vitamin E, and, most recently, the approval of new Food and Drug Administration (FDA)-approved medications for TD, valbenazine and deutetrabenazine, which inhibit vesicular monoamine transporter 2 (VMAT2).

Neuroleptic malignant syndrome (NMS), a life-threatening emergency characterized by severe muscular rigidity, autonomic instability, and altered consciousness, can occur uncommonly with all FGAs and may also occur with SGAs. Rapid dose escalation, use of high-potency FGAs at higher doses, and younger

Table 38–5

Antipsychotic Dosing of Long-Acting Preparations

Drug	Starting Dose	Maintenance Dose	Comments
Aripiprazole long-acting injection (Abilify Maintena)	400 mg monthly Give 14 consecutive days of concurrent oral aripiprazole (10–20 mg) or current oral antipsychotic after first injection	300–400 mg monthly	Establish tolerability with oral agent first Dosage adjustments for CYP2D6 poor metabolizers, and in persons who take strong CYP2D6 or 3A4 inhibitors; recommend to avoid use if strong 3A4 inducer Available as 300-, 400-mg kits
Aripiprazole lauroxil (Aristada)	441 if 10 mg/day oral 662 if 15 mg/day oral 882 if 20 mg/day or more oral Give 21 days of concurrent oral aripiprazole overlapping with first dose	Average 441–882 monthly or 882 every 6 weeks or 1064 every 2 months	Dose adjustments for CYP2D6 poor metabolizers, and persons who take strong CYP2D6 or 3A4 inhibitors; or CYP3A4 inducers > 2 weeks Available as 441-, 662-, 882, or 1064-mg prefilled syringes
Aripiprazole lauroxil (Aristada Initio)	675-mg injection and one 30-mg dose of aripiprazole as first dose	To be used as a single dose and not for repeated dosing; for initiating Aristada treatment	Avoid use in CYP2D6 poor metabolizers Not interchangeable with Aristada First Aristada injection may be administered on the same day as Aristada Initio or up to 10 days after Do not inject both concomitantly into the same deltoid muscle
Haloperidol decanoate	10–20 × oral haloperidol daily dose; in the elderly use 10–15 × oral haloperidol daily dose Generally, 100–450 mg/month Initial dose should not exceed 100 mg regardless of previous dose requirements (if > 100 mg, give 3–7 days apart) Oral supplementation may temporarily be necessary for first 2–3 injections unless loading dose given	10–15 × oral haloperidol daily dose, generally 50–300 mg/month	Deep IM injection generally with 21-gauge needle; maximum volume per injection site should not exceed 3 mL Available in 50 and 100 mg/mL (5-mL vials and 1-mL ampules)
Fluphenazine decanoate	Approximately 12.5-mg injection = 10-mg oral daily dose; usual starting dose 12.5–25 mg; generally, 12.5–mg/2–3 weeks Give ½ oral dose after first injection, discontinue oral after second injection	Based on starting dose and clinical response but usually 2–4 weeks; doses above 50 mg increase cautiously in 12.5-mg increments; do not exceed 100 mg Generally, 12.5–25 mg dosed at 2–4-week intervals (may be up to 6 weeks in some cases)	Can be administered IM or SC; 21-gauge needle, must be dry Should not exceed 100 mg; when dosing above 50 mg, should increase in increments of 12.5 mg Available in 25 mg/mL (5-mL vials)
Olanzapine (Zyprexa Relprevv)	To target oral 10-mg/day dose: Either 210 mg/2 weeks or 405 mg/4 weeks during first 8 weeks To target oral 15-mg/day dose: 300 mg/2 weeks for first 8 weeks To target 20-mg/day oral dose: 300 mg/2 weeks Establish tolerance with oral administration prior to initiation	To target oral 10-mg/day dose: after 8 weeks, give 150 mg/2 weeks or 300 mg/4 weeks To target oral 15-mg/day dose: after 8 weeks, 210 mg/2 weeks or 405 mg/4 weeks To target 20-mg/day oral dose: continue with 300 mg/2 weeks	Gluteal injection, 19-gauge needle Do not confuse with rapid-acting IM injection Must reconstitute with included diluent Measure amount to inject from vial (there will be remaining suspension in vial) Zyprexa Relprevv Patient Care Program: 3-hour observation period due to risk of postinjection delirium/sedation syndrome; patient must be accompanied to destination No refrigeration needed, use within 24 hours, or immediately once suspension is in syringe Available as 210, 300, 405 kits
Paliperidone monthly (Invega Sustenna)	Initiate with 234 mg on day 1 and 156 mg 1 week later, both in deltoid muscle Establish tolerance with oral administration prior to initiation	Recommended monthly maintenance dose is 117 mg (range, 39–234 mg)	First two doses must be given in the deltoid muscle; after that, monthly doses given in either the deltoid or gluteal muscle Adjust dose in mild renal impairment; avoid in moderate-to-severe impairment Available as 39-, 78-, 117-, 156-, and 234-mg prefilled syringes

(Continued)

Table 38–5

Antipsychotic Dosing of Long-Acting Preparations (*Continued*)

Drug	Starting Dose	Maintenance Dose	Comments
Paliperidone (every 3 months) (Invega Trinza)	If monthly 78 mg, 273 mg/3 months If monthly 117 mg, 410 mg/3 months If monthly 156 mg, 546 mg/3 months If monthly 234 mg, 819 mg/3 months Only initiate after at least 4 months of paliperidone monthly injections.	273–819 mg/3 months	Adjust dose in mild renal impairment; avoid in moderate to severe impairment Available as 273-, 410-, 546-, or 819-mg prefilled syringes
Risperidone long-acting injection (Risperdal Consta)	25 mg every 2 weeks Previous antipsychotics should be continued for 3 weeks after initial dose of risperidone long-acting injection	25–50 mg every 2 weeks	Recommended to establish tolerability with oral risperidone prior to initiation of long-acting injection Lower starting dose of 12.5 mg may be appropriate in some patients with renal/hepatic impairment Available in 12.5-, 25-, 37.5-, and 50-mg vial/kit; must use needle supplied with kit, administer IM
Risperidone subcutaneous long-acting injection (Perseris)	90 mg to 120 once monthly	90 to 120 mg every month	Establish tolerability with oral risperidone No oral supplementation recommended Administer monthly in abdomen by subcutaneous injection by a healthcare professional; Must reconstitute when ready to give dose; Available as 90 mg and 120 mg injection kits

IM, intramuscular; SC, subcutaneous.

patients have a higher risk of NMS. When NMS is diagnosed or suspected, antipsychotics should be discontinued and supportive, symptomatic treatment begun (eg, antipyretics, cooling blanket, intravenous fluids, oxygen, monitoring of liver enzymes, and complete blood cell count). Benzodiazepines and dantrolene are recommended treatments along with intensive care management as needed.[28]

Dermatologic side effects, photosensitivity, and cataracts may occur with the phenothiazine FGAs. Sedation is mediated by H_1 receptor antagonism; anticholinergic side effects (constipation, blurred vision, dry mouth, and urinary retention) are caused by M_1 receptor antagonism; and α_1 receptor blockade is associated with orthostatic hypotension and tachycardia (Table 38–6). QTc prolongation may occur with the lower-potency FGAs, and thioridazine has a black box warning for QTc prolongation.

Pharmacologic Treatment Guidelines and Algorithms

There have been a variety of treatment recommendations published for schizophrenia. The American Psychiatric Association (APA) Practice Guidelines for Schizophrenia[8] were updated in 2020. The World Federation of Societies of Biological Psychiatry Guidelines (WFSBP),[29] British Association of Psychopharmacology (BAP),[30] the Canadian Schizophrenia Guidelines,[31] and the National Institute for Health and Care Excellence (NICE) guidelines are also available.[10] While guidelines from the early 2000s generally recommend SGAs as first-line treatment, more recent guidelines generally suggest first-line treatment with either an FGA or SGA. Choice of the FGA/SGA is guided by side effect profiles and patient clinical characteristics. Treatment with a given antipsychotic at a recommended therapeutic dose should

Table 38–6

Side Effects of First-Generation Antipsychotics

	Relative Potency	Extrapyramidal Symptoms	Sedation	Anticholinergic Side Effects	Cardiovascular Side Effects	Seizure Effects/ QTc Prolongation
Chlorpromazine	100	++	++++	+++	++++	++
Thioridazine	100	++	++++	++++	++++	+++
Loxapine	10	+++	+++	++	+++	+
Perphenazine	8–10	+++	++	++	++	+
Trifluoperazine	2–5	+++	++	++	++	+

Haloperidol	2	++++	+	+	+	+

+, very low; ++, low; +++, moderate; ++++, high.

be continued for 4 to 6 weeks to assess response. If response is not achieved, switching and cross titration to monotherapy with a different antipsychotic in conjunction with psychosocial support are recommended. Use of two antipsychotic medications concomitantly is discouraged in most circumstances due to increased side effect burden and paucity of data for increased efficacy.

Treatment Adherence

Antipsychotic nonadherence is estimated to occur in at least 40% to 50% of patients with schizophrenia. Patients who are nonadherent have about a fourfold greater risk of a relapse than those who are adherent.[32] Neurocognitive deficits, poor insight, and paranoid symptoms may hamper adherence, and identification of nonadherence by caretakers and providers can be challenging. Antipsychotic side effects such as EPS, weight gain, sexual dysfunction, substance use, and negative symptoms may all contribute to treatment nonadherence. For patients who have relapsed several times because of nonadherence have a history of dangerous behavior, or risk a significant loss of social or vocational gains when relapsed; treatment with long-acting injection (LAI) should be encouraged. However, more recent data suggest that both FGA and SGA LAIs are more effective at reducing rehospitalization risk compared to oral treatment,[33] and thus may be considered for all patients as a routine treatment option. The new APA guidelines[8] recommend LAI to patients who are interested in this delivery. Risperidone, paliperidone, olanzapine, and aripiprazole are available as LAIs. In general, oral tolerability of these agents should be ensured prior to initiating most of the LAIs. In recent years, many new SGA formulations have become available offering more flexibility with longer dosing intervals and easier loading strategies. Dosing and other information about these formulations are shown in Table 38–5. LAIs should be introduced early to patients as an option to improve efficacy and not just reserved for patients with lack of adherence to other treatments.

Special Populations

▶ *Dosing in Renal and Hepatic Impairment*

Table 38–7 shows dosing guidance on specific antipsychotic medications.

▶ *Children and Adolescents*

Around 10% to 30% of patients with schizophrenia have psychotic symptoms before their 18th birthday. The diagnosis of schizophrenia in children and adolescents is often challenging, and the differential diagnosis includes autistic spectrum disorders, attention-deficit/hyperactivity disorder, and language or communication disorders. The existence of prominent hallucinations or delusions helps make the diagnosis because they are not prominent in other disorders. Children and adolescents developing schizophrenia before age 18 years have premorbid abnormalities such as withdrawal, odd traits, and isolation. Treatment for psychotic children and adolescents ideally is intensive, comprehensive, and structured. Early intervention in psychosis services such as NAVIGATE should be employed in first-episode schizophrenia.[34] Pharmacologic treatment is indicated if psychotic symptoms cause significant impairments or interfere with other interventions. Children and adolescents are more vulnerable to EPS, particularly dystonias, than adults. Because of concerns about EPS and TD in children and adolescents, it is recommended that antipsychotic therapy be initiated with SGAs. Aripiprazole, risperidone, quetiapine, olanzapine, paliperidone, and lurasidone are approved by the FDA for the treatment of schizophrenia in adolescent patients. Initiation and target doses are lower for adolescents than adults.

Agents with significant sedative and anticholinergic side effects are not preferred because they can interfere with school performance. Compared with adults, children and adolescents tend to gain more weight when taking these agents.

▶ *Elderly*

Psychotic symptoms in late life (after 65 years of age) generally result from an ongoing chronic illness; however, a small percentage of patients develop psychotic symptoms *de novo*, defined as late-life schizophrenia. Other illnesses with psychotic symptoms are common in this population; approximately one-third of patients with Alzheimer disease, Parkinson disease, and vascular dementia experience psychotic symptoms.

Antipsychotics can be safe and effective for the treatment of schizophrenia in the elderly, if used at lower doses than those commonly used in younger adults. Older adults are particularly vulnerable to the side effects of the FGAs, and TD risk is over threefold risk in elderly patients.[17]

Orthostasis, estimated to occur in 5% to 30% of elderly patients, is a major contributing factor to falls that often lead to injuries and loss of independence. Low-potency antipsychotics and clozapine are more likely to cause significant orthostasis. Antipsychotics may cause or worsen anticholinergic effects, including constipation, dry mouth, urinary retention, and cognitive impairment. Greater antipsychotic-associated impairment in cognitive functioning may occur in the elderly compared to younger adults. In the elderly, this can lead to decreased independence, a very problematic issue. As a result of data showing a statistically significant increase in elderly dementia patients taking SGAs, a black box warning was added to the manufacturer's information for all antipsychotics. Patients and families should be informed of this risk before using these agents in patients with dementia. Dosing in the elderly is initiated lower, and titration is slower than in younger adults. Maximum doses are often half of adult doses (see Table 38–7).

▶ *Co-Occurring Substance Use Disorder*

Alcohol and illicit drug use is about threefold higher in schizophrenia than the general population.[5] In addition, nicotine use (most frequently, smoking tobacco) is highly prevalent in persons with schizophrenia, with rates at 58% to 90%. The most common drugs of abuse besides nicotine are cannabis, cocaine, and alcohol. Substance use often worsens the clinical course and complicates treatment. People with schizophrenia and substance use disorders are more likely to be nonadherent with treatment. They may have a poorer response rate to the FGAs, more severe psychosis, and higher rates of relapse and rehospitalization than people without co-occurring disorders. EPS may occur more frequently in substance-using patients, and alcohol use is a risk factor for developing TD. It is important to incorporate a dual treatment approach for substance use disorders and schizophrenia with nonpharmacologic and pharmacologic treatments.[35]

▶ *Treatment-Resistant Schizophrenia*

For 20% to 30% of people with schizophrenia, first-line antipsychotic treatment is ineffective, and another 30% of people have a partial treatment response.[29] A consensus guideline defines treatment-resistant schizophrenia (TRS) as (a) moderately severe

Table 38–7

Second-Generation Antipsychotic Dosing Recommendations for Special Populations

Medication	Pediatric	Geriatric	Renal Impairment	Hepatic	Pharmacogenomic Considerations
Aripiprazole	Oral: Ages 13–17 years (schizophrenia): Initiate 2 mg every day, increasing to 5 mg daily after 2 days and target of 10 mg after several days, 30 mg/day maximum	Long-acting injection: in general, dose selection should be cautious. Oral: No adjustment recommended	No adjustment required for oral or LAI	No adjustment required for oral or LAI	2D6 poor metabolizers: administer half of usual dose
Asenapine	No pediatric FDA indication for schizophrenia (bipolar I indication only)	No adjustment necessary based on age alone	No adjustments necessary	No adjustment necessary for mild-to-moderate impairment, but use contraindicated in severe impairment	
Brexpiprazole	No pediatric FDA indication	Experience is limited; low-dose initiation, up to 3 mg/day kinetics similar to adults with MDD in safety/tolerability trial	CrCl < 60 mL/min (1.0 mL/s): maximum 3 mg	Moderate to severe: Maximum 3 mg	2D6 poor metabolizers: Administer half of usual dose
Cariprazine	No pediatric FDA indication	Experience is limited; low-dose initiation	CrCl < 30 mL/min (0.50 mL/s): not recommended	Mild to moderate: No adjustment required; severe: not recommended	
Clozapine	No pediatric FDA indication	Experience is limited; low dose and slow titration	Adjustments may be necessary with significant impairment; no specific recommendations available	Adjustments may be necessary with significant impairment; no specific recommendations available	Dose reductions may be necessary in 2D6 poor metabolizers
Iloperidone	No pediatric FDA indication	Not sufficient information for recommendation	No adjustment information provided, but unlikely necessary	No adjustment needed for mild impairment; exercise caution with moderate impairment; not recommended for severe impairment	Dose reduced by one-half in 2D6 poor metabolizers
Lumateperone	No pediatric FDA indication	Not sufficient information for recommendation. Studies did not include any patients aged 65 or older	No recommendations listed	Not recommended for moderate-to-severe impairment	
Lurasidone	Ages 13–17 years (schizophrenia): Initial dose, 40 mg/day with target dose of 40–80 mg/day	Unknown if necessary to modify based on age alone	With moderate-to-severe renal impairment, recommended starting dose 20 mg daily; do not exceed 80 mg daily	With moderate impairment, initial dose 20 mg daily; maximum dose 80 mg daily With severe impairment, initial dose 20 mg daily, maximum dose 40 mg daily	
Olanzapine	Oral: Ages 13–17 years (schizophrenia): Initial dose, 2.5–5 mg orally every day with target dose of 10 mg/day; maximum dose, 20 mg/day Long-acting injection: Not approved in children	Oral: 5 mg/day, if escalation needed use caution Long-acting injection: Consider starting dose of 150 mg every 4 weeks for elderly or debilitated patients	Oral: In renal impairment, no adjustment usually necessary; however, consider a lower initial dose of 5 mg/day Long-acting injection: No information given	Oral: No dosage adjustment noted in prescribing information except in combination with fluoxetine Long-acting injection: No information given	

(Continued)

Table 38–7

Second-Generation Antipsychotic Dosing Recommendations for Special Populations (*Continued*)

Medication	Pediatric	Geriatric	Renal Impairment	Hepatic	Pharmacogenomic Considerations
Paliperidone	Oral: Ages 12–17 years (schizophrenia): Dose by body weight: < 51 kg, initiate 3 mg/day oral, increase at increments of > 5 days; maximum, 6 mg/day At least 51 kg, initiate at 3 mg/day, increase at increments of > 5 days, maximum of 12 mg/day	Long-acting injection: adjust dose based on renal function Oral: For patients with normal renal function, no adjustment is required, but if renal impairment guidance is available	Long-acting injection: CrCl 50–79 mL/min (0.83–1.32 mL/s); initiate with 156 mg IM day 1, 117 mg IM 1 week later, with maintenance at 78 mg IM monthly CrCl < 50 mL/min (0.83 mL/s): Use not recommended Oral: CrCl 50–79 mL/min (0.83–1.32 mL/s): 3 mg once daily initiation, maximum 6 mg/day CrCl between 10 and 49 mL/min (0.17–0.82 mL/s): 1.5 mg once daily initiation; maximum, 3 mg/day CrCl < 10 mL/min (0.17 mL/s): Use not recommended	Long-acting injection: No dosage adjustment needed for mild or moderate impairment; no guidance given for severe impairment Oral: No dose adjustment is required for mild or moderate impairment	
Quetiapine	Regular-release tablets: Indicated for schizophrenia (ages 13–17 years): Initiate 25 mg twice daily; recommended target dose 400–800 mg/day; maximum 800 mg/day Extended-release tablets: Initiate 50 mg/day; recommended target dose 400–800 mg	Regular-release tablets: Slower dose escalation and a lower target dose Extended-release tablets: Initiate at 50 mg/day and increase at 50-mg/day increments based on response or tolerance	No dosing recommendations for renal dysfunction	Regular-release tablets: Lower starting dose (25 mg) and slower titration may be needed Extended-release tablets: Should be initiated with 50 mg/day, increasing in 50-mg/day increments	
Risperidone	Oral: Pediatric ages 13 years and older (schizophrenia): Initiate at 0.5 mg orally daily, adjusting at intervals of at least 24 hours and in increments of 0.5–1 mg/day as tolerated Recommended target dose 3 mg/day	Long-acting IM: Initial dose, 25 mg IM every 2 weeks with a 3-week oral crossover; may consider 12.5 mg as starting dose Oral: Initiate at 0.5 mg twice daily; may increase by 0.5 mg twice daily, increases above 1.5 mg twice daily done at intervals of at least 1 week	Long-acting IM: Patients with renal impairment should receive titrated doses of oral risperidone before initiation of IM (more detail in prescribing information) Oral: Recommended initial dose in CrCl < 30 mL/min (0.50 mL/s), 0.5 mg twice daily; dose may be increased by 0.5 mg twice daily, but increases above 1.5 mg twice daily should be done at intervals of at least 1 week. Clearance of risperidone is decreased by 60% in patients with moderate-to-severe renal disease (CrCl < 60 mL/min [1.0 mL/s])	Long-acting IM: Titrate with oral risperidone (see renal dosing) Oral: Recommended initiation in Child-Pugh Class C (see renal dosing)	
Ziprasidone	No pediatric FDA indication	No official adjustment recommended; consider starting at lower end of the dosage range	Oral doses: No adjustment necessary for mild-to-moderate renal impairment IM doses: Use with caution because of cyclodextrin sodium excipient	No adjustment necessary for mild-to-moderate hepatic impairment; however, caution is warranted	

CrCl, creatinine clearance; FDA, Food and Drug Administration; IM, intramuscular; MDD, major depressive disorder.

illness as defined by rating instruments with a persistence of at least 5 years, (b) moderate or worse functional impairment, (c) treatment with at least two different antipsychotics given at adequate doses (a dose equivalent to at least 600 mg of chlorpromazine) for an adequate duration (6 weeks), (d) meeting minimum criteria of being adherent to current treatment, and (e) ideally having one prospective antipsychotic trial.[36]

Clozapine Clozapine is the only antipsychotic with proven superior efficacy and approved by the FDA for TRS.[16] It is efficacious after nonresponse to other SGAs, in partially responsive patients and patients who have had a poor response to other medication for years. According to published guidelines and recommendations, clozapine should be considered after two failed antipsychotic trials,[10,28,30] but may be considered sooner if the individual patient situation warrants.[8,29] Additionally, it is FDA approved for reducing the risk of recurrent suicidal behavior in schizophrenia or schizoaffective disorder[37] and recommended for those with a substantial risk of aggression.[8]

It remains unknown which pharmacologic properties account for clozapine's superior efficacy. Clozapine interacts with a multitude of receptors but notably has a low affinity for and rapid dissociation from D_2 receptors, antagonism of D_1 receptors, and is a 5-HT_{2A} antagonist.

Clozapine's use is limited by the regulatory requirements resulting from the risk for severe neutropenia (ANC < 0.5×10^9/L [or 0.5×10^3/mm^3], was termed agranulocytosis previously). This is a rare but potentially life-threatening side effect occurring in less than 1% of people treated and is a "black box" warning for the medication. The required long-term hematologic monitoring (Table 38–8) can be a barrier for both patients and care providers. Other rare side effects include seizures, myocarditis, and cardiomyopathy (also "black box" warnings). Orthostatic hypotension, bradycardia, and syncope are also "black box" warning for clozapine. Common unpleasant side effects include sedation, dizziness, constipation, enuresis, weight gain, and hypersalivation.

Registration for clozapine must first occur prior to dispensing using a Clozapine REMS website. APA guidelines recognize the underuse of this medication and encourage its more widespread acceptance.[8]

The optimal plasma level of clozapine is a minimum trough level of 918 to 1071 nmol/L (300–350 ng/mL or mcg/L), usually corresponding to a daily dose of 200 to 400 mg, although dosage

Table 38–8

Monitoring of Absolute Neutrophil Count During Clozapine Treatment

	General Population	BEN Population
Initiation to 6 months	Initiate if ANC ≥ 1.5×10^9/L; weekly monitoring for 6 months as long as ANC remain ≥ 1.5×10^9/L	Initiate if ANC ≥ 1.0×10^9/L (obtain at least 2 baseline levels); weekly monitoring for 6 months if ANC remain ≥ 1.0×10^9/L
6–12 months	Every 2-week monitoring for 6 months as long as ANC levels remain ≥ 1.5×10^9/L	Every 2-week monitoring for 6 months as long as ANC remain ≥ 1.0×10^9/L
After 12 months of therapy	Every 4-week monitoring as long as ANC levels remain ≥ 1.5×10^9/L	Every 4-week monitoring as long as ANC levels remain ≥ 1.0×10^9/L
ANC 1.0–1.49 × 10^9/L	**Mild neutropenia (general population)** 1.0 to 1.49 × 10^9/L (confirm with repeat ANC within 24 hours) Recommendation to continue treatment Monitor ANC three times weekly until ANC ≥ 1.5×10^9/L, then return to patient's last normal range monitoring interval if appropriate	These ANC levels considered normal for BEN population, continue monitoring as generally indicated above
ANC 0.5–0.99 × 10^9/L	**Moderate neutropenia (general population)** ANC 0.5–0.99 × 10^9/L (confirm with repeat ANC within 24 hours) Recommend hematology consult; interrupt treatment if clozapine-induced neutropenia is suspected. Resume treatment once ANC is ≥ 1.0×10^9/L Monitor ANC daily until ANC ≥ 1.0×10^9/L, then three times weekly until ANC ≥ 1.5×10^9/L, then check weekly × 4 weeks, then return to patient's last normal range ANC interval, if appropriate	**BEN neutropenia** 0.5–0.99 × 10^9/L (confirm with repeat ANC within 24 hours) Recommend hematology consult Continue treatment Monitor ANC thrice weekly until ANC ≥ 1.0×10^9/L or up to patient's known baseline Once at ANC ≥ 1.0×10^9/L or patient's known baseline, check ANC weekly for 4 weeks, then return to patient's last normal BEN range ANC monitoring interval, if appropriate
ANC < 0.5×10^9/L	**Severe neutropenia (general population)** Daily ANC until ANC ≥ 1.0×10^9/L, then three times weekly until ANC ≥ 1.5×10^9/L Recommend hematology consultation Interrupt treatment for suspected clozapine-induced neutropenia; no rechallenge unless benefits > risks If patient is rechallenged, resume treatment as a new patient under "normal range" monitoring once ANC ≥ 1.5×10^9/L	**BEN severe neutropenia** Daily ANC until ≥ 0.5×10^9/L, then thrice weekly until ANC ≥ patient's baseline Recommend hematology consultation Interrupt treatment for suspected clozapine-induced neutropenia. Do not rechallenge unless benefit > risk. If patient is rechallenged, resume treatment as a patient under normal range monitoring once ANC ≥1.0×10^9/L or at patient's baseline
Whenever clozapine is discontinued	Weekly for at least 4 weeks from day of discontinuation	Weekly for at least 4 weeks from day of discontinuation

ANC, absolute neutrophil count (10^9/L is equivalent to 10^3/mm^3); BEN, benign ethnic neutropenia.

must be individualized. Males and smokers tend to require higher doses to achieve the targeted blood level due to more rapid metabolism.

▶ *Acutely Psychotic and Agitated Patients*

Psychiatric emergencies occur in emergency departments, psychiatric units, medical facilities, and outpatient settings. Although nonpharmacologic interventions such as relaxation techniques and decreasing sensory stimulation are most ideal for initial management, acutely psychotic and agitated patients also require pharmacologic interventions. Short-acting, intramuscular (IM) formulations are available for a number of FGAs (haloperidol most frequently) as well as the SGAs (ziprasidone and olanzapine). IM benzodiazepines are commonly used in addition to IM antipsychotics. IM lorazepam is generally suggested as it is the only benzodiazepine with rapid and complete IM absorption. Concomitant IM olanzapine and benzodiazepines may cause cardiorespiratory depression and should be avoided if possible. Loxapine oral inhalation is also available for acute agitation but is restricted to a REMS program and to enrolled healthcare facilities with onsite equipment and personnel to handle bronchospasm.

▶ *Pregnancy and Lactation*

Women with schizophrenia have higher rates of unwanted pregnancies and obstetric complications (eg, stillbirth, infant death, preterm delivery, low infant birth weight, and infants who are small for gestational age). Prolactin-related effects secondary to certain FGA and SGA treatments have led to infertility in the past. Irregular menstruation also complicates the ability to plan for pregnancies and potential false protection with sexual activity. When pregnancy occurs, the management of pregnancy and lactation in females with schizophrenia should include a multidisciplinary team and the patient's family should be involved if possible. The decision to continue antipsychotic must be weighed by the risks and benefits. The fetus is at risk for antipsychotic side effects, but also the risk of relapse with schizophrenia during pregnancy is associated with a higher risk of birth complications. Guidelines suggest that antipsychotics are increasingly being used in pregnancy. Older data suggested teratogenic effects; however, larger and more recent epidemiologic studies find the majority of antipsychotics to be associated with no greater risk. Patients should still be cautioned that while the risk is low, congenital malformations have occurred rarely. There is now more published safety data with SGAs than FGAs. The safety data for FGAs is primarily for haloperidol. Low-potency phenothiazines may increase the risk of congenital abnormalities when used in the first trimester. There is some evidence to suggest a higher risk of congenital malformations with risperidone; however, this risk difference is only slightly higher at 5% versus 3% in the general population comparative group. If pregnancy occurs during antipsychotic treatment, continuation of previous antipsychotic is preferred to decrease relapse risk. Data suggest that mothers who are pregnant have about a twofold risk of developing gestational diabetes; thus, monitoring and promoting healthy eating is very important. Babies born to mothers taking SGAs may also have increased birth weights compared to nonexposed mothers.[35,38] A labeling change for antipsychotic medications has been implemented by the FDA to address the potential risk for EPS and symptoms of withdrawal in newborns whose mothers were treated with antipsychotics in the third trimester. Withdrawal symptoms may include agitation, abnormal muscle tone (increased or decreased), tremor, sleepiness, and difficulty in breathing or feeding, which may last for hours to days after delivery. In some newborns, specific treatment for withdrawal is not needed, whereas in others, longer hospital stays may be required.

Although SGAs are excreted in breast milk, most case reports document a low frequency of deleterious effects on the infant. Breast-feeding while on clozapine should be avoided.[35,38]

Pharmacokinetics and Drug Interactions

Most antipsychotics are, at least to some extent, metabolized by hepatic cytochrome P450 (CYP450) metabolic enzymes to water-soluble compounds that are excreted by the kidneys (Table 38–9).[39] Unlike other antipsychotics, ziprasidone is mostly metabolized by aldehyde oxidase, a metabolic system independent of the CYP450 system. Paliperidone, the 9-OH metabolite of risperidone, is mostly excreted unchanged in the urine, although up to one-third may be metabolized. The transmembrane energy-dependent efflux transporter P-glycoprotein may limit the ability of drugs to penetrate the blood–brain barrier and therefore impact pharmacologic activity in the brain. Antipsychotics currently known to use this pathway include perphenazine, haloperidol, fluphenazine, quetiapine, risperidone, paliperidone, aripiprazole, and olanzapine.[40]

Patient Encounter, Part 4

The patient's olanzapine dose was maintained at 10 mg once daily for the next 3 months. She returned again for follow-up with her outpatient psychiatrist who noted the patient's symptoms were responding very well. The patient also stated she was very pleased with her treatment, and the pseudoparkinsonism symptoms were resolved. She again brought up the idea of returning to school. She really wants to go back to school but is worried about her friends seeing her take medications for a mental illness and feels uncomfortable about it. Her mother is afraid that if she goes back to school, she may not take the olanzapine. The physician suggests that the patient consider getting "a shot" of olanzapine once a month, then she would not need to take a pill every day. The patient's mother readily agrees that this is a reasonable solution. The patient is initially reluctant to get "a shot" but finally agrees, as she also does not want to get into power struggles with her mother about whether or not she is taking her medication.

The patient receives the loading dose of olanzapine and moves back to school. She sees a provider at the school's health clinic to receive her monthly injection. She remains stable on the long-acting intramuscular form of olanzapine.

How would a clinician discuss the advantages of taking a long-acting intramuscular medication?

What dose of olanzapine long-acting injection (Zyprexa Relprevv) is appropriate for someone taking oral olanzapine 10 mg once daily?

What side effects can occur and what monitoring is required with olanzapine injection?

Table 38–9

Metabolism and Drug Interactions With Antipsychotics

Antipsychotic	Major Metabolic Pathways	Other Metabolic Pathways	Increase Antipsychotic Concentrations	Decrease Antipsychotic Concentrations
Aripiprazole	CYP3A4	CYP2D6	Fluvoxamine, ketoconazole	Carbamazepine
Asenapine	Glucuronidation by UGT1A4 and CYP1A2	CYP3A4, CYP2D6	Fluvoxamine	
Brexpiprazole	CYP3A4, 2D6		Itraconazole, clarithromycin, ketoconazole, quinidine, paroxetine, fluoxetine	Rifampin, St. John's wort
Cariprazine	CYP3A4	CYP2D6	Itraconazole, ketoconazole	Rifampin, carbamazepine (use not recommended with strong CYP3A4 inducer)
Chlorpromazine	CYP2D6	CYP1A2, CYP3A4		
Clozapine	CYP1A2	CYP3A4, CYP2D6, CYP2C19, CYP2C9	Fluvoxamine, ciprofloxacin, paroxetine	Cigarette smoking
Fluphenazine	CYP2D6		Paroxetine	
Haloperidol	CYP2D6, CYP3A4	CYP1A2	Fluvoxamine, fluoxetine, ketoconazole	Carbamazepine
Iloperidone	CYP2D6, CYP3A4	CYP1A2, CYP2E1	Ketoconazole, fluoxetine, paroxetine	
Loxapine	CYP1A2, CYP2D6, CYP3A4			
Lumateperone	CYP3A4, UGT 1A1, 1A4, and 2B15	AKR 1C1, 1B10, and 1C4 CYP2C8, CYP1A2	Moderate or strong CYP3A4 inhibitors, UGT inhibitors (valproic acid)	CYP3A4 inducers (carbamazepine)
Lurasidone	CYP3A4		Ketoconazole, diltiazem	Rifampin
Olanzapine	CYP1A2, glucuronidation by UGT1A4	CYP2D6	Fluvoxamine, ciprofloxacin, paroxetine	Cigarette smoking
Paliperidone	CYP2D6, CYP3A4 (in vitro, but limited role in vivo)		Divalproex sodium, paroxetine	Carbamazepine (via increased renal elimination)
Perphenazine	CYP2D6		Fluvoxamine, fluoxetine, paroxetine	
Pimozide	CYP3A4	CYP1A2, CYP2D6	Strong CYP2D6 inhibitors, CYP3A4 inhibitors	CYP3A4 inducers
Quetiapine	CYP3A4	CYP2D6	Fluvoxamine, ketoconazole	Carbamazepine
Risperidone	CYP2D6	CYP3A4	Fluoxetine, paroxetine	Carbamazepine
Thioridazine	CYP2D6	CYP2C19	Fluvoxamine	Cigarette smoking
Thiothixene	CYP1A2		CYP1A2 inhibitors	CYP1A2 inducers
Trifluoperazine	CYP1A2		CYP1A2 inhibitors	CYP1A2 inducers
Ziprasidone	Aldehyde oxidase	CYP1A2, CYP3A4	Fluvoxamine, ketoconazole	Carbamazepine

AKR, aldoketoreductase; CYP450, cytochrome P450 isoenzyme; UGT, uridine 5′-diphospho-glucuronosyltransferase.

Additive side effects may occur with combined drug therapies, and a few clinically significant drug interactions are notable (see Table 38–9). Cigarette smoking decreases serum concentrations of clozapine and olanzapine by induction of CYP1A2. Although antipsychotics are highly protein bound, protein-binding interactions are generally not clinically significant. Absorption of most antipsychotics is not affected by food, with the exception of lumateperone, lurasidone, and ziprasidone. The mean maximum concentration of lurasidone increases threefold when administered with food, and ziprasidone's absorption is increased by 60% to 70% when given with meals. Ingesting a high-fat meal with lumateperone increases the mean area under the curve (AUC) by 9%. Caloric intake of 500 calories (2100 J) is recommended with ziprasidone and 350 calories (1500 J) with lurasidone.

Among SGAs, ziprasidone, iloperidone, and quetiapine have potential to prolong the QTc interval. Using them with other agents that prolong the QTc interval should be undertaken with caution. These other agents include, but are not limited to, quinidine, sotalol, chlorpromazine, droperidol, mesoridazine, pimozide, thioridazine, mefloquine, moxifloxacin, and pentamidine. Combining higher doses of ziprasidone, iloperidone, or quetiapine with ketoconazole or erythromycin should be undertaken cautiously.

Added pharmacodynamic effects are possible when combining antipsychotics with other drugs that can cause sedation, hypotension, anticholinergic symptoms, and weight gain or metabolic abnormalities.

Adjunct Treatments

The judicious use of pharmacologic therapies other than antipsychotics is often necessary for the treatment of motor side effects, anxiety, depression, mood elevation, and TRS that does not respond to clozapine. Anticholinergic medications (eg, benztropine, 1–2 mg twice daily; trihexyphenidyl, 1–3 mg thrice daily; and diphenhydramine, 25–50 mg twice daily) are used to treat EPS. They may be prescribed prophylactically with high-D_2-binding agents or in patients at risk for EPS or for treatment of EPS. β-Blockers (eg, propranolol 30–120 mg/day) are sometimes effective for patients who develop akathisia. In some situations, such as on an inpatient unit, the concomitant use of benzodiazepines (eg, lorazepam 1–3 mg/day) with the SGAs may be necessary for agitation.[28]

More recent guidelines suggest that regular assessment of depressive symptoms in schizophrenia is important and that waiting for the effect of antipsychotics to work instead of immediately adding an antidepressant is recommended. Evidence suggests that SGAs may be more effective than FGAs for depressive symptoms in people with schizophrenia; however, this evidence is limited.[35] Antidepressants may be useful for patients with schizophrenia who have depressive symptoms in the stable phase of schizophrenia; however, these agents may have the potential to worsen symptoms in the acute phase.[35] Because suicide risk may be increased, aggressive treatment may be necessary when depression is present. The selective serotonin reuptake inhibitors (SSRIs) are the preferred agents, but many (eg, fluoxetine, fluvoxamine, paroxetine, sertraline) may inhibit the CYP450 enzymes, thus potentially raising plasma concentrations of many antipsychotics. Mood stabilizers, such as lithium and the anticonvulsants, have been used adjunctively with the antipsychotics to treat the affective component of schizoaffective disorder.[35] One antipsychotic, olanzapine, is marketed in combination with fluoxetine for bipolar disorder. For patients with an inadequate response to clozapine, limited treatment options are available for these patients. A number of augmentation strategies have been tried, including FGAs, SGAs, mood stabilizers (eg, lithium, valproate, and topiramate), minocycline, antidepressants, transcranial magnetic stimulation (TMS), and electroconvulsive therapy (ECT). Though controlled trial results are mixed, some data support the adjunctive use of risperidone, lamotrigine, or aripiprazole in clozapine-treated patients.[29]

Patient Education

KEY CONCEPT Education of the patient and family regarding the benefits and risks of antipsychotic medications and the importance of treatment adherence must be ongoing and integrated into pharmacologic management. Medication management discussions offer an opportunity to provide illness and treatment education including the nature and course of schizophrenia and can serve as a time to hear the patient's life goals. Key considerations include:

- Involve families in the education and treatment plans because family psychoeducation may decrease relapse, improve symptomatology, and enhance psychosocial and family outcomes.[14]
- Be clear that there is no cure for schizophrenia and that medications can be effective in improving many symptoms.
- Explain common and rare but dangerous side effects.
- Stress the importance of medication and treatment adherence for improving long-term outcomes.
- Decision making on the best course of treatment should be a shared process. Shared decision making is a process where clinicians and patients work together to make treatment decisions based on clinical evidence. This process incorporates patient's preference and values as well as risks and expected outcomes.

Patient Encounter, Part 5

The patient remained on olanzapine long-acting injection for several years and graduated from college, but eventually her paranoia returned and she felt agitated on the drug. Over the next several years, she was switched to various other agents including ziprasidone, aripiprazole, and asenapine, to which she only had a partial response. At her most recent outpatient appointment, the doctor suggested that she might benefit from a trial of clozapine, but the patient was not sure if clozapine was right for her. In a separate phone call to her mother, the doctor reviewed the pros and cons of the clozapine trial. The patient and her mother discussed everything they discussed with the doctor and agreed to a trial of clozapine.

Why is the clinician considering a clozapine trial?

What are the rare serious side effects of clozapine versus the common manageable side effects?

The patient smokes cigarettes. How will cigarette smoking affect clozapine therapy?

OUTCOME EVALUATION

Developing a good working alliance with the patient is essential. In the absence of a solid therapeutic relationship, patients are frequently reluctant to share their beliefs, personal experiences, and life goals.

Symptom Monitoring

Many assessments are available to objectively rate positive and negative symptoms, level of function, and life satisfaction. The most commonly used scales in clinical trials to measure symptoms include:

- Positive and Negative Symptom Scale (PANSS)
- Brief Psychiatric Rating Scale (BPRS)
- Clinical Global Impression (CGI) Scale
- Calgary Depression Scale for Schizophrenia (CDSS)

Using these scales on a regular basis, particularly when switching medications or changing doses, is a more reliable means of monitoring symptoms. Symptom assessments cannot capture the full range of possible improvements, but they can be useful in deciding whether a medication is having substantial benefit.

Side Effect Monitoring

KEY CONCEPT Regularly monitor for side effects and overall health status.[8,27,31] Perform orthostatic blood pressure measurements and vital sign assessments before initiating antipsychotics and regularly throughout treatment. Ask about prolactin-related side effects such as impaired menstruation, libido, and sexual performance regularly. At baseline, check body weight and height (to calculate body mass index [BMI]), screen for diabetes risk factors, and measure fasting glucose and lipid profile. BMI should be assessed at every visit for 6 months, and least quarterly thereafter. Lipid profile and either fasting glucose or hemoglobin A_{1C} should be monitored at 4 months after initiating and at least annually thereafter. For patients at higher risk of developing diabetes and those who gain weight, check body weight more often. Every effort should be made to help with weight and metabolic side effects.[6,41-43] Metformin may be an option in addition to nonpharmacologic techniques for weight loss or attenuation of weight gain.[44]

Additionally, perform baseline electrocardiography for patients with preexisting cardiovascular disease or risk for arrhythmia. With clozapine therapy, there is a risk for the development of severe neutropenia, which is greatest in the first 6 months of treatment. Required monitoring of absolute neutrophil count (ANC) is described in Table 38–8. Separate monitoring guidelines now

Patient Care Process

Collect Information:

- Chief complaint and history of present illness.
- Family history, psychiatric history (age when first diagnosed, time of first hospitalization for mental illness), medical history. Obtain collateral information from family, past medical records, and other providers to help clarify the psychiatric history.
- Social history (housing arrangements, social and vocational goals, support systems, employment, substance use history).
- Physical examination.
- Key laboratory data and imaging studies.
- Mental status examination.
- Past and current medications (psychiatric and somatic, prescription, nonprescription, herbal or other dietary supplements).

Assess the Information:

- Review the patient's chief complaint, presenting symptoms, and history, including psychiatric history. Assess mental status examination for organization of thoughts and range of affect, presence of mood disturbance, likelihood of harm to self or others, and presence of hallucination, paranoia and/or delusions of control, evaluate judgment and insight.
- Assess medical records, including laboratory and imaging studies, to rule out medical causes of psychosis.
- Assess current treatments and outcomes of prior treatments for effectiveness and safety.
- Assess adherence to medications and willingness to take medications.

Develop a Care Plan:

- Identify medication-related problems.
- Determine the goals of therapy.
- Select or optimize the dose of an antipsychotic based on the side effect profile that is most appropriate and acceptable to the patient.
- Collaborate with other healthcare professionals or caregivers in the development of the plan.
- Consider how income, insurance coverage, and access to care might influence pharmacotherapy choice.

Implement the Care Plan:

- Initiate, modify, discontinue, or administer the appropriate medication therapy.
- Educate patient and caregiver (with patient consent) about the illness, medication treatments, possible side effects, and goals of treatment.
- Discuss medication adherence and healthy lifestyle goals, including substance and cigarette use.
- Enlist adjunctive treatments, including psychosocial therapies to optimize outcomes.
- Coordinate referrals or transition of care to other healthcare professionals, such as social workers, home care nurses, or other medical specialists.
- Recommend placement of individuals in ACT, group homes, transitional housing, rehabilitation, or long-term care.
- Schedule follow-up appointments.

Follow-up: Monitor and Evaluate:

- Monitor medication therapy for effectiveness, using psychiatric rating scales when necessary.
- Monitor medication therapy for adverse events of antipsychotics using the AIMS, Simpson–Angus Scale, and Extrapyramidal Symptom Rating Scale.
- Monitor appropriate laboratory measures to prevent or minimize adverse effects, including metabolic abnormalities.
- Assess for emergence of new target symptoms.
- Monitor for adherence to the medication regimen.
- Optimize dosing and consider clozapine if criteria are met for treatment resistance.

exist for general patients and those with benign ethnic neutropenia. Overall, encourage patients to have annual physical, gynecologic, and ophthalmologic examinations and regularly ask about physical health and side effects at each visit.

Commonly used rating scales to monitor for EPS include the Simpson–Angus Scale (SAS) and the Extrapyramidal Symptom Rating Scale (ESRS). Akathisia is commonly monitored by the Barnes Akathisia Scale (BAS). The emergence of dyskinesias could represent the emergence of TD. Monitor patients on SGAs for TD at least annually and patients taking FGAs at each visit. The most commonly used instrument to measure these symptoms is the Abnormal Involuntary Movement Scale (AIMS).

Abbreviations Introduced in This Chapter

5-HT	Serotonin
ACT	Assertive Community Treatment
AIMS	Abnormal Involuntary Movement Scale
ANC	Absolute neutrophil count
APA	American Psychiatric Association
BAS	Barnes Akathisia Scale
BPRS	Brief Psychiatric Rating Scale
CATIE	Clinical Antipsychotics Trials of Intervention Effectiveness
CBT	Cognitive behavioral therapy
CGI	Clinical Global Impression Scale
CR	Cognitive remediation
CYP450	Cytochrome P450 isoenzyme
D	Dopamine
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders*, 5th edition
ECT	Electroconvulsive therapy
EPS	Extrapyramidal symptoms
ESRS	Extrapyramidal Symptom Rating Scale
FDA	Food and Drug Administration
FGA	First-generation antipsychotic
H	Histamine

IM	Intramuscular
LAI	Long-acting injection
M	Muscarinic
NMDA	*N*-methyl-D-aspartate
NMS	Neuroleptic malignant syndrome
PANSS	Positive and Negative Symptom Scale
PCP	Phencyclidine
PORT	Schizophrenia Patient Outcomes Research Team
QTc	Corrected QT interval
SAS	Simpson–Angus Scale
SGA	Second-generation antipsychotic
SSRI	Selective serotonin reuptake inhibitor
SST	Social skills training
TD	Tardive dyskinesia
TIMA	Texas Implementation of Medication Algorithms
TMS	Transcranial magnetic stimulation
TRS	Treatment-resistant schizophrenia
WBC	White blood cell

Major Depressive Disorder

J. Michael McGuire and Cherry W. Jackson

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the etiology and pathophysiology of major depressive disorder (MDD).
2. Identify the signs and symptoms of MDD.
3. Outline the treatment goals for a patient with MDD.
4. Recommend pharmacotherapy given a specific patient with MDD.
5. Develop a monitoring plan for a specific patient with MDD that includes the assessment of efficacy as well as adverse effects.
6. Predict, prevent, identify, and resolve potential drug-related problems.
7. Educate patients and caregivers on the proper use of antidepressant therapy.

INTRODUCTION

Major depression is a common, seriously disabling disorder nonresponsive to volitional efforts to feel better. Individuals with major depressive disorder (MDD) experience pervasive symptoms affecting mood, thinking, physical health, work, and relationships. Inadequately treated MDD increases the risk of suicide.[1]

Although antidepressants and agents used adjunctively in depression account for 16 of the top 200 prescription drugs dispensed in the United States, inadequate treatment remains a serious concern.[2,3]

Patient Encounter Part 1

A 35-year-old man presents to the psychiatry clinic with his brother. He complains of increased sleep and increased appetite although he still feels fatigued when he wakes up. He states that he has gained 12 lb (5.4 kg) in the last month. With prompting from his brother, he admits that he has lost interest in hunting, which is his favorite activity, especially now that it is deer hunting season. He has been going through a difficult divorce, and his wife has custody of his two children. He has been having difficulty waking up to go to work in the morning. He states that he has thoughts about driving his car across the interstate into oncoming traffic, but he would not do that because it is against his religion.

What symptoms of MDD does the patient have?

What medical or psychiatric issues could be contributing to the symptoms?

What additional information do you need to know before creating a treatment plan for this patient?

EPIDEMIOLOGY AND ETIOLOGY

At least 17.3 million adults over the age of 18 experience at least one episode of depression, and 8.1% of individuals over 20 years of age in the United States experienced depression in any given 2-week period.[4] Women are twice as likely to experience MDD.[4,5] According to the World Health Organization (WHO), depression is the leading cause of disability worldwide and a major contributor to the overall global burden of disease.[6]

PATHOPHYSIOLOGY

The cause of MDD is probably multifactorial. Multiple theories abound, and practitioners suggest that development of depression likely involves a complex interaction of genetic predisposition, psychological stressors, and underlying pathophysiology. There are no currently accepted unifying theories to adequately explain the pathophysiology of depression.[7]

Genetics

First-degree relatives of MDD patients are about two to four times more likely to develop MDD compared with controls.[5] Twin studies also suggest that MDD is due to genetic influences.[8] Major depression has been associated with four different genes including polymorphisms in the glucocorticoid receptor gene *NR3C1*, the monoamine oxidase A gene, the gene for glycogen synthase kinase-3β, and a group-2 metabotropic glutamate receptor gene (*GRM3*).[9]

Stress

There is an association between stress and depression, especially if a genetic predisposition exists. However, major life stressors do not always cause depression. Although acute stressors may precipitate depression, chronic stressors cause longer episodes and are more likely to lead to relapse and recurrence.[10]

Biogenic Amine and Receptor Hypotheses

KEY CONCEPT The primary hypothesis is the biogenic amine hypothesis which states that a deficit of norepinephrine (NE), dopamine (DA), or serotonin (5-HT) at the synapse is the cause of depression.[7] The fact that existing antidepressants increase synaptic monoamine concentrations supports this hypothesis (see Pharmacologic Therapy). One argument against this hypothesis is that patients with depression do not always have decreased monoamine levels. Additionally, monoamine levels are altered within hours of initiating antidepressant therapy, but response (usually defined as 50% reduction of symptoms) is delayed by 2 to 4 weeks or more.[7]

The receptor hypothesis suggests that depression is related to upregulation of monoamine neurotransmitter receptors in response to a depletion of monoamine neurotransmitters. In this hypothesis, chronic administration of antidepressants alters receptor sensitivity causing desensitization or downregulation of monoamine neurotransmitter receptors leading to therapeutic response.[7] Importantly, the time required for changes in receptor sensitivity correlates with antidepressant onset.[7] These hypotheses are oversimplifications of the pathophysiology of depression. MDD probably involves a complex dysregulation of monoamine systems that affect and are modulated by other neurobiological systems.

Other Neurobiological Hypotheses

At least three categories of peripheral hormones are associated with the pathophysiology of depression. They include (a) neurotrophic and other growth factors including brain-derived neurotrophic factor (BDNF); (b) the hypothalamic pituitary axis (HPA); and (c) proinflammatory cytokines including interleukin-1β, interleukin-6, and tumor necrosis factor-α.[11]

Proinflammatory cytokines are increased in individuals with MDD, and antidepressants suppress the synthesis of these cytokines.[11] HPA regulation is impaired in depression, and antidepressants can attenuate the neuroendocrine response.[11] Similarly, BDNF is decreased in patients with MDD, and antidepressants reverse this response.[11]

CLINICAL PRESENTATION AND DIAGNOSIS

The diagnosis of a major depressive episode (MDE) requires the presence of five symptoms for a minimum of 2 weeks that cause clinically significant distress or impairment.[5] The diagnosis of MDD is based on the presence of one or more MDEs during a person's lifetime (Table 39–1).[5]

Differential Diagnosis and Comorbidities

MDEs also occur in bipolar disorder. Individuals with bipolar disorder also experience hypomanic, manic, or mixed episodes (see Chapter 40) during the course of their illness, but individuals with MDD do not.[5]

Conditions that may coexist with MDD include anxiety, eating, personality, and substance use disorders.[5] Several chronic medical conditions including diabetes and coronary artery disease also have strong correlations with MDD.[12] Other medical disorders associated with depression are listed in Table 39–2. Identification and treatment of MDD in patients with chronic medical conditions is important. Inadequate recognition and undertreatment of depression may increase the mortality associated with these medical disorders.[12,13] Medications associated with depression are listed in Table 39–2.[14,15]

Other depressive disorders in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) include persistent depressive disorder (dysthymia), premenstrual dysphoric disorder, and disruptive mood dysregulation disorder.[5]

Table 39–1

Clinical Presentation of Depression: Diagnostic Criteria for Major Depressive Episode[5]

At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning.

- Depressed mood[a]
- Markedly diminished interest or pleasure in usual activities[a]
- Increase or decrease in appetite or weight
- Increase or decrease in amount of sleep
- Increase or decrease in psychomotor activity (ie, agitation or retardation)
- Fatigue or loss of energy
- Feelings of worthlessness or guilt
- Diminished ability to think, concentrate, or make decisions
- Recurrent thoughts of death, suicidal ideation, or suicide attempt

The symptoms cause clinically significant distress or impairment in functioning.

The symptoms are not due to the direct physiologic effects of a substance or medical condition.

[a]One of these two symptoms must be present.

Data from American Psychiatric Association. Major Depressive Disorders. Diagnostic and Statistical Manual of Mental Disorders, 5th ed. Washington, DC: American Psychiatric Association; 2013:160–168.

COURSE AND PROGNOSIS

MDD may affect an individual at any age including children and elderly, although, the incidence peaks between 20 and 30 years of age in the United States.[5] Some individuals will experience only one

Table 39–2

Medical Conditions and Medications Associated with Depression[5,12-15]

Medical disorders	Medications
Hypothyroidism	CNS depressants (alcohol, benzodiazepines, opioids)
Cancer	Corticosteroids
Anemia	Contraceptives
Infections	Phenobarbital
Electrolyte disturbances	Brivaracetam
Folate deficiency	Levetiracetam
Neurologic disorders	Perampanel
Cardiovascular disease	Tiagabine
Respiratory disease	Topiramate
	Vigabatrin
	Gonadotropin-releasing hormone agonists
	Interferon α
	Interleukin 2
	Varenicline
	Mefloquine
	Isotretinoin
	Propranolol
	Clonidine
	Methyldopa
	Reserpine

CNS, central nervous system.

episode of depression, others will experience distinct episodes with few or no symptoms between, while others will rarely experience remission. The course of MDD varies markedly between patients.[5] **KEY CONCEPT** It is not uncommon for a patient to experience only a single MDE, but many patients with MDD experience multiple episodes. The longer an individual is in remission, the lower their risk of recurrence. Individuals with longer symptom duration, psychotic features, prominent anxiety, and severe symptoms predict lower recovery rates.[5] The risk of recurrence increases in individuals with persistent mild depressive symptoms, severe episodes, younger age, and in those with a history of previous episodes.[5,16] Individuals who have experienced one episode of depression have a 60% chance of recurrence, and those with a second episode of depression have a 70% chance of recurrence, while those with a third episode of depression have a 90% risk of recurrence and should continue antidepressant treatment indefinitely.[16] The presence of residual symptoms such as sleep or appetite disturbances after achieving remission increases the likelihood of relapse.[17]

MDD is a risk factor for suicide.[18] The WHO estimates that nearly 800,000 people die from suicide every year, and suicide is the second leading cause of death among 15- to 29-year-olds.[6]

TREATMENT

Desired Outcomes

The goal of therapy for patients with MDD is resolution of depressive symptoms, return to euthymia, and prevention of relapse and recurrence of symptoms.[18] **KEY CONCEPT** One extremely important goal is prevention of suicide and suicide attempts.

Nonpharmacologic Therapy

Evidence supports the efficacy of interpersonal and cognitive-behavioral therapy in the treatment of MDD. Psychotherapy alone is an initial treatment option for mild-to-moderate depression and may be useful when combined with pharmacotherapy for the treatment of severe depression.[18] This combination can be more effective than either treatment alone in severe or recurrent MDD.[18]

Electroconvulsive therapy (ECT) is a highly efficacious and safe treatment alternative for MDD. The response rate is about 80%, and it exceeds 50% for patients who have failed pharmacotherapy.[18] ECT may be beneficial for MDD that is complicated with psychotic features, severe suicidality, refusal to eat, pregnancy, or contraindication or nonresponse to pharmacotherapy.[18] Typically, 6 to 12 treatments are necessary with response occurring in 10 to 14 days.[18] Antidepressants are typically started or continued when initiating ECT, and when ECT is discontinued, antidepressants help maintain response.[18] In addition, some patients will receive maintenance ECT with/without antidepressants. Side effects after ECT include temporary confusion and retrograde and anterograde amnesia.[18]

Light therapy may be an effective treatment for mild-to-moderate depression associated with seasonal (eg, winter) exacerbations.[19] Light therapy involves using light intensity of 10,000 lux for 30 minutes daily for up to 6 weeks.[20,21] The mechanism of action of light therapy is thought to be readjustment of circadian rhythms.[20,21] Light therapy is well tolerated, and adverse effects can include eye strain, headache, nausea, and sedation.[20,21]

Vagus nerve stimulation (VNS) was approved by the Food and Drug Administration (FDA) in 2005 for treatment-resistant depression.[18] A pulse generator is surgically implanted around the vagal nerve that sends signals to the brain that may help relieve depressive symptoms.[22] Adverse effects of VNS include alterations in patients' voice, hoarseness, dyspnea, and neck pain.[18]

Transcranial magnetic stimulation is a noninvasive, well-tolerated procedure that is FDA approved for use after one failed trial of an antidepressant.[18]

Physical exercise is effective for mild-to-moderate depression.[20,21] The mechanism of action is thought to involve reduction of cortisol and increase in neurotransmitters including BDNF.[20,21] Both aerobic and nonaerobic exercises have been shown to be beneficial for reducing depression.[20,21] At least 30 minutes of supervised, moderate-intensity exercise, 3 days weekly, for at least 9 weeks has been proven effective.[20,21] Physical exercise is well tolerated with rare instances of adverse effects.[20,21]

Patient Encounter Part 2

PMH: History of diabetes, rheumatoid arthritis, hypertension, hypertriglyceridemia, gastric reflux

Past Psychiatric History: He was diagnosed with MDD when he was 16 and has had two previous psychiatric hospitalizations with the last being 6 months ago.

Past Psychiatric Medication Trials: Paroxetine (current), fluoxetine, sertraline, amitriptyline, alprazolam, and trazodone.

FH: Mother had diabetes mellitus and MDD, died at age 60; father had a history of alcoholism and died at age 58; brother has a history of alcohol use disorder.

SH: High school diploma. Works as an auto mechanic at Jiffy Lube franchise but is at risk of losing his job due to difficulty getting to work. Drinks a couple of beers at night and admits to drinking a 12 pack of beer on weekends. Currently going through a divorce. Has two children ages 8 and 10, but he does not have custody. Smokes 1.5 packs of cigarettes per day.

Current Meds:

- Paroxetine 50 mg by mouth once daily
- Metoprolol succinate 50 mg by mouth once daily
- Omeprazole 40 mg by mouth once daily
- Prednisone 20 mg by mouth once daily
- Metformin 1000 mg by mouth twice daily with meals
- Fish oil capsules by mouth once daily

ROS: Increased sleep; increased appetite; weight gain; fatigue

PE:

VS: Ht 5′11″ (180 cm), Wt 251 lb (114 kg), weight gain of 12 lb (5.4 kg) over past 4 weeks

MSE: Lack of interest/pleasure, increased sleep, increased appetite, fatigue, positive suicidal ideation with plan

Labs: Within normal limits. Urine drug screen—negative

Given this additional information, what is your assessment of the patient's condition?

Does the patient have risk factors for depression?

Identify treatment goals for the patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient?

Table 39–3

Primary Pharmacologic Actions[a] of Antidepressants[7,11,30]

Action	MAOI	TCA	SSRI	Bup	SNRI	Esket	Brex	Vilaz	Traz	Nefaz	Mirtaz	Vorti

[a]See text for discussion of secondary pharmacologic actions.

Brex, brexanolone; Bup, bupropion; Esket, esketamine; MAOI, monoamine oxidase inhibitor; Mirtaz, mirtazapine; Nefaz, nefazodone; SNRI, serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; Traz, trazodone; Vilaz, vilazodone; Vorti, vortioxetine.

Pharmacologic Therapy

Individual antidepressants, even those within the same class, have important pharmacologic differences (Tables 39–3 and 39–4).[7,23] Treatment guidelines categorize antidepressants by mechanism of action, chemical structure, or whether the medication is an "older antidepressant" that includes monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs).

► *Selective Serotonin Reuptake Inhibitors*

Selective serotonin reuptake inhibitors (SSRIs) inhibit postsynaptic reuptake of serotonin resulting in increased serotonin in the synaptic cleft.[7] Each SSRI has a unique pharmacologic profile.[7] For example, paroxetine has mild anticholinergic effects; citalopram has mild antihistaminic effects; and fluoxetine antagonizes the 5-HT$_{2C}$ receptor which may contribute to its antibulimic effects.[7]

Table 39–4

Efficacy and Adverse Effect Profile Based on Pharmacology[7,9]

Pharmacologic Action	Result
SRI	Antidepressant and antianxiety efficacy (via interaction of 5-HT at 5-HT$_{1A}$ receptors) Anxiety, insomnia, sexual dysfunction (via interaction of 5-HT at 5-HT$_{2A}$ receptors) Anxiety, anorexia (via interaction of 5-HT$_{2C}$ receptors) Nausea, GI problems (via interaction of 5-HT at 5-HT$_3$ receptors)
NRI	Antidepressant efficacy Tremor, tachycardia, sweating, jitteriness, increased blood pressure
Dopamine reuptake inhibition	Antidepressant efficacy, euphoria, psychomotor activation, aggravation of psychosis
α_2-Adrenergic receptor blockade	Increase in serotonergic and noradrenergic activity—see actions of SRI and NRI above
Serotonin$_{1A}$ receptor agonist	Antianxiety, antidepressant augmentation, decreased blood pressure
Serotonin$_{1A}$ partial agonism	Antianxiety, antidepressant augmentation, decreased blood pressure, decreased heart rate
Serotonin$_{2A}$ receptor blockade	Antianxiety efficacy Increased REM sleep; decreased sexual dysfunction
Serotonin$_{2C}$ receptor blockade	Antianxiety efficacy Increased appetite or weight gain
Serotonin$_3$ receptor blockade	Antiemetic, decreased GI problems
Serotonin$_7$ receptor blockade	Antidepressant, modulates glutamate
α_1-Adrenergic receptor blockade	Orthostatic hypotension, dizziness, reflex tachycardia
Histamine-1 receptor blockade	Sedation, weight gain
Muscarinic cholinergic receptor blockade	Dry mouth, blurred vision, constipation, urinary hesitancy, sinus tachycardia, memory problems

GI, gastrointestinal; 5-HT, serotonin; NRI, norepinephrine reuptake inhibition; REM, rapid eye movement; SRI, serotonin reuptake inhibition.

Serotonin Norepinephrine Reuptake Inhibitors

Venlafaxine, desvenlafaxine, duloxetine, and levomilnacipran are 5-HT and NE reuptake inhibitors (SNRIs). Compared with venlafaxine and desvenlafaxine, which have primarily serotonin reuptake inhibitor (SRI) activity and dose-related affinity for norepinephrine reuptake inhibition (NRI), duloxetine has more balanced SRI and NRI activities.[7] Levomilnacipran has higher activity at NRI than SRI.[7]

Norepinephrine Dopamine Reuptake Inhibitor

Bupropion is a NE and DA reuptake inhibitor (NDRI).[7] Bupropion's effects on NRI and dopamine reuptake inhibition (DRI) are weak, but it is an efficacious antidepressant.[7] Bupropion is generally activating and may be especially useful at improving energy, alertness, as well as other symptoms of depression.[7]

Serotonin Antagonist and Reuptake Inhibitors

Nefazodone and trazodone are 5-HT antagonists (SARIs).[7] Their SRI activity is not as pronounced as that of the SSRIs, but they potently block 5-HT_{2A} receptors, which allow more 5-HT to interact at postsynaptic 5-HT_{1A} sites.[7] In addition, trazodone blocks histaminergic and α-adrenergic receptors, and nefazodone possesses weak NRI and α-adrenergic blocking properties.[7]

Other Newer Antidepressants

Finally, mirtazapine is a **noradrenergic** and specific serotonergic antidepressant (NaSSA).[7] It blocks presynaptic **α_2 autoreceptors** on noradrenergic neurons and **α_2 heteroreceptors** on serotonergic neurons, resulting in increases in NE and 5-HT synaptic concentrations.[7] Mirtazapine also blocks postsynaptic serotonergic receptors and histamine-1 receptors at lower doses inducing sleep and weight gain.[7] At higher doses, histaminic activity is offset by noradrenergic activity that reduces its effects on sleep and weight gain.[7,24]

Vilazodone is best characterized pharmacologically as a SRI and a partial agonist at 5-HT_{1A} receptors.[7] The 5-HT_{1A} effect is thought to reduce negative feedback on endogenous serotonin receptors which may improve the medication's antidepressant effect.[7]

Vortioxetine is an agonist/antagonist/partial agonist at various 5-HT receptors.[25] Vortioxetine has affinity for β-adrenergic receptors which may be associated with side effects, and histaminic and acetylcholine receptors which may have a positive effect on memory.[25]

Esketamine acts by nonselective and noncompetitive inhibition at the *N*-methyl-D-aspartate (NMDA) receptor to decrease the effects of glutamate which can be elevated by stress.[26] Brexanolone provides positive allosteric modulation of γ-aminobutyric acid (GABA) receptors which restores progesterone levels in the postpartum period.[27]

Monoamine Oxidase Inhibitors

MAOIs inhibit the enzyme responsible for the breakdown of 5-HT, NE, and DA.[7] There are two main forms of the MAO enzyme—MAO-A and MAO-B.[7] MAO-A and MAO-B are both located in the brain, and MAO-A is also present in the gut. MAO-A is responsible for the breakdown of 5-HT, DA, NE, and tyramine.[7] MAO-B is responsible for the breakdown of dopamine, phenylethylamine, and tyramine.[7] Dietary restrictions limiting the consumption of tyramine are necessary for orally available MAOIs due to inhibition of MAO-A in the gut.[7] Dietary restrictions are not required for the transdermal formulation of selegiline at the starting dose of 6 mg/24 hours.[7]

Tricyclic Antidepressants

The TCAs possess both SRI and NRI properties, but they also block other receptors, including α_1-adrenergic, histamine-1, and muscarinic cholinergic receptors, which contribute to side effects.[7]

Complementary and Alternative Treatments

The most recent Canadian Network for Mood and Anxiety Treatments (CANMAT) Guidelines and the American Psychiatric Association (APA) Task Force on Complementary and Alternative Medicine (CAM) offer recommendations on how CAM treatments should be used for treatment of depression.[20,21] From those recommendations, there is sufficient evidence to recommend several complementary treatments either as first- or second-line therapies. These include bright light therapy, exercise, St. John's wort, and omega-3 fatty acids as monotherapies for mild-to-moderate depression or adjunctive therapies for moderate-to-severe depression.

St. John's wort (*Hypericum perforatum*) is a herbal medication that has shown efficacy in mild-to-moderate depression and efficacy as an adjunctive therapy for moderate-to-severe depression.[20] It has mild MAO-inhibiting properties.[20] Many patients believe that herbal medications are devoid of adverse effects and drug interactions; however, St. John's wort can cause gastrointestinal (GI) irritation, headache, skin irritation, photosensitivity, and dry mouth.[20] It also triggers drug interactions through induction of CYP3A4 enzymes and P-glycoprotein.[18] St. John's wort should be used cautiously when combined with standard antidepressant medications due to risk of potential drug interactions and serotonin syndrome.[20]

S-adenosyl methionine (SAM-e), a naturally occurring compound in the body, tends to be lower in people with major depression.[20] The proposed mechanism of action involves its effects on the monoaminergic system. It is sold as a nutritional supplement and lacks the standardization of FDA-approved medications. The dose range is typically between 800 and 1600 mg/day, divided into three doses that are given with meals. The most common adverse effects with SAM-e include GI upset, insomnia, headache, anxiety, tachycardia, and fatigue.[20]

Low doses of omega-3 fatty acids (eicosapentaenoic [EPA], docosahexaenoic [DHA] acid, or both) have been used adjunctively for depression.[28] The usual dose is 3 to 9 g of EPA in addition to 1 to 2 g of DHA daily.[20] Omega-3 fatty acids are usually well tolerated. Adverse effects include nausea, diarrhea, and an aftertaste.[20,28]

Adverse Effects

The adverse effects of the antidepressants are often a function of their underlying pharmacologic profiles (see Table 39–4).

The adverse effect profile of the SSRIs includes sexual dysfunction, central nervous system (CNS) stimulation (eg, nervousness, insomnia), nausea, diarrhea, weight gain, anhedonia, and fatigue.[23] Nausea, anxiety, headache, and fatigue are often transient and improve with time.[7] **KEY CONCEPT** Sexual dysfunction, common and challenging to manage, may lead to nonadherence.[29] Various strategies to manage antidepressant-induced sexual dysfunction include waiting for symptoms to subside, reducing the dosage, permitting "drug holidays," prescribing adjunctive therapy, and switching antidepressants.[18,29] Some patients report an improvement in sexual functioning as a result of improvement in depressive symptoms.[30] Reducing the dose and drug holidays may weaken the antidepressant effects.[29] Clinicians often prescribe adjunctive therapy such as bupropion, cyproheptadine, and sildenafil or simply switch to antidepressants with less likelihood

Table 39–5

of causing these effects, such as bupropion, mirtazapine, nefazodone, or vortioxetine.[29]

Bupropion causes insomnia, nightmares, decreased appetite, anxiety, and tremors, but the most concerning adverse effect is seizures.[18,23] Because of the risk for seizures, patients with a CNS lesion, history of seizure disorder, head trauma, anorexia, or bulimia should not receive bupropion.[18,30] The total daily dose of bupropion should not exceed 450 mg/day, and any single dose of the immediate-release formulation should not exceed 150 mg.[30] The maximum dose of sustained release is 200 mg twice daily.[30] Insomnia and/or nightmares often respond to moving the last daily dose from bedtime to late afternoon.

The adverse effects of the SNRIs are similar to those of the SSRIs.[18] Nausea can be troublesome with venlafaxine and desvenlafaxine, which sometimes necessitates using lower starting doses and giving the medication with food.[18] A dose-related elevation in blood pressure can occur at higher doses, and blood pressure monitoring should be conducted for patients receiving venlafaxine or desvenlafaxine.[18] Duloxetine should not be prescribed to patients with substantial alcohol use or evidence of chronic liver disease due to the potential for hepatic injury.[30]

Trazodone causes sedation and is often used adjunctively with other antidepressants for sleep rather than as an antidepressant.[18] Priapism is a rare but serious adverse effect of trazodone.[18] There are no reported cases of priapism with nefazodone.[18] Unfortunately, nefazodone carries a black box warning for fatal hepatotoxicity.[18]

Mirtazapine can cause sedation and weight gain by blocking histamine-1 receptors.[7] Despite being serotonergic, it rarely causes serotonin-related adverse effects such as sexual dysfunction and nausea due to its blockade of postsynaptic 5-HT_2 and 5-HT_3 receptors, respectively, that may be associated with those effects.[7]

Esketamine can cause nausea, sedation, dizziness, derealization, taste distortions, anxiety, and blood pressure elevation.[30] Esketamine is available through a Risk Evaluation and Mitigation Strategy (REMS) program due to its sedative and dissociative effects.[31]

Brexanolone can cause sedation or sudden loss of consciousness during administration and is only available through a REMS program.[27] Other common adverse effects are hot flashes and dry mouth.[27]

The TCAs cause sedative, anticholinergic, and cardiovascular adverse effects.[7] The tertiary TCAs (eg, amitriptyline, imipramine) are more sedating and anticholinergic than the secondary TCAs (eg, desipramine, nortriptyline).[18] TCAs have a quinidine-like effect on the heart, which makes them toxic in overdose.[7] The lethal dose of a TCA can occur with as little as 15 mg/kg in a young adult, which is typically less than a 1-month supply.[23]

The incidence of adverse effects among the newer antidepressants is shown in Table 39–5.

Pharmacokinetic Parameters

Pharmacokinetic parameters related to the newer antidepressants are shown in Table 39–6. The elimination half-lives of paroxetine, nefazodone, and venlafaxine are relatively short compared with the other agents.[30] Conversely, fluoxetine has a very long half-life (ie, 4–6 days) with chronic dosing, and its active metabolite (norfluoxetine) has an even longer half-life.[18,30] Because of this, a 5-week washout of fluoxetine is required before starting an MAOI, whereas a 2-week washout is generally considered sufficient for other serotonergic agents.[18] Several antidepressants have active metabolites including amitriptyline (nortriptyline), imipramine (desipramine), and venlafaxine (desvenlafaxine), which have all been approved separately for the treatment of depression.[18]

Drug Interactions

Antidepressant drug interactions can be pharmacokinetic or pharmacodynamic resulting in a variety of drug-related problems. The usual pharmacodynamic drug interactions involve receptors blocked by some antidepressants (eg, histamine 1 [H_1], muscarinic, α-1).[7] TCAs can cause significant additive effects with other drugs that cause sedation, hypotension, or anticholinergic effects.[7,18] Similarly, trazodone can interact with other drugs that cause hypotensive and sedative effects.[18] By far, the most concerning pharmacodynamic interactions are hypertensive crisis and serotonin syndrome, which are both life-threatening.

Table 39–6

Pharmacokinetic Parameters of Newer Antidepressants,[15,30]

Drug	Protein Binding (%)	Elimination Half-Life (hours)	Active Metabolite	Cytochrome P450

Hypertensive crisis is characterized by sharply elevated blood pressure, occipital headache, stiff or sore neck, nausea, vomiting, and sweating.[18] It may result during MAOI therapy if the patient takes a sympathomimetic drug, such as ephedrine, pseudoephedrine, phenylephrine, or stimulants such as amphetamines or methylphenidate or if the patient consumes foods rich in tyramine, such as tap beers, aged cheeses, fava beans, yeast extracts, liver, dry sausage, sauerkraut, or tofu.[18,32] There are lists of foods and drinks that are not permitted during therapy with MAOIs, and these should always be provided to patients.[32] Because many over-the-counter (OTC) products contain sympathomimetics, patients should always be told to consult with their healthcare provider before using OTC drugs with an MAOI.[18]

Serotonin syndrome is due to serotonin toxicity that may result from multiple serotonergic agents or overdose of a serotonergic agent(s). The Hunter Serotonin Toxicity criteria are described in Table 39–7.[33,34] Serotonin syndrome is complicated by (a) an unawareness by clinicians of the diagnosis and (b) the fact that many implicated drugs such as dextromethorphan, meperidine, tramadol, linezolid, and methylene blue are not primarily serotonergic in nature, and clinicians may not recognize their serotonergic properties.[35]

Many antidepressants inhibit cytochrome P450 isoenzymes, elevating plasma levels of substrates for those isoenzymes and potentially leading to adverse effects or toxicity (see Table 39–6).[30,36]

Table 39–7

Hunter Serotonin Toxicity Criteria[34]

History of serotonergic agent(s) and one of the following from 1-5 below

2. Inducible clonus with agitation or diaphoresis OR
3. Ocular clonus with agitation or diaphoresis OR
4. Tremor and hyperreflexia OR
5. Hypertonia, temperature >100.4°F (38°C), and ocular or inducible clonus

Dosing

Antidepressant dosing is summarized in Table 39–8.[18,30] The extended-release formulations of venlafaxine and bupropion allow for once-daily dosing.[23] There is a once-weekly formulation of fluoxetine that can be started 7 days after the last regular-release capsule or tablet.[30] Selegiline is available as a transdermal patch, and a dose of 6 mg/24 hours can be used without the dietary restrictions associated with MAOI use, although patients on the higher doses (9 and 12 mg/24 hours) should follow the usual MAOI dietary restrictions.[18] A number of antidepressants have liquid dosage forms and disintegrating tablets, which may be helpful for patients who have difficulty swallowing tablets or capsules. Esketamine is administered as a nasal spray by the patient in the presence of a clinician, and the patient must stay in the clinic to be monitored for 2 hours after the dose.[37] Blood pressure is monitored before and after the dose is given.[37] Brexanolone is given as an intravenous infusion over 60 hours, and a clinician must monitor the patient continuously for sedation and hypoxia.[38]

The starting dose is often a therapeutic dosage for most SSRIs, desvenlafaxine, duloxetine, and mirtazapine. Dose titration is necessary for venlafaxine, vilazodone, vortioxetine, bupropion, sertraline, levomilnacipran, nefazodone, and TCAs.[18] A common first step in the management of partial response to an antidepressant is to optimize the dose even if the initial starting dose is within the therapeutic range.[18] An advantage of TCAs is that

Table 39–8

Dosing of Antidepressants in Adults,[15,30]

Generic Name	Brand Name	Generic	Form	Initial Dose (mg/day)	Usual Dosing Range (mg/day)	Usual Dosage Schedule	Renal Dosing Adjustment	Hepatic Dosing Adjustment
MAOIs								
Phenelzine	Nardil	Yes	T	15	45–90	Three times daily	CI in severe renal disease	CI with history of liver disease
Selegiline	Emsam	No	TD	6	6–12	Once daily	No adjustment for mild or moderate symptoms renal impairment, not studied in ESRD	No adjustment for mild or moderate hepatic impairment; not studied in severe impairment
Tranylcypromine	Parnate	Yes	T	10	30–60	Twice daily	None	None
Isocarboxazid	Marplan	No	T	20	40–60	Twice daily	Avoid in severe renal impairment	Avoid with history of liver disease or abnormal LFTs
TCAs								
Amitriptyline	Elavil	Yes	T	25–50	100–300	Once or twice daily	None	Use with caution
Desipramine	Norpramin[a]	Yes	T	25–50	100–300	Once to four times daily	Use with caution	Use with caution
Doxepin	Sinequan[a]	Yes	C, Sol, T	25–50	100–300	Once to three times daily	Use with caution	Use a lower dose
Imipramine	Tofranil[a]	Yes	C, T	25–50	100–300	Once daily or divided doses	Use with caution	Use a lower dose
Nortriptyline	Pamelor	Yes	C, Sol	25	50–150	Once or twice daily	Use with caution	Use a lower dose
SSRIs								
Citalopram	Celexa	Yes	Sol, T	20	20–40[b]	Once daily	No adjustment for CrCl > 20 mL/min (0.33 mL/s); for CrCl < 20 mL/min (0.33 mL/s), use with caution	20 mg/day maximum
Escitalopram	Lexapro	Yes	Sol, T	10	10–20	Once daily	No adjustment for CrCl > 20 mL/min (0.33 mL/s); for CrCl < 20 mL/min (0.33 mL/s), use with caution	10 mg/day
Fluoxetine	Prozac	Yes	Sol, Syr, C, T	10–20	20–80	Once daily	None	Use lower or less frequent dosing
	Prozac weekly	Yes	C	20	80	Once weekly	None	Use lower or less frequent dosing
Fluvoxamine	Luvox[a]	Yes	T	50	50–300	Twice daily	None	Reduce dose
	Luvox CR	Yes	C	100	100–300	Once daily	None	Reduce dose
Paroxetine	Paxil	Yes	Sus, T	10–20	20–50	Once daily	In CrCl < 30 mL/min (0.5 mL/s), initial dose 10 mg/day; increase weekly to a dose of 40 mg/day or less	Severe impairment, initial dose 10 mg daily; increase weekly to dose of 40 mg/day
	Paxil CR	Yes	T	12.5–25	25–62.5	Once daily	In CrCl < 30 mL/min (0.5 mL/s), initial dose 12.5 mg daily; may increase weekly to a dose of 50 mg/day or less	Severe impairment, initial dose 12.5 mg daily, increase weekly to dose of 50 mg/day or less
Sertraline	Zoloft	Yes	Sol, T	25–50	50–200	Once daily	None	Use a lower dose

plasma levels may help guide dosing, especially with nortriptyline which has a well-defined therapeutic plasma level (50–150 mcg/mL [190–570 nmol/L]).[39]

Efficacy of Pharmacotherapy

KEY CONCEPT Each antidepressant has a response rate of approximately 50% to 75%, and no antidepressant medication or class has been reliably shown to be more efficacious than another.[18] There is some evidence that dual-action antidepressants, such as TCAs and SNRIs, may be more effective in patients with severe depression than the single action drugs such as the SSRIs, but the more general assertion that multiple mechanisms of action confer efficacy advantages is controversial.[18]

Selection of Medication

Figure 39–1 depicts an algorithm based on the APA Practice Guideline for the Treatment of Patients with Major Depressive Disorder and the Veterans Affairs/Department of Defense (VA/DoD) Clinical Practice Guideline for the Management of Major Depressive Disorder.[18,40] As depicted in the algorithm, the guidelines recommend the use of SSRI, SNRI, bupropion, or mirtazapine as a first-line treatment for patients with mild-to-severe depression.[18,40] Patients with mild depression may be managed with psychotherapy alone.[18,40]

Various factors must be taken into account when selecting antidepressant therapy for a particular patient. The most reliable predictor of response is the patient's history of response (eg, efficacy, side effects, and overall satisfaction) to antidepressants.[18] To a lesser extent, the history of a first-degree relative's response to antidepressants may be used to predict a patient's response.[18] Adverse effect profiles should be considered, because adherence is influenced by tolerability.[23] The patient is the best source of information regarding acceptability of adverse effects. Patients should be educated about how to manage side effects (eg, using sugarless chewing gum, hard candy, or ice chips for dry mouth). The clinician must anticipate and be vigilant for potential drug–drug and drug–disease interactions. For instance, a patient with a seizure disorder would be an inappropriate candidate for bupropion therapy. The presence of comorbid psychiatric conditions can suggest the best antidepressant to choose. For example, an SSRI can treat both MDD and panic disorder, obviating the need for two separate medications. Likewise, a patient with MDD and a chronic pain condition may be treated with an SNRI with efficacy for both conditions. The potential for accidental or intentional overdose must be considered. Patients with risk of accidental or intentional overdose should not be prescribed TCAs. Additionally, affordability of the medication influences drug selection.

Time Course of Response

Antidepressants do not produce an immediate clinical response. Improvement in physical symptoms, such as sleep, appetite, and energy, can occur within the first or second week of treatment. **KEY CONCEPT** Although a meta-analysis suggests earlier effects of antidepressant treatment, it is widely accepted that approximately 2 to 4 weeks of treatment is required before improvement

FIGURE 39–1. Algorithm based on the American Psychiatric Association Practice Guideline for the Treatment of Patients with Major Depressive Disorder and VA/DoD Clinical Practice Guideline for the Management of Major Depressive Disorder.[18,40] (AD, antidepressant; BUP, bupropion; ECT, electroconvulsive therapy; Li, lithium; MAOI, monoamine oxidase inhibitor; MDD, major depressive disorder; MDE, major depressive episode; MRT, mirtazapine; Rx, prescription; SGA, second-generation antipsychotic; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant).

is seen in emotional symptoms such as sadness and anhedonia. Six to eight weeks may be required to see full antidepressant effects.[18,41]

Managing Partial or No Response

Approximately one-third of patients with MDD do not respond satisfactorily to their first antidepressant medication.[42] In such cases, the clinician must evaluate the adequacy of antidepressant therapy, including dosage, duration, patient adherence, verification of the patient's diagnosis, and reconsideration of clinical factors that could be impeding successful therapy, such as concurrent medical conditions (eg, thyroid disorder), comorbid psychiatric conditions or substance use disorders (eg, alcohol abuse), and psychosocial issues (eg, marital stress).[18]

A series of reports from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial revealed that remission is associated with a better overall prognosis than symptom improvement alone.[3] STAR*D also established that in patients with a greater level of nonresponse to treatment, clinicians are less likely to push the patient to achieve remission, and those patients with the greatest levels of nonresponse had the highest rates of relapse.[3] STAR*D established that for patients experiencing a partial response, extending the medication trial and/or using higher doses within the recommended dosage range may be helpful.[3] Another option used in the STAR*D trials is augmentation therapy, that is adding a nonantidepressant such as lithium, buspirone, or triiodothyronine.[3]

Second-generation antipsychotics, aripiprazole, brexpiprazole, and the extended-release formulation of quetiapine are approved by the FDA for adjunctive treatment of MDD along with an antidepressant.[43,44] Efficacy has been suggested for dopaminergic drugs (eg, pramipexole), psychostimulants (eg, methylphenidate), anticonvulsants (eg, lamotrigine), and modafinil although the evidence is less for these agents.[18,43] A third option is combination therapy, whereby another antidepressant, typically from a different pharmacologic class, is added to the first antidepressant.[43] Examples include combining bupropion or mirtazapine with SSRIs or SNRIs.[7] Switching to a different

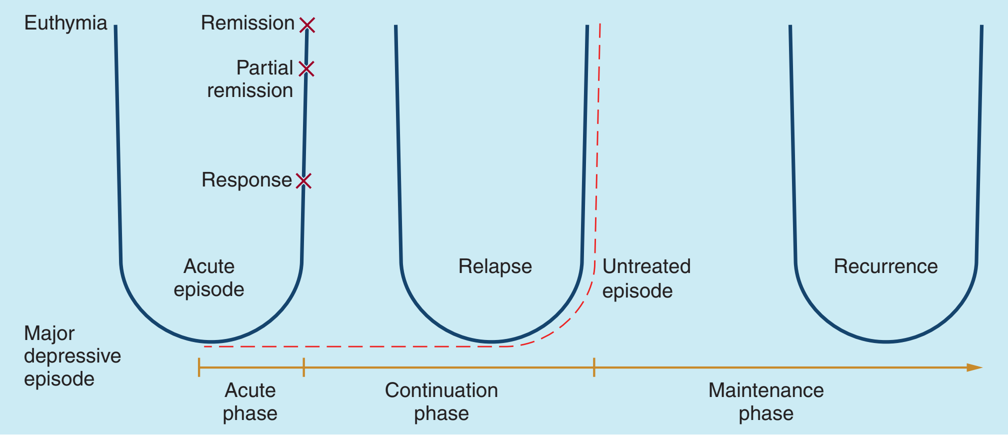

FIGURE 39–2. The course of depression and phases of treatment.[7,18]

antidepressant is a common strategy for patients who have had no response to initial antidepressant therapy, but also is acceptable in cases of partial response.[18] Relative to augmentation or combination therapy, advantages of switching include improved adherence, decreased costs, and less concern over drug–drug interactions. Disadvantages include loss of time, exacerbation of illness, and loss of any improvement seen with the initial drug. When switching from one antidepressant to another, clinicians may choose to stay within the same class (eg, sertraline to fluoxetine) or go outside of the class (eg, paroxetine to venlafaxine). The olanzapine-fluoxetine combination, Symbyax, and esketamine (Spravato) nasal spray, are approved for treatment-resistant depression.[37,43]

Nonpharmacologic interventions in cases of treatment nonresponse include adding or changing to psychotherapy or initiating ECT.[18,40]

Duration of Therapy

Treatment of MDD encompasses three phases: acute, continuation, and maintenance (Figure 39–2).[18] The acute phase of treatment typically lasts 6 to 12 weeks.[18] **KEY CONCEPT** Because the typical MDE lasts 6 months or longer, if antidepressant therapy is interrupted after the acute phase, the patient may relapse into a depressive episode.[16,18] When treating the first depressive episode, antidepressants must be given for an additional 4 to 9 months in the continuation phase to prevent relapse.[18]

Maintenance treatment takes place after the normal course of an MDE to prevent recurrence, which is the development of future episodes.[18] This phase can last for years, or for a lifetime.[18] Although patients who have an MDE should receive acute and continuation treatment, not all of them require maintenance treatment, because not all patients experience multiple MDEs.[18] In some patients with multiple episodes, many years may separate the episodes.[18] Therefore, the clinician must consider various factors in determining whether an individual requires maintenance treatment. A major factor is the number of prior episodes experienced by the patient. The more prior episodes experienced, the higher the risk for future episodes.[18] After three MDEs, maintenance treatment is recommended due to the risk of recurrence.[15,18] Other factors to consider are the severity of previous episodes, previous suicide attempts, presence of psychotic features, and patient preference.[18] The antidepressant dose required in the acute phase of treatment should be sustained during the continuation and maintenance phases.[18]

Discontinuing Therapy

When discontinuing therapy, it is best to gradually taper the antidepressant for two reasons. First, almost all antidepressants can produce withdrawal syndromes if discontinued abruptly or tapered too rapidly, especially antidepressants with shorter half-lives (eg, venlafaxine, paroxetine).[18,45] Antidepressant withdrawal can cause flu-like symptoms including nausea, headache, light-headedness, chills and body aches, and other symptoms such as insomnia and paresthesias.[18,45] In general, the antidepressant dose should be tapered by no more than 25% per week to minimize the risk of withdrawal symptoms. Tapering and discontinuation can be completed over weeks to months depending on the pharmacokinetics of the antidepressant.[45] Second, depression may return upon taper or discontinuation of the antidepressant.[45] So, if the medication is gradually tapered, then early signs of depression can be countered with a return to the original dosage.[45] Depending on the patient's illness and the clinical circumstances, tapering of the antidepressant can be extended for weeks or even months because of the concern over relapse or recurrence. Liquid formulations may be utilized to achieve small doses for individuals having difficulty with discontinuation.[45]

Special Considerations

▶ *Pregnant or Breast-feeding Patients*

Depression is common in pregnancy, especially for women with a history of depression.[18] Untreated depression carries risks for both the fetus and the mother. Likewise antidepressants have reported risks.[18] As such, both maternal and fetal well-being must be considered when weighing risks and benefits of antidepressant therapy during pregnancy.[18] Overall risk of teratogenicity with antidepressants after the first trimester appears to be low.[18] Paroxetine has been associated with an increased risk of cardiac malformations and should not be considered a first-line treatment in pregnancy.[18] Fluoxetine has a long half-life and is more likely to be present at high levels in newborns after in utero exposure.[18] Antidepressant use late in pregnancy has been reported to occasionally cause perinatal sequelae, such as poor neonatal adaptation, feeding problems, and jitteriness.[18] Use of a single medication over multiple medications is favored in managing depression during pregnancy.[18] ECT may also be considered as a treatment option for pregnant patients.[18] Brexanolone is an antidepressant marketed specifically for postpartum depression.[38] It is given to women who develop postpartum depression between the third trimester and up to 4 weeks after delivery.[38] Studies show an

Patient Encounter Part 3

On the basis of information presented, create a care plan. Your plan should include (a) a statement of the drug-related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

improvement in symptoms versus placebo for up to 4 weeks after a 60-hour infusion.[38]

There is some drug exposure to the infant from nursing mothers who are taking antidepressants.[18] Although there have been rare anecdotal reports of respiratory depression and seizure-like episodes in infants exposed to antidepressants through breast milk, it is generally accepted that the benefits of breastfeeding outweigh the risks.[18,46] However, the decision needs to be made on an individual basis. Esketamine should be avoided in breast-feeding due to possible neurotoxicity in infants.[37] One to two percent of brexanolone passes into breast milk.[38]

▶ *Geriatric Patients*

Depression in older adults is underrecognized and undertreated.[18,47,48] There is some evidence that depression in older adulthood presents with more somatic complaints (eg, pain and GI problems) possibly contributing to underdiagnosis.[48] Age-related pharmacokinetic and pharmacodynamic changes cause older patients to be more sensitive to antidepressant medications. Thus, lower starting doses of antidepressants and slow upward titrations as tolerated are generally recommended for geriatric patients. However, many older patients require the same dose as younger adult patients.[47] The SSRIs are chosen frequently for geriatric depression because of their overall favorable adverse effect profiles and low toxicity; however, the maximum dose of citalopram in patients over 60 years is 20 mg due to a risk of QT prolongation.[30,47] Most TCAs are avoided due to anticholinergic, cardiovascular, and sedative properties.[47] Desipramine and nortriptyline are more tolerable in terms of these adverse effects and may be used in geriatric depression.[18] Other antidepressants, such as SNRIs, bupropion, vortioxetine, and mirtazapine, are alternatives for the treatment of geriatric patients.[47] Esketamine has a favorable safety profile, but no studies have found efficacy of esketamine versus placebo in patients over 64 years.[37]

▶ *Pediatric Patients*

Antidepressants appear to be useful for children and adolescents with depression, particularly those who have severe or psychotic depression, fail psychotherapy, or experience chronic or recurrent depression.[49] Fluoxetine and escitalopram are the only antidepressants FDA approved for depression in children younger than 18 years.[30] The SSRIs generally are considered the initial antidepressants of choice, but comorbid conditions may favor alternative agents.[49] "Behavioral activation" can occur with SSRIs, including symptoms such as impulsivity, silliness, daring conduct, and agitation.[49] Esketamine and brexanolone have not been studied in pediatric patients.[37,38]

▶ *Suicidal Patients*

All antidepressants have a black box warning regarding an increase in suicidal thinking and behavior in children and young adults.[50] A large analysis of clinical trials showed the risk of such events was 4% for antidepressants versus 2% for placebo, although no completed suicides occurred in the trials.[50] Following the addition of the black box warning in 2003, prescriptions for antidepressants decreased among primary care providers by 58%.[51] The Centers for Disease Control and Prevention (CDC) estimated that suicide rates increased 8% in 2003 to 2004; however, a definite link between the black box warning and increased suicide rates has not been conclusively determined.[51] Because antidepressants carry a black box warning regarding suicide among children and young adults, medication guides must be distributed with each prescription or refill of antidepressants.[50] **KEY CONCEPT** Patients 24 years and younger should be observed closely for suicidality, worsened depression, agitation, irritability, and unusual changes in behavior, especially during the initial few months of therapy and at times of dosage changes. Furthermore, families and caregivers should be advised to monitor patients for such symptoms.[50] Whereas the TCAs and MAOIs have significant toxicity risk on overdose, most newer antidepressants are safer in overdose.[18]

Patient Counseling

Major counseling points are outlined in Table 39–9. **KEY CONCEPT** Lack of patient understanding concerning optimal antidepressant therapy frequently leads to partial or nonadherence with therapy; thus, the primary purpose of antidepressant counseling is to enhance adherence and improve outcomes.[52] Patients should be educated that while they may see some improvement in some symptoms like sleep and appetite as early as the first week, generally at least 4 to 8 weeks is required for optimal mood changes to occur. Patients should also recognize common side effects including how long those side effects might last, and if there are any simple remedies for treatment (eg, using ice chips or sugarless gum for dry mouth).

OUTCOME EVALUATION

Symptom Assessment

The patient interview should assess response of target symptoms. Rating scales are useful in this regard and may improve treatment outcomes. The Hamilton Depression Scale (HAM-D) and the Montgomery-Åsberg Depression Rating Scale (MADRS) are clinician-rated scales often used in depression research studies to assess treatment efficacy.[18] The Patient Health Questionnaire (PHQ-9) is a nine-item depression scale that is patient-rated (Table 39–10).[18,53] A score of four or less would be considered normal mood and greater than 20 as severe depression.[18,53]

Monitoring Adverse Effects

Adverse effects associated with the treatments for depression can often be predicted based on knowledge of pharmacologic profiles (Table 39–3) as well as familiarity with the most common adverse effects (Table 39–4). Evaluation for suicidal ideation should be a part of every patient visit. Patients can be taught to manage side effects such as sedation, constipation, and dry mouth. Potential side effects such as weight gain and sexual dysfunction should be discussed with the patient and monitored at each visit. SNRIs may increase blood pressure, and patients should have their blood pressure monitored regularly during treatment.[18] Patients with cardiovascular risk factors or over the age of 40 should have an electrocardiogram (ECG) completed prior to initiating a TCA.[18] Patients

Table 39–9

Patient Counseling[14, 18]

Counseling Point	Clinical Rationale
Mechanism of action—The medication works by affecting certain chemicals in the brain	Patient may feel that depression is a character weakness or personality flaw instead of a biological disorder
Lack of addiction potential—Although the medication affects certain chemicals in the brain, it is not addicting	Patient may worry that because the antidepressant is psychoactive, it must be addicting
Need for routine use—The medication will only work if it is taken as prescribed every day	Patient may try taking the medication on an as-needed basis
Delayed onset of action—It may take several weeks to see significant improvement in symptoms	Patient may prematurely discontinue therapy before the onset of beneficial effects
Prolonged duration of therapy—The medication should be taken for at least 6–12 months; do not discontinue it without consulting with the prescriber	Patient may prematurely discontinue therapy after symptoms have remitted, which could lead to relapse or recurrence
Adverse effects—Mention common and expected adverse effects as well as what to do if they occur	Patient may be more likely to discontinue therapy and distrust the prescriber if adverse effects occur without forewarning
Avoidance of alcohol and CNS depressants—Use of alcohol or other CNS depressants could cause worsened depression and additive adverse effects with the medicine	Patient may be unaware of the possible consequences of drinking alcohol or taking other drugs with antidepressants
Risk of suicidality—Be alert to symptoms of worsening depression and suicidality	Patient may become suicidal or have suicidal thinking while taking the antidepressant

CNS, central nervous system.

taking TCAs such as amitriptyline, imipramine, nortriptyline, or desipramine should have antidepressant serum levels checked if overdose, side effects, or nonadherence is an issue.[18] Patients should be monitored for serotonin syndrome if they are taking two or more serotonergic medications.[18,34]

Pharmacogenomic testing is currently available for evaluating enzymes that metabolize antidepressants, especially cytochrome P450 2D6 and 2C19. These pharmacogenomic tests can measure whether an individual is a fast or slow metabolizer. Patients might be more susceptible to decreased medication efficacy in the case of fast or rapid metabolizers, or they might experience more adverse effects in the case of slow or poor metabolizers. There is controversy in the medical community over the usefulness of pharmacogenomic testing. The Clinical Pharmacogenetics Implementation Consortium (CPIC) has evidence-based guidelines that can be used to help guide clinicians regarding medication adjustments.[54] At the current time, more research needs to be completed in order to determine the best use of pharmacogenomics monitoring for antidepressant use.[55]

Table 39–10

Patient Health Questionnaire-9[53]

Over the last 2 weeks, how often have you been bothered by any of the following problems?

	Not at All	Several Days	More Than Half the Days	Nearly Every Day
Little interest or pleasure in doing things	0	1	2	3
Feeling down, depressed, or hopeless	0	1	2	3
Trouble falling or staying asleep, or sleeping too much	0	1	2	3
Feeling tired or having little energy	0	1	2	3
Poor appetite or overeating	0	1	2	3
Feeling bad about yourself—or that you are a failure or have let yourself or your family down	0	1	2	3
Trouble concentrating on things, such as reading the newspaper or watching TV	0	1	2	3
Moving or speaking so slowly that other people could have noticed? Or the opposite—being so fidgety or restless that you have been moving around a lot more than usual	0	1	2	3
Thoughts that you would be better off dead or of hurting yourself in some way	0	1	2	3

Total Score = ________

Depression Severity, PHQ-9 Total Score: 1–4 minimal, 5–9 mild, 10–14 moderate, 15–19 moderately severe, 20–27 severe

If you checked any problems, how difficult have these problems made it for you to do your work, take care of things at home or get along with other people?

	Not Difficult at All	Somewhat Difficult	Very Difficult	Extremely Difficult

Patient Care Process

Collect Information:

- Perform a medication history for antidepressant and other psychotropic drug use as well as nonprescription medications and dietary supplements. Identify allergies to medications and other substances.
- Review the psychiatric history, medical history, physical assessment, laboratory findings, family history, and social history.
- Speak with the patient and review medical records to identify lifestyle habits, preferences, beliefs, health goals, and socioeconomic factors that may affect medication access and other aspects of care.

Assess the Information:

- Determine whether the patient is taking any substances that could induce or worsen the depressive episode.
- Based on the psychiatric and medical history, determine whether the patient has any factors that would suggest the selection of certain antidepressants or adjunctive agents.
- Identify comorbidities associated with MDD.
- Evaluate relevant laboratory tests (eg, complete blood count [CBC], thyroid-stimulating hormone [TSH], urine drug screen).
- Assess the efficacy, safety, and patient adherence with current pharmacotherapy.
- Identify any significant adverse drug effects or interactions.
- Determine whether the patient may benefit from nonpharmacologic therapy (ie, psychotherapy, lifestyle modifications).

Develop a Care Plan:

- Based on discussions with the patient, determine whether a change in antidepressant therapy is warranted or if the addition of another antidepressant or nonantidepressant adjunctive agent is more appropriate.
- Select lifestyle modifications nonpharmacologic and pharmacologic therapy that are likely to be effective and safe for the patient.
- Choose medications and doses that are optimal for the patient.

Implement the Care Plan:

- Educate the patient about changes in drug therapy, medication administration, potential new adverse effects, and how to manage and report any adverse effects that may occur.
- Review the patient's practices for self-monitoring symptoms of depression as well as his support system.
- Address any patient concerns about depression and its management.
- Discuss importance of medication adherence and lifestyle modifications to manage symptoms of depression.
- Determine whether recommended agents are included on the institution's formulary (for inpatient setting) and whether the patient has insurance coverage for the medication as an outpatient.

Follow-up: Monitor and Evaluate:

- Follow-up every 2 to 4 weeks after changes in pharmacotherapy until the patient reaches remission, then every 3 to 6 months.
- Review medication adherence as well as rating scale assessment of patient's symptoms of depression and adverse effects.

Abbreviations Introduced in This Chapter

5-HT	Serotonin
APA	American Psychiatric Association
BDNF	Brain-derived neurotrophic factor
CAM	Complementary and alternative medicines
CANMAT	Canadian Network for Mood and Anxiety Treatments
CBC	Complete blood count
CDC	Centers for Disease Control and Prevention
CNS	Central nervous system
CPIC	Clinical Pharmacogenetics Implementation Consortium
DA	Dopamine
DHA	Docosahexaenoic acid
DRI	Dopamine reuptake Inhibitor
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders*, 5th edition
EPA	Eicosapentaenoic acid
ECG	Electrocardiogram
ECT	Electroconvulsive therapy
FDA	Food and Drug Administration
GABA	γ-Aminobutyric acid
GI	Gastrointestinal
GRM3	Glutamate metabotropic receptor 3
HAM-D	Hamilton Depression Rating Scale
HPA	Hypothalamic pituitary axis
MADRS	Montgomery-Åsberg Depression Rating Scale
MAOI	Monoamine oxidase inhibitor
MAO-A	Monoamine oxidase A
MAO-B	Monoamine oxidase B
MDD	Major depressive disorder
MDE	Major depressive episode
NaSSA	Noradrenergic and specific serotonergic antidepressant
NDRI	Norepinephrine and dopamine reuptake inhibitor
NE	Norepinephrine
NMDA	*N*-methyl-D-aspartate
NRI	Norepinephrine reuptake inhibitor
NR3C1	Nuclear receptor subfamily 3 group C member 1
OTC	Over-the-counter
PHQ-9	Patient Health Questionnaire-9
REMS	Risk Evaluation and Mitigation Strategy
SAM-e	S-adenosyl methionine
SARI	Serotonin antagonist and reuptake inhibitor
SNRI	Serotonin and norepinephrine reuptake inhibitor
SRI	Serotonin reuptake inhibition
SSRI	Selective serotonin reuptake inhibitor
STAR*D	Sequenced Treatment Alternatives to Relieve Depression
TSH	Thyroid-stimulating hormone

TCA	Tricyclic antidepressant
VA/DoD	Veterans Administration Department of Defense
VNS	Vagus nerve stimulation
WHO	World Health Organization

Bipolar Disorder

Sarah E. Goldsborough, Opal M. Bacon, and Lydia E. Weisser

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying bipolar disorder.
2. Recognize the symptoms of a manic episode in patients with bipolar disorder.
3. Identify common psychiatric comorbidities of bipolar disorder.
4. Recognize the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), criteria for bipolar disorder as well as the subtypes of bipolar I disorder, bipolar II disorder, and cyclothymic disorder.
5. List the desired therapeutic outcomes for patients with bipolar disorder.
6. Identify the optimal use of medications as first-line therapy in bipolar disorder, including appropriate dosing.
7. Recommend drug therapy for acute treatment of mania and depressive episodes.
8. Recommend baseline and routine monitoring for assessment of adverse effects of medications used in the treatment of bipolar disorder.
9. Identify general treatment differences for agents used to treat bipolar disorder in the pediatric population.
10. Explain why medication education is important for patients with bipolar disorder.

INTRODUCTION

Bipolar disorder is characterized by one or more episodes of mania or hypomania, in addition to one or more major depressive episodes.[1] It is chronic, with recurrent episodes and remissions. Mood episodes can be manic, hypomanic, or depressed, and each separated by periods of long stability or cycle rapidly. They occur with or without psychosis. Disability and other consequences (eg, increased risk of suicide) can be devastating to patients and families. Correct and early diagnosis and treatment are essential to prevent complications and maximize response to treatment.

EPIDEMIOLOGY

The lifetime prevalence of bipolar I disorder and bipolar II disorder in the United States is estimated at approximately 1% and 1.1%, respectively. When including the entire spectrum of bipolar disorders, the prevalence is 2.4% worldwide.[2] Bipolar I disorder affects men and women equally. Bipolar II, rapid cycling, and mixed mood features are more common in women.

The mean age of onset is 20 years, although onset may occur in early childhood to the mid-40s.[1] If onset occurs after age 60, medical causes, such as thyroid dysfunction, electrolyte imbalances, or dementia should be ruled out as they can cause symptoms that mimic mania, hypomania, or depression. An early onset of bipolar disorder is associated with greater comorbidities, more mood episodes, a greater proportion of days depressed, and greater lifetime risk of suicide attempts compared with later onset. Substance use and anxiety disorders are more common in patients with early onset. Patients with bipolar disorder have higher rates of suicidal thoughts, attempts, and completed suicides than the general population.

ETIOLOGY

The precise etiology is unknown. Results of family studies suggest a genetic basis. Heritability of bipolar disorder is estimated to be between 5% and 10% with first-degree relatives and up to 70% in monozygotic twin studies. A variety of factors may enhance gene expression such as trauma, environmental factors, anatomical abnormalities, and exposure to chemicals or drugs.[3,4]

PATHOPHYSIOLOGY

Neurochemical

The pathophysiology of bipolar disorder remains incompletely understood. Imaging techniques such as positron emission tomography (PET) scans and functional magnetic resonance imaging (fMRI) are used to elucidate the cause. Historically, research focused on neurotransmitters such as norepinephrine (NE), dopamine (DA), and serotonin. One hypothesis is that bipolar disorder is caused by an imbalance of cholinergic and catecholaminergic activity. Serotonin is suggested to modulate catecholamines. Dysregulation of this relationship could cause mood disturbance. A variety of neurotransmitters are involved that interact with multiple neurochemical and neuroanatomic pathways.[3] The pathophysiology is also hypothesized based on the mechanisms of lithium and other drugs. Lithium, a gold standard medication in the treatment of bipolar disorder, has effect on neuronal growth that is reversible by inositol, supporting a hypothesis that bipolar disorder may be related to inositol

Patient Encounter Part 1

Chief Complaint: "I was arrested for disorderly conduct and public indecency. The judge recommended to my family that I get psychiatric help."

History of Present Illness: Patient is a 23-year-old graduate student accompanied by her parents following an incident at a football tailgating party. Per her parents, the patient attended a pre-football game tailgating party where large quantities of alcohol were consumed, and the patient apparently began to disrobe while dancing. The patient refused to put her clothes back on and became belligerent and aggressive toward police officers. She was subsequently arrested and jailed briefly overnight. The patient has had no prior medical or psychiatric history.

Labs and Diagnostics: Comprehensive metabolic profile, complete blood count, thyroid function, B_{12} and folate, electrocardiogram, and chest X-ray were unremarkable.

Mental Status Examination: Well-nourished, well-developed, Caucasian female appearing her stated age. She is attired in a revealing halter top and cut-off shorts with stiletto heels. She is wearing heavy makeup to include blue lipstick and nail polish as well as silver glitter eye shadow. She has difficulty maintaining appropriate social distance during the interview and is flirtatious and seductive at times. Speech is loud, pressured, and difficult to interrupt. She is distractible, looking around the room, and frequently changing topics in midsentence. Patient's mood is expansive and described as "fabulous."

Patient states she has lost 10 lb (4.5 kg) recently. She also admits to partying more than usual with friends, and her grades have been slipping. She expresses plans to go to Los Angeles and become a famous actress. Patient's parents report that recently she has been calling and asking them for money when her bank notified her of insufficient funds, and her credit cards were cancelled. The patient stated she needed an expensive new wardrobe to impress the directors and producers in Los Angeles.

What diagnoses are suggested by this patient's presentation?

What additional information is needed to clarify the diagnosis?

disturbance.[5] Brain-derived neurotrophic factor (BDNF) may play a role in bipolar disorder. Serum BDNF is low in mania and improves with treatment.[6]

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis of Bipolar Disorder

KEY CONCEPT Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder. According to the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), the diagnostic manual for psychiatric disorders, bipolar disorder is a mood disorder defined by distinct episodes of mania and/or hypomania in addition to major depressive episodes that are not caused by a medical condition, substance use, or other psychiatric disorder. Bipolar disorders are categorized into five subtypes: bipolar I disorder, bipolar II disorder, and other specified and unspecified bipolar and related disorders (ie, cyclothymic disorder). Bipolar I disorder is characterized by one or more manic episodes, whereas bipolar II disorder is characterized by at least one hypomanic episode. Both disorders also include alternating periods of euthymia and/or major depressive episodes. [1]

Initial episodes of bipolar disorder are mostly depressive with studies showing patients with bipolar I spend about 32% of weeks with depressive symptoms compared with 9% of weeks with manic or hypomanic symptoms.[7,8] Patients with bipolar II disorder spend 50% of weeks symptomatic for depression and only 1% with hypomania.[9] Bipolar disorder is often misdiagnosed as major depressive disorder (MDD) or underdiagnosed. It is helpful to use a screening tool such as the Mood Disorder Questionnaire.[10] *DSM-5* criteria for the diagnosis of major depressive, manic, and hypomanic episodes are summarized in Table 40–1.

▶ *Bipolar I Disorder*

The diagnosis of bipolar I disorder requires at least one episode of mania lasting for at least 1 week (or any duration if hospitalization due to symptoms is required). Mania is characterized by a persistently elevated, expansive, or irritable mood with related symptoms of increased goal-directed activity or energy including grandiosity, decreased need for sleep, excessive talkativeness, racing thoughts, flight of ideas (FOI), distractibility, and a propensity to be involved in high-risk activities.[1] It is essential to rule out past episodes of hypomania or mania to avoid misdiagnosing bipolar disorder as MDD. If bipolar depression is mistaken for MDD and the patient is treated with antidepressants, it can precipitate a manic episode or induce rapid cycling.

▶ *Bipolar II Disorder*

The distinguishing feature of bipolar II disorder is a current or past hypomanic episode and a current or past major depressive episode. Hypomanic symptoms last for at least 4 days, but fewer than 7 and include the same symptoms as mania without causing severe impairment or requiring hospitalization. Psychotic features are not present,[1] while irritability and anger are common. There cannot have been a prior full-manic episode.[1]

▶ *Cyclothymic Disorder*

Cyclothymic disorder is a chronic mood disturbance lasting at least 2 years (1 year in children and adolescents) and is characterized by mood swings that include periods of hypomanic symptoms that do not meet the criteria for a hypomanic episode and depressive symptoms that do not meet the criteria for a major depressive episode.

Suicide

Patients with bipolar disorder have high risk of suicide. Factors that increase risk are early age at onset, high number and severity of depressive episodes, comorbid alcohol use disorder, comorbid personality disorder, history of antidepressant-induced mania, history of previous suicide attempt, and family history of suicidal behavior. About one-third of individuals with bipolar disorder report a previous suicide attempt.[11] The risk of suicide in people with bipolar disorder is at least 15 times higher than the general population.[1] Patients should be assessed for potential for violence and harm to themselves or others. Friends or family can be asked to remove from the home guns, caustic chemicals, medications, and objects that patients might use to harm themselves or others.

Table 40–1

Evaluation and Diagnosis of Mood Episodes

Diagnosis Episode	Impairment of Functioning or Need for Hospitalization[a]	*DSM-5* Criteria[b]
Major depressive	Yes	At least 2-week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms: • Depressed, sad mood (adults); can be irritable mood in children • Decreased interest and pleasure in normal activities • Decreased or increased appetite, weight loss or weight gain • Insomnia or hypersomnia • Psychomotor retardation or agitation • Decreased energy or fatigue • Feelings of excessive guilt or worthlessness • Impaired concentration or indecisiveness • Recurrent thoughts of death, suicidal thoughts or attempts
Manic	Yes	At least 1-week period of abnormally and persistently elevated mood (expansive or irritable) and energy, associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractibility (poor attention) • Increased goal-directed activity (socially, at work, or sexually) or psychomotor agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)
Hypomanic	No	At least 4 days of abnormally and persistently elevated mood (expansive or irritable) and energy, associated with at least three of the following symptoms (four if the mood is only irritable): • Inflated self-esteem (grandiosity) • Decreased need for sleep • Increased talking (pressure of speech) • Racing thoughts (flight of ideas) • Distractibility (poor attention) • Increased goal-directed activity (socially, at work, or sexually) or psychomotor agitation • Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)

[a] Impairment in social or occupational functioning; may include need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.

[b] The disorder is not caused by a medical condition (eg, hypothyroidism) or substance-induced disorder (eg, antidepressant treatment, medications, drugs of abuse). Numerous specifiers are available to further characterize episodes (eg, with mixed features, with anxious distress, with rapid cycling, with melancholic features).

DSM, Diagnostic and Statistical Manual of Mental Disorders.

Reproduced, with permission, from Drayton SJ, Fields CS. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 10th ed. New York, NY: McGraw-Hill; 2017:1063–1078.

Differential Diagnosis

Schizophrenia, schizoaffective disorder, and bipolar disorder can share certain symptoms, including psychosis.[1] A thorough history with collateral from friends and family, if possible, needs to be obtained to differentiate between the illnesses. Personality disorders and bipolar disorder may be comorbid, and patients with personality disorders may have mood symptoms. The two diagnoses are distinguished by the episodic course of bipolar disorder in contrast to the stability and persistence of the behavioral patterns of personality disorders.

Comorbid Psychiatric and Medical Conditions

Lifetime prevalence rates of psychiatric comorbidity with bipolar disorder are as high as 75%.[2] Comorbidities place the patient at risk for a poorer outcome, higher rates of suicidality, increased episodes of depression, and higher costs of treatment. Common psychiatric comorbidities include personality disorders, alcohol and substance use disorders, anxiety disorders, obsessive-compulsive disorder, eating disorders, and attention-deficit/hyperactivity disorder. Medical comorbidities include migraine, multiple sclerosis, type 2 diabetes mellitus, and obesity.

TREATMENT

Desired Outcomes

KEY CONCEPT Goals of treatment are to reduce symptoms, induce remission, prevent relapse, improve patient functioning, and minimize adverse effects of drug therapy.

General Approach to Treatment

Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders (ISBD) treatment guidelines are commonly used for treating bipolar

Patient Encounter Part 2: Medical History, Physical Examination, and Laboratory Examination

Past Medical History: No known medical problems, however, patient admits to being treated for chlamydia and gonorrhea several months ago.

Past Psychiatric History: Noncontributory.

Family History:

Parents: Alive and well with no known medical or psychiatric illnesses.

Paternal aunt: Depression.

Grandfather: Completed suicide in his 40s.

Brother: Anxiety.

Patient denies prior suicide attempts or psychiatric hospitalizations.

Social History: Single, never married, has no children, and denies prior pregnancies. She admits to multiple sexual partners beginning during her senior year in high school and during college. She has had several brief relationships while in college, none lasting more than a few weeks.

Substance Use History: The patient denies use of hallucinogens, opioids, amphetamines, benzodiazepines, or intravenous drugs. She admits to smoking two to three joints of marijuana several times per week. She drinks alcohol occasionally, consuming four to five mixed drinks with either gin or vodka. She does not drink coffee but consumes three to four energy drinks such as Red Bull each day. She denies use of vitamins, herbal supplements, or nicotine products.

Medications: Oral contraceptives.

Review of Systems: Decreased need for sleep over the past week, obtaining 2 to 3 hours per night. Decreased appetite with recent 10-lb (4.5-kg) weight loss. Increased energy, pressured speech, distractibility with difficulty concentrating on schoolwork, hypersexuality, and grandiosity. Last menstrual period 3 weeks ago.

Physical Examination:

Vital Signs: BP 140/94 mm Hg, P 100 beats/min, RR 20 breaths/min, T 98.5°F (36.7°C).

HEENT: Everything within normal limits.

CV: Heart with increased rate and regular rhythm; no murmurs, gallops, or rubs.

Abdomen: Soft, nontender, no organomegaly or masses. Positive bowel sound in all four quadrants.

Extremities: Without clubbing, cyanosis or edema. Peripheral pulses full and equal bilaterally.

CN: Cranial nerves II to XII intact.

Labs: Urine drug screen positive for tetrahydrocannabinol (THC). HIV negative. Basic metabolic profile reveals Na$^+$ 138 mEq/L (mmol/L); K$^+$ 3.8 mEq/L (mmol/L); Cl$^-$ 100 mEq/L (mmol/L); CO$_2$ 25 mEq/L (mmol/L); BUN 20 mg/dL (7.1 mmol/L); creatinine 1.3 mg/dL (115 μmol/L); glucose 80 mg/dL (4.4 mmol/L). Urinalysis clear, dark yellow, negative for glucose, ketones, or protein.

The team decides to start lithium for this patient. What additional laboratory values would you recommend prior to starting pharmacotherapy with lithium?

disorder. A general treatment algorithm for manic and depressive episodes of bipolar disorder, including evidence provided from the CANMAT, ISBD guidelines as well as clinical research, can be found in Table 40–2.

The mainstay of drug therapy has been mood-stabilizing drugs, but research indicates antipsychotic drugs, both first-generation (FGAs) and second-generation (SGAs), may be more effective for acute mania.[12] Antipsychotic drugs may be used as monotherapy or adjunctively with mood-stabilizing drugs. A person receiving treatment for a first mood episode in bipolar disorder must have a complete assessment and careful diagnosis to rule out nonpsychiatric causes. A variety of conditions can cause similar symptoms (Table 40–3). Because early and accurate diagnosis is essential to maximizing response to treatment, pharmacologic and nonpharmacologic therapy should begin as soon as possible. Although it is a goal of treatment, not all patients achieve remission, and treatment is often lifelong. Comorbid conditions should also be addressed.

Patient Encounter Part 3: Creating a Care Plan

Based on all information presented, create a care plan for this patient's bipolar disorder. Your plan should include (a) a statement of the drug-related needs or problems, (b) the goals of therapy, (c) a patient-specific therapeutic plan, and (d) a plan for follow-up to assess therapeutic response and adverse effects.

Nonpharmacologic Therapy

KEY CONCEPT Interpersonal, family, or group psychotherapy with a qualified therapist or clinician adjunctive to medication assists individuals with bipolar disorder to improve functional outcomes. They may also help treat or prevent mood episodes, establish a daily routine and sleep schedule, and improve interpersonal relationships.[13]

Cognitive-behavioral therapy (CBT) is a type of psychotherapy that stresses the importance of recognizing patterns of cognition and how thoughts influence subsequent feelings and behaviors. Other people, situations, and events external to the individual are not seen as the sources of thoughts and behaviors. With CBT, patients are taught self-management skills to change negative thoughts even if external circumstances do not change.

Electroconvulsive therapy (ECT) is the application of electrical impulses to the brain for the treatment of severe or treatment refractory depression, psychotic depression, and treatment refractory mania. It also may be used in pregnant women who cannot take carbamazepine, lithium, or divalproex.

Education for patients, families, and groups about chronicity of bipolar disorder and self-management through sleep hygiene, nutrition, exercise, stress reduction, and abstinence from alcohol or drugs is critical to success. The development of a crisis intervention plan is essential.

Pharmacologic Therapy

KEY CONCEPT The primary treatment modality for manic episodes is mood-stabilizing agents or antipsychotic drugs, often in combination with each other.[14,12]

Table 40–2

Guidelines for the Acute Treatment of Mood Episodes in Patients With Bipolar I Disorder

Acute Manic or Mixed Episode	Acute Depressive Episode
General Guidelines	**General Guidelines**
Assess for secondary causes of mania or mixed states (eg. alcohol or drug use) Discontinue antidepressants Taper off stimulants and caffeine if possible Treat substance abuse Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy	Assess for secondary causes of depression (eg. alcohol or drug use) Taper off antipsychotics, benzodiazepines, or sedative-hypnotic agents if possible Treat substance abuse Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy

Hypomania	Mania	Mild-to-Moderate Depressive Episode	Severe Depressive Episode
First, optimize current mood stabilizer if noncompliance is suspected OR initiate mood-stabilizing medication: lithium[a], valproate[a], carbamazepine[a], or SGAs Consider adding a benzodiazepine (lorazepam or clonazepem) for short-term adjunctive treatment of agitation or insomnia if needed Alternative medication treatment options: oxcarbazepine **Second**, if response is inadequate, consider a two-drug combination: Lithium[a] **plus** an anticonvulsant or an SGA Aanticonvulsant **plus** an anticonvulsant or SGA	**First**, optimize previously prescribed mood stabilizer or medication regimen if noncompliance suspected OR initiate new mood-stabilizing two- or three-drug combinations (lithium[a], valproate[a], or SGA) **plus** a benzodiazepine (lorazepam or clonazepam) and/or antipsychotic for short-term adjunctive treatment of agitation or insomnia; lorazepam is recommended for catatonia Do not combine antipsychotics Alternative medication treatment options: carbamazepine[a]; if patient does not respond or tolerate, consider oxcarbazepine **Second**, if response is inadequate, consider a three-drug combination: Lithium[a] **plus** an anticonvulsant **plus** an antipsychotic Aanticonvulsant **plus** an anticonvulsant **plus** an antipsychotic **Third**, if response is inadequate, consider ECT for mania with psychosis or catatonia,[b] or add clozapine for treatment-refractory illness	**First**, initiate and/or optimize mood-stabilizing medication: lithium[a], quetiapine, lurasidone Alternative anticonvulsants: lamotrigine[c], valproate[a]; antipsychotics: fluoxetine/olanzapine combination	**First**, optimize current mood stabilizer if noncompliance is suspected OR initiate a new mood-stabilizing medication: lithium[a] or quetiapine or lurasidone Alternative fluoxetine/olanzapine combination If psychosis is present, initiate an antipsychotic in combination with above Do not combine antipsychotics Alternative anticonvulsants: lamotrigine[c], valproate[a] **Second**, if response is inadequate, consider carbamazepine[a] or antidepressant[d] **Third**, if response is inadequate, consider a three-drug combination: Lithium **plus** lamotrigine[c] **plus** an antidepressant[d] Lithium **plus** quetiapine **plus** antidepressant[d] **Fourth**, if response is inadequate, consider ECT for treatment-refractory illness and depression with psychosis or catatonia[b]

[a] Use standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

[b] ECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, and benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

[c] Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated up to decrease adverse effects if used for maintenance therapy of bipolar I disorder. Lamotrigine may be initiated during acute treatment with plans to transition to this medication for long-term maintenance. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (ie, lamotrigine doses must be halved from standard dosing titration).

[d] Controversy exists concerning the use of antidepressants, and they are often considered third line in treating acute bipolar depression, except in patients with no recent history of severe acute mania or potentially in bipolar II patients.

ECT, electroconvulsive therapy; SGA, second-generation antipsychotic.

Reproduced with permission from DiPiro JT, Yee GC, Posey LM, et al. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill:2020: 1149–1164.

Mood-stabilizing drugs like lithium and divalproex are generally first-line treatments for acute mania. Many of the SGAs also have approvals for acute mania and are often used in combination with mood stabilizers especially if psychosis is present or faster response is needed. Carbamazepine can be considered as second-line therapy. Oxcarbazepine can be considered as third-line treatment in combination with divalproex or lithium. Benzodiazepines are used adjunctively for agitation and insomnia in acute manic episodes. Often the medications used for acute episodes are continued for maintenance therapy.

KEY CONCEPT The primary treatment for depressive episodes in bipolar disorder is mood-stabilizing agents or certain antipsychotics.

For treatment of bipolar depressive episodes, quetiapine, lithium, lamotrigine, or lurasidone monotherapy are recommended as first-line treatment options. Combinations of two mood-stabilizing drugs or a mood-stabilizing drug and either an

Table 40–3

Secondary Causes of Mania

Medical conditions that induce mania

- CNS disorders (brain tumors, strokes, head injuries, subdural hematoma, multiple sclerosis, systemic lupus erythematosus, temporal lobe seizures, Huntington's disease)
- Infections (encephalitis, neurosyphilis, sepsis, human immunodeficiency virus)
- Electrolyte or metabolic abnormalities (calcium or sodium fluctuations, hyperglycemia or hypoglycemia)
- Endocrine or hormonal dysregulation (Addison's disease, Cushing disease, hyperthyroidism or hypothyroidism, menstruation-related or pregnancy-related or perimenopausal mood disorders)

Medications or drugs that induce mania

- Alcohol intoxication
- Drug withdrawl states (alcohol, α_2-adrenergic agonists, antidepressants, barbiturates, benzodiazepines, opiates)
- Antidepressants (MAOIs, TCAs, 5-HT and/or NE and/or DA reuptake inhibitors, 5-HT antagonists)
- DA-augmenting agents (CNS stimulants: amphetamines, cocaine, sympathomimetics; DA agonists, releasers, and reuptake inhibitors)
- Hallucinogens (LSD, PCP)
- Marijuana intoxication precipitates psychosis, paranoid thoughts, anxiety, and restlessness
- NE-augmenting agents (α_2-adrenergic antagonists, β-agonists, NE reuptake inhibitors)
- Steroids (anabolic, adrenocorticotropic hormone, corticosteroids)
- Thyroid preparations
- Xanthines (caffeine, theophylline)
- Nonprescription weight loss agents and decongestants (ephedra, pseudoephedrine)
- Herbal products St. John's wort

Somatic therapies that induce mania

- Bright light therapy
- Deep brain stimulation
- Sleep deprivation

CNS, central nervous system; DA, dopamine; 5-HT, serotonin; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; PCP, phencyclidine; TCA, tricyclic antidepressant.

Reproduced with permission from DiPiro JT, Yee GC, Posey LM, et al. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill:2020: 1149–1164.

antipsychotic or antidepressant drug are common, especially in acute mood episodes. Antidepressants may be used but along with a mood stabilizer to reduce risk of a mood switch to mania and after the patient has failed to respond adequately to mood-stabilizing therapy. Evidence of efficacy of antidepressant drugs in bipolar depression is considered controversial.[14,15] Among antidepressants, serotonin-norepinephrine reuptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs), and tricyclic antidepressants (TCAs) are more likely than other antidepressants to cause a pharmacologic mood switch to mania or a mood episode with mixed mood features and are not recommended by current guidelines.[14]

KEY CONCEPT The primary treatment for relapse prevention is mood-stabilizing agents, often combined with antipsychotic drugs.

Lamotrigine, lithium, aripiprazole (oral and long-acting injectable [LAI] formulations), risperidone LAI, and quetiapine are approved for maintenance therapy. Table 40–4 includes a summary of current drug therapy for bipolar disorder. An algorithm for treatment of bipolar mania is shown in Table 40–2.

▶ *Mood-Stabilizing Drugs*

The optimal mood-stabilizing drug is effective in treatment of acute mania, hypomania, acute bipolar depression, and in prevention of mania relapse and bipolar depression relapse. All currently approved mood-stabilizing drugs have demonstrated efficacy over placebo for one or more of these types of episodes, but there are differences among them especially for specific patient populations. The choice of treatment is dictated by patient characteristics, patient history, and side effect profile. Few studies systematically compare mood stabilizers with each other. Efficacy of individual agents in placebo-controlled trials is similar.

Lithium Lithium, the first approved mood-stabilizing drug, remains a first-line agent and sets the standard for efficacy against which other drugs are measured. It is antimanic, prevents relapse, and has modest efficacy for acute bipolar depression.[14] In most studies, the efficacy of lithium is equivalent to that of anticonvulsant mood stabilizers and SGAs. It is most effective for patients with few previous episodes, symptom-free interepisode remission, and a family history of bipolar disorder with good response to lithium.[14,16] However, patients with rapid cycling are less responsive to lithium than to other mood-stabilizing drugs such as divalproex.[14,17] It may also be less effective in mood episodes with mixed mood features (symptoms of mania and depression occurring simultaneously). Evidence shows lithium reduced the risk of suicide when compared to placebo.[18]

The mechanism of action of lithium is not well understood and is multimodal. Possibilities include altered ion transport, effects on neurotransmitter signaling, blocking adenyl cyclase, effects on inositol, neuroprotection or increased BDNF, and inhibition of second messenger systems.[19]

Lithium is usually initiated at a dosage of 600 to 900 mg/day. Although it is commonly given in a divided dosage, once-daily dosing is recommended, especially with sustained-release formulations. Once-daily dosing can improve adherence and reduce the risk of developing renal insufficiency. Lithium has a narrow therapeutic index, meaning the toxic dosage is not much greater than the therapeutic dosage. Lithium requires regular serum concentration monitoring as a guide to titration and to minimize adverse effects. At least weekly monitoring is recommended until the level is therapeutic; then the frequency can be decreased. Well-maintained patients who tolerate lithium without difficulty can be monitored by serum concentration as infrequently as twice yearly. The dosage is titrated to achieve a serum lithium concentration of 0.6 to 1.2 mEq/L (mmol/L). Higher serum concentrations are required to treat an acute episode than to prevent relapse. Serum lithium above 0.8 mEq/L (mmol/L) may be more effective at preventing relapse than lower serum concentrations. The suggested therapeutic serum concentration range is based on a 12-hour postdose sample collection at steady state. At least 2 weeks at a suggested therapeutic serum concentration is required for an adequate trial. If unable to achieve remission with lithium monotherapy, it is common to combine with other mood stabilizers or antipsychotics to achieve complete remission.

The most common adverse effects are gastrointestinal (GI) upset, tremor, and polyuria, which are dose-related.[20] Nausea, dyspepsia, and diarrhea are minimized by coadministration with food, use of the sustained-release formulation, and giving smaller doses more frequently to reduce the amount of drug in the GI tract. Fine hand tremor at therapeutic serum levels is common in patients. Low-dose β-blockers, such as propranolol 20 to 60 mg/day, may be used to reduce tremor.

Lithium impairs the kidney's ability to concentrate urine because of its inhibitory effect on vasopressin. This causes an increase in thirst, urine volume, and frequency of urination.

Table 40–4

Product Formulation, Dose, and Clinical Use of Agents Used in Treatment of Bipolar Disorder

Drug "Brand Name"	Initial Dosing	Usual Dosing; Special Population Dosing	Comments
Lithium salts			
Lithium carbonate "Eskalith[a,b]" "Eskalith CR" Lithium citrate "Cibalith-S[a,b]"	300 mg twice daily	900-2,400 mg/day in two to four divided doses, preferably with meals Renal impairment: lower doses required with frequent serum monitoring There is wide variation in the dosage needed to achieve therapeutic response and trough serum lithium concentration (ie, 0.6-1.2 mEq/L [mmol/L] for maintenance therapy and 0.8-1.2 mEq/L [mmol/L] for acute mood episodes taken 12 hours after the last dose)	Use alone or in combination with other medications (eg, valproate, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment
Anticonvulsants			
Divalproex sodium "Depakote[a]" "Depakote ER" Valporic acid[a] "Depakene" Valproate sodium "Depacon"	250-500 mg twice daily A loading dose of divalproex (20-30 mg/kg/day) can be given	750-3,000 mg/day (20-60 mg/kg/day) given once daily or in divided doses Titrate to clinical response Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment Use caution when combining with lamotrigine of potential drug interaction
Lamotrigine "Lamictal[b]"	25 mg daily	50-400 mg/day in divided doses. Dosage should be slowly increased (eg, 25 mg/day for 2 weeks, then 50 mg/day for weeks 3 and 4, and then 50-mg/day increments at weekly intervals up to 200 mg/day) Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, carbamazepine) for long-term maintenance treatment for bipolar I disorder
Carbamazepine "Equetro[a]" "Tegretol" "Epitol" "Tegretol-XR" "Carbatrol"	200 mg twice daily	200-1,800 mg/day in two to four divided doses Titrate to clinical response Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, valproate, antipsychotics) for the acute and long-term maintenance treatment of mania or mixed episodes for bipolar I disorder. APA guidelines recommend reserving it for patients unable to tolerate or who have inadequate response to lithium or valproate Extended-release tablets should be swallowed whole and not be broken or chewed "Carbatrol" capsules can be opened and contents sprinkled over food
Oxcarbazepine "Trileptal"	300 mg twice daily	300-1,200 mg/day in two divided doses Titrate based on clinical response Dose adjustment required with severe renal impairment	Use after patients have failed treatment with carbamazepine or have intolerable side effects May have fewer adverse effects and be better tolerated than carbamazepine
Atypical antipsychotics			
Aripiprazole "Abilify[a,b]" "Abilify Maintena[b]"	10-15 mg daily	10-30 mg/day once daily	
Asenapine "Saphris[a]"	5-10 mg twice daily sublingually	5-10 mg twice daily sublingually	
Cariprazine "Vraylar[a]"	1.5 mg daily	3-6 mg daily	
Lurasidone "Latuda[c]"	20 mg daily	20-120 mg daily with food	
Olanzapine "Zyprexa[a,b]" "Zyprexa Zydis"	2.5-5 mg twice daily	5-20 mg/day once daily or in divided doses	
Olanzapine and fluoxetine "Symbyax[c]"	6 mg olanzapine and 25 mg fluoxetine daily	6-12 mg olanzapine and 25-50 mg fluoxetine daily	
Quetiapine "Seroquel[a,b]"	50 mg twice daily	50-800 mg/day in divided doses or once daily when stabilized

Table 40–4

Product Formulation, Dose, and Clinical Use of Agents Used in Treatment of Bipolar Disorder (*Continued*)

Drug "Brand Name"	Initial Dosing	Usual Dosing; Special Population Dosing	Comments
Risperidone "Risperdal[a]" "Risperdal M-Tab" "Risperdal Consta[b]"	0.5-1 mg twice daily	0.5-6 mg/day once daily or in divided doses	
Ziprasidone "Geodon[a]"	40-60 mg twice daily	40-160 mg/day in divided doses	
Benzodiazepines			
Various	Dosage should be slowly adjusted up and down according to response and adverse effects	Use in combination with other medications (eg, antipsychotics, lithium, valproate) for the acute treatment of mania or mixed episodes Use as a short-term adjunctive sedative–hypnotic agent	

[a]FDA-approved for acute mania.

[b]FDA-approved for maintenance.

[c]FDA-approved for acute bipolar depression.

FDA-approved agents may be used as monotherapy in various phases of the illness as noted in table footnotes.[a,b,c]

Reproduced with permission from DiPiro JT, Yee GC, Posey LM, et al. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill:2020: 1149–1164.

Polyuria and polydipsia occur in up to 60% of patients.[19] A severe form of polyuria, when urine volume exceeds 3 L/day, is termed lithium-induced nephrogenic diabetes insipidus. It can be treated with hydrochlorothiazide or amiloride. If the former is used, the lithium dosage should be reduced to account for the drug–drug interaction that increases serum lithium and causes toxicity. Long-term lithium has been associated with structural kidney changes, such as glomerular sclerosis or tubular atrophy. Once-daily dosing of lithium is less likely to cause renal adverse effects than divided-daily dosing.[19]

Hypothyroidism can develop in up to 10% of patients taking lithium, and 23% have subclinical disease. Women are at greater risk of this adverse effect.[19] Lithium-induced hypothyroidism is not usually an indication to discontinue the drug. Patients can be supplemented with thyroid hormone replacement therapy.

Other common adverse effects include poor concentration, acneiform rash, alopecia, worsening of psoriasis, weight gain, metallic taste, impaired glucose regulation, and benign leukocytosis. Lithium causes a flattening of the T wave of the electrocardiogram (ECG), considered benign and not clinically significant. Less commonly, it can cause or worsen arrhythmias.[20]

Lithium and other mood-stabilizing drugs require baseline and routine laboratory monitoring to help determine medical appropriateness for initiation of therapy and monitoring of adverse effects. Guidelines for such monitoring are outlined in Table 40–5.

Acute lithium toxicity, which usually occurs at serum concentrations over 2 mEq/L (mmol/L), can be severe and life threatening, necessitating emergency treatment. Milder toxicity can occur at concentration between 1.5 and 2 mEq/L (mmol/L).[20] Symptoms of toxicity include vomiting and diarrhea; deterioration in motor coordination, including coarse tremor, ataxia, and dysarthria; and impaired cognition. In its most severe form, seizures, cardiac arrhythmias, coma, and kidney damage are reported. Treatment includes discontinuation of lithium, IV fluids to correct fluid and electrolyte imbalance, and osmotic diuresis or hemodialysis. In case of overdose, gastric lavage is indicated if the person presents within 1 hour of ingestion and is not somnolent. Clinical symptoms continue after the serum concentration is lowered because clearance from the central nervous system (CNS) is slower than from serum. Factors predisposing people to lithium toxicity include dehydration, acute illness, exercise (sweating), or drug interactions that increase serum lithium.[20]

Drug interactions involving lithium are common. Because lithium is not metabolized or protein bound, it is not associated with metabolic drug interactions that occur with other mood-stabilizing drugs. Common and significant drug interactions involve thiazide diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin receptor blockers (ARBs), and angiotensin-converting enzyme (ACE) inhibitor drugs. If a diuretic must be used with lithium, and a thiazide is not required, loop or potassium-sparing diuretics such as furosemide or spironolactone are less likely to increase lithium retention. ACE inhibitors and ARBs can abruptly increase serum lithium with the potential for acute toxicity, including fatal toxicity, even after months of no change in serum lithium. This combination is strongly discouraged.[20] Any drug or condition that can cause hyponatremia may increase lithium toxicity.

Divalproex Sodium and Valproic Acid Divalproex sodium is composed of sodium valproate and valproic acid. The delayed- and extended-release formulations are converted in the intestine into valproic acid (VPA), which is systemically absorbed. It is FDA approved for treatment of the manic phase of bipolar disorder. It is equal in efficacy to lithium and some antipsychotics for bipolar mania. It has utility in bipolar disorder with rapid cycling, mood episodes with mixed mood features, and substance use comorbidity. Although not FDA approved for relapse prevention, studies support its use, and it is widely prescribed for maintenance therapy. Divalproex can be used as monotherapy or in combination with lithium or an antipsychotic.[14]

Its mechanism for bipolar disorder is not well understood. It is known to affect ion transport and enhance activity of γ-aminobutyric acid (GABA).[19]

Divalproex is commonly initiated at 500 to 1000 mg/day, but studies indicate a therapeutic serum VPA concentration can be reached more quickly through a loading dose approach of 20 to 30 mg/kg/day. Using this approach, patients may respond with

Table 40–5

Guidelines for Baseline and Routine Laboratory Tests and Monitoring for Agents Used in the Treatment of Bipolar Disorder

	Baseline: Physical Examination and General Chemistry[a]	Hematologic Tests[b]		Metabolic Tests[c]		Liver Function Tests[d]		Renal Function Tests[e]		Thyroid Function Tests[f]		Serum Electrolytes[g]		Dermatologic[h]		Pharma-cogenomic Testing
	Baseline	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline
SGAs[i]	X			X	X											
Carbamazepine[j]	X	X	X			X	X	X				X	X	X	X	X
Lamotrigine[k]	X													X	X	
Lithium[l]	X	X	X	X	X			X	X	X	X	X	X	X	X	
Oxcarbazepine[m]	X											X	X			X
Valproate[n]	X	X	X	X	X	X	X							X	X	

[a] Screen for drug abuse and serum pregnancy.

[b] Complete blood cell count (CBC) with differential and platelets.

[c] Fasting glucose, serum lipids, and weight.

[d] Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, and alkaline phosphatase.

[e] Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, and specific gravity.

[f] Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.

[g] Serum sodium.

[h] Rashes, hair thinning, and alopecia.

[i] Second-generation antipsychotics: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.

[j] Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (eg, CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, and then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are$<100,000/\text{mm}^3$ (100×10^9/L), if white blood cell (WBC) count is$<3,000/\text{mm}^3$ (3×10^9/L), or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.

[k] Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2 to 8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dosage escalation, or using doses exceeding the recommended titration schedule.

[l] Lithium: Obtain baseline electrocardiogram for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2 to 3 months during the first 6 months, and then every 6 to 12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume >3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, and then every 6 to 12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1 to 2 months until thyroid function indices are within normal range, and then monitor every 3 to 6 months.

[m] Oxcarbazepine: Hyponatremia (serum sodium concentrations<125 mEq/L [mmol/L]) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (eg, diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (eg, confusion, headache, lethargy, malaise). Hypersensitivity reactions have occurred in approximately 25% to 30% of patients with a history of carbamazepine hypersensitivity and require immediate discontinuation.

[n] Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3 to 6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are$<100,000/\text{mm}^3$/L (100×10^9/L) or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.

SGAs, second-generation antipsychotics.

a significant reduction in symptoms of acute mania within the first few days of treatment but with increased risk of GI adverse effects. The dosage is titrated according to response, tolerability, and serum concentration. The most often referenced VPA serum concentration is 50 to 125 mcg/mL (mg/L; 347–866 μmol/L); however, this range was initially established for seizure control, and the correlation with these levels and response in the treatment of bipolar disorder is not well established. It is not unusual for patients to require higher concentrations in the therapeutic range for optimal efficacy. Some patients require high dosages in order to reach a desired serum concentration. The suggested serum concentration range is based on trough values at steady state. Serum concentration monitoring is recommended at least every 2 weeks until stabilized, then less frequently. The systemic bioavailability of extended-release divalproex is about 15% less than that of the delayed-release formulation. Patients who have difficulty swallowing large tablets can use the sprinkle formulation, which is delayed release. The immediate-release formulation, either capsules or syrup, is given three or four times per day.[21]

The most common adverse effects are GI-related (loss of appetite, nausea, dyspepsia, diarrhea), tremor, and drowsiness. GI distress can be reduced by coadministration with food, switching to the delayed- or extended-release formulations, or reducing the dose. As with lithium, a low-dose β-blocker may alleviate tremor.

Other adverse effects include alopecia or a change in hair color or texture. Hair loss can be minimized by supplementation with a vitamin containing selenium and zinc. Weight gain also commonly occurs. Polycystic ovarian syndrome associated with increased androgen production is reported. Thrombocytopenia is more common with high serum levels, and the platelet count should be monitored periodically. It is a dose-related, reversible adverse effect and usually asymptomatic, but the drug is usually stopped if the platelet count is less than $100 \times 10^3/\text{mm}^3$ ($100 \times 10^9/\text{L}$). Rarer are hepatic toxicity and pancreatitis, which are not always dose related. There is a black box warning for both as fatalities have occurred. Severe GI symptoms of hepatic or pancreatic toxicity include vomiting, abdominal pain, and loss of appetite. When these occur, the patient should be evaluated for possible hepatitis or pancreatitis. Hyperammonemia has been reported. If patients develop unexplained lethargy and vomiting or changes in mental status, an ammonia level should be measured. Divalproex has a wide therapeutic index. Acute toxicity for high dosages or over dosage is not life threatening.

Drug interactions involving divalproex are common. It is a weak inhibitor of some drug metabolizing liver enzymes and can affect metabolism of other drugs. The interaction between divalproex and lamotrigine is significant. The risk of Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN), a dangerous, life-threatening rash, increases with this combination due to divalproex inhibiting the metabolism of lamotrigine causing rapid increases in lamotrigine serum concentrations. Conversely, the metabolism of divalproex can be increased by enzyme-inducing drugs such as carbamazepine and phenytoin. Divalproex is highly protein bound and may displace other protein-bound medications (ie, phenytoin, warfarin, etc). Carbapenem antibiotics can significantly reduce serum valproic acid levels, requiring close therapeutic monitoring.[21]

Carbamazepine Although all formulations are used as a mood stabilizer, only the extended-release formulation is FDA approved for treatment of bipolar disorder. Carbamazepine has efficacy for mood stabilization; however, it is less desirable as a first-line agent because of adverse effects and drug interactions. Carbamazepine may be considered in patients who have a history of head trauma, comorbid anxiety, and substance use disorder. Carbamazepine can be used as monotherapy or in combination with lithium or divalproex.[14]

The mechanism of action of carbamazepine for bipolar disorder is not well understood. It blocks ion channels and inhibits sustained repetitive neuronal excitation, but whether this explains its efficacy as a mood stabilizer is not known.[22]

Carbamazepine is initiated at 400 to 600 mg/day. The immediate-release formulation can be given in two to four divided doses and the sustained-release formulation can be given in two divided doses. An additional extended-release formulation contains a matrix of 25% immediate-release, 40% extended-release, and 35% enteric-release beads.[22] The suggested therapeutic serum concentration is 4 to 12 mcg/mL (mg/L; 17–51 μmol/L); however, this range was initially established for seizure control, and the correlation with these levels and response in the treatment of bipolar disorder is not well established. The dosage can be increased by 200 to 400 mg/day as often as every 2 to 4 days. Serum concentration monitoring is suggested at least every 2 weeks until concentrations stabilize, due to autoinduction.[22]

The most common adverse effects are GI upset, drowsiness, dizziness, ataxia, lethargy, and confusion. At mildly toxic levels, it causes diplopia and dysarthria. These can be minimized through dosage adjustments, use of sustained-release formulations, and giving more of the drug late in the day. Carbamazepine has an antidiuretic effect similar to the syndrome of inappropriate antidiuretic hormone secretion and can cause hyponatremia. Mild elevations in liver enzymes can occur; hepatotoxicity is less common. Mild, dose-related leukopenia is not unusual and not an indication for discontinuation. Black box warnings exist for aplastic anemia and agranulocytosis, which are rare but life threatening.[22] Additionally, TEN and SJS have been reported. Higher risk of these serious dermatologic reactions is associated with the HLA-B*1502 allele found almost exclusively in Asian ancestry. Per the black box warning, patients with ancestry from the at-risk population should have genetic testing done prior to initiation of carbamazepine.[22,23] See Chapter 32 for a full discussion. Suggested baseline and routine laboratory monitoring are reviewed in Table 40–5.

Carbamazepine induces hepatic metabolism of many drugs, including other anticonvulsants, antipsychotics, some antidepressants, oral contraceptives, and antiretroviral agents. Carbamazepine is an autoinducer (ie, it induces its own metabolism). The dosage may require an increase up to a month after initiation because of this effect. Conversely, the metabolism of carbamazepine can be slowed by enzyme-inhibiting drugs such as some antidepressants; macrolide antibiotics, including erythromycin and clarithromycin; azole antifungal drugs, including ketoconazole and itraconazole; and grapefruit juice.

Lamotrigine Lamotrigine is effective for maintenance treatment of bipolar disorder. It is more effective for depression relapse prevention than for mania relapse prevention. Its primary limitation as an acute treatment is the time required for titration to an effective dosage. In addition to maintenance monotherapy, lamotrigine is sometimes used in combination with other mood stabilizers.[24]

The mechanism of action of lamotrigine appears to involve blockage of ion channels and effects on glutamate transmission, although the precise mechanism in bipolar disorder is not clear.[24]

Lamotrigine is initiated at 25 mg/day for 2 weeks, then increased in a dose-doubling manner every 2 weeks to a target of 200 to 400 mg/day if no drug interactions are present. However, differing dose titrations are required with certain other drugs like divalproex or phenytoin. For example, lamotrigine would be initiated at a 50% higher dose with phenytoin and the titration with divalproex would be slowed by 50% to 25 mg every other day for 2 weeks, then 25 mg daily. If lamotrigine therapy is interrupted for more than five half-lives, it should be restarted at the initial dosage and retitrated. Serum concentration monitoring is not recommended.[24]

The adverse effect of greatest significance is a maculopapular rash, occurring in up to 10% of patients.[24] Although usually benign and temporary, some rashes can progress to life-threatening SJS and TEN. The risk of rash is greater with a rapid dosage titration, when given concurrently with divalproex or other metabolic enzyme inhibitors, and in pediatric patients.[24] The risk is minimal in adults when the dosage titration schedule is completed according to the package insert. Other side effects include dizziness, drowsiness, headache, blurred vision, and nausea. In contrast to other mood-stabilizing drugs such as lithium and divalproex, lamotrigine does not significantly influence body weight.

The mechanisms of drug–drug interactions involving lamotrigine are unclear. The primary route of metabolism for lamotrigine is conjugative glucuronidation. It is not significantly metabolized by CYP P450 enzymes. It does not affect drug-metabolizing hepatic enzymes. When the combination of divalproex and lamotrigine is used, 50% dose decreases of lamotrigine are necessary due to the drug–drug interaction. Conversely, carbamazepine and estrogen-containing oral contraceptives increase the rate of lamotrigine metabolism. Upward adjustment in lamotrigine dosage is usually needed.[24]

Oxcarbazepine Oxcarbazepine is an analogue of carbamazepine, developed as an anticonvulsant. An advantage over carbamazepine is that routine monitoring of hematology profiles and serum concentrations is not indicated because it is less likely to cause hematologic abnormalities.[25] Additionally, drug interactions are less significant, although it is a mild inducer of certain metabolic pathways. Vigilance for drug interactions is needed, especially with oral contraceptives. Oxcarbazepine appears in the most recent treatment algorithms for bipolar disorder,[14] but clinical trial data are limited.[26]

Common adverse effects include drowsiness, dizziness, GI upset, and hyponatremia, the latter two of which may be more likely than with carbamazepine.[25]

Others Benzodiazepine agents such as clonazepam and lorazepam are used as adjunctive therapy, especially during acute mania, to reduce anxiety and improve sleep.[14,27] As complementary or alternative medicines gain wider usage, omega-3 fatty acids have been studied in mood disorders but are not recommended in treatment guidelines.

▶ *Antipsychotic Drugs*

Antipsychotics, such as aripiprazole, asenapine, cariprazine, haloperidol, olanzapine, quetiapine, risperidone, and ziprasidone, are effective and frequently used in the treatment of acute mania both as monotherapy and in combination with mood stabilizers. Studies demonstrate combination therapy with SGAs, and lithium or divalproex is more effective, with 20% more patients responding compared to monotherapy with lithium or divalproex. In addition, adjunctive therapy with antipsychotics is preferred if a rapid response is needed. Antipsychotics also play a role in the treatment of bipolar depression. Quetiapine, lurasidone, cariprazine, and the combination of olanzapine and fluoxetine are approved for treatment of acute bipolar depression.[14,28]

The mechanisms of action, usual dosages, pharmacokinetics, adverse effects, and drug interactions involving antipsychotic drugs are discussed in detail in Chapter 38. Dosages in bipolar disorder are similar to those used in schizophrenia; however, higher dosages are often required to treat an acute manic episode while lower doses are used in the treatment of bipolar depressive episodes. The recommended dosage of aripiprazole for bipolar disorder is 20 to 30 mg/day, somewhat higher than the average dosage used in schizophrenia.[29] The recommended dosage for quetiapine in treatment of acute bipolar depression is 300 mg/day, whereas 600 mg/day is recommended in acute mania.[30]

The SGAs are less likely than FGAs to cause movement abnormalities but are more likely to cause metabolic side effects, such as weight gain, glucose dysregulation, and dyslipidemia.[31] Among SGAs approved for treatment of bipolar disorder, olanzapine is most likely to cause metabolic side effects.

▶ *Antidepressants*

Treatment of depressive episodes in patients with bipolar disorder presents a challenge because of the risk of a drug-induced mood switch to mania. The FDA requires the product label of all antidepressants to contain language about the potential risk of inducing a mood switch to mania. Most research shows no advantage for adjunctive antidepressant use compared with mood-stabilizer therapy alone.[14,15] When usual treatment fails, antidepressants may be used.[14,15]

When antidepressants are used, they should be combined with a mood stabilizer to reduce risk of mood switch.[14] The MAOIs, TCAs, and SNRIs are thought to carry greater risks of causing a mood switch to mania. A comparison of venlafaxine, sertraline, and bupropion as adjunctive therapy to a mood stabilizer showed venlafaxine with highest risk of a mood switch to mania or hypomania and bupropion with the least.[32]

Special Populations

Assessment and management by appropriate psychiatric specialists are important for special populations, such as pediatric, geriatric, and pregnant patients.

▶ *Pediatrics*

Evidence regarding treatment of bipolar disorder in children and adolescents is more limited than in adults. Lithium is FDA approved for treatment of bipolar disorder in children and adolescents as young as age 12. Aripiprazole, olanzapine/fluoxetine combination, quetiapine, and risperidone are FDA approved in children and adolescents as young as age 10.[14,33]

Initial dosages in the pediatric population are lower than in adults. Metabolic elimination rates of many drugs are increased in children, so they may require higher dosages on a weight-adjusted basis. Dosages are titrated carefully according to response and tolerability.

Children and adolescents are especially likely to experience weight gain from SGAs.[34] Cognitive toxicity, manifested as confusion, memory or concentration impairment, or impaired learning, is difficult to detect and is a consideration in the pediatric population so that intellectual and educational development is not hindered.

For comorbid bipolar disorder and attention-deficit/hyperactivity disorder when stimulant therapy is indicated, treatment of mania is recommended before starting the stimulant to avoid exacerbation of mood symptoms.

▶ *Geriatrics*

Treatment of older adults with bipolar disorder requires care because of increased risks associated with medical conditions and drug–drug interactions.[35] General medical conditions, including endocrine, metabolic, or infectious diseases, can mimic mood disorders. Patients should be evaluated for such medical illnesses that cause or worsen mood symptoms. As physiologic systems change with aging, elimination of drugs is slowed. Examples are slowed renal elimination of lithium and slowed hepatic metabolism of VPA. Also, changes in membrane permeability increase risk of CNS side effects. As a result, older patients may respond at lower serum levels of drugs and may experience toxicity when serum levels are within the normal therapeutic range for younger adults. Increased frequency of patient monitoring is required, including serum drug concentration monitoring.

Vigilance for drug–drug interactions in the geriatric population is required because more medications tend to be prescribed to older adults. Pharmacokinetic interactions include metabolic enzyme induction or inhibition and protein binding displacement interactions (eg, divalproex and warfarin). Pharmacodynamic interactions include additive sedation and cognitive toxicity, which increase risk of falls and other impairments.

▶ *Pregnancy and Postpartum*

Treatment of bipolar disorder during pregnancy is complex, and the relative risk of teratogenicity of medications must be balanced with the risk of harm to patient and fetus from untreated bipolar disorder. Clinicians should discuss pregnancy planning with every patient with bipolar disorder who is of childbearing potential. A pregnancy test should be obtained before initiating therapy. For a patient with severe illness or a history of multiple mood episodes, rapid cycling, or suicide attempts, discontinuing treatment, even for a planned pregnancy, is unwise. For a patient with a remote history of a single mood episode with subsequent long-term stability and contemplating pregnancy, the answer is less clear. Patients should be provided clear and reliable information about risks versus benefits of stopping or continuing therapy so they can make an informed decision. Patients who decide to discontinue medication before pregnancy should taper medication slowly.[14,36]

Lithium administration during the first trimester is associated with **Ebstein anomaly**, a downward displacement of the tricuspid valve. Although cardiac defects are more likely to occur in children of patients who took lithium during pregnancy, the absolute risk appears to be small.[37] Lithium can also cause hypotonicity and cyanosis in the neonate, termed the "floppy baby" syndrome.[36]

Pharmacokinetic handling of lithium changes as pregnancy progresses. Renal lithium clearance increases, which requires a dosage increase to maintain a therapeutic serum concentration. It is advisable to decrease or discontinue lithium at term or onset of labor to avoid toxicity postpartum when there is a large reduction in fluid volume.[38]

Lithium is readily transferred via breast milk. Breastfeeding is not advised for patients taking lithium unless the benefits to the mother outweigh the risks to the infant.[20]

The risk of facial abnormalities is increased with VPA and carbamazepine. Neural tube defects such as spina bifida occur in up to 3.8% of infants exposed to VPA.[36]. The risk of neural tube defects is related to exposure during the third and fourth weeks of gestation. As such, women with unplanned pregnancies may not know they are pregnant until after the risk of exposure has occurred. Children born to mothers exposed to VPA during pregnancy have substantially lower IQ than children exposed to other antiseizure medications. Women of childbearing potential should not receive VPA therapy unless all other therapies have failed and utilize effective contraception.[38]

Carbamazepine can cause fetal vitamin K deficiency. Vitamin K is important for facial growth and for clotting factors, and neonatal bleeding is increased in infants of mothers who are treated with carbamazepine during pregnancy.[39,40]

Fewer data are available on other anticonvulsant mood-stabilizing drugs. Lamotrigine may be associated with an increased risk of oral clefts but, overall, is relatively safer in pregnancy than other anticonvulsants.[39,40]

The FGAs have been available for many years, and more data are available on their use in pregnancy compared with SGAs, but guidelines for bipolar disorder do not support FGAs as an initial choice.[14]

Use of antidepressant drugs during pregnancy is discussed in Chapter 39.

OUTCOME EVALUATION

Assessment of Therapeutic Effects

Effective interviewing skills and a therapeutic relationship with the patient are essential to assessing medication therapy. It is important to understand the patient's symptom profile and specific needs of individual patients. In addition, therapeutic level monitoring is indicated for optimal efficacy of some mood-stabilizing drugs. These are some of the primary therapeutic monitoring parameters. In addition to the clinical interview, some clinicians use symptom rating scales such as the Young Mania Rating Scale (YMRS) for mania and the Hamilton Depression Rating Scale (HAM-D) for depression (discussed in Chapter 39). The YMRS is composed of 11 items based on a patient's perception over the preceding 48 hours. Adjunctive information is obtained from clinical observations. The scale takes about 15 to 30 minutes to administer.[41] The frequency of follow-up visits depends on response, tolerability, and adherence.

Assessment of Adverse Effects

Adverse effects frequently contribute to medication nonadherence. Monitor patients regularly for adverse effects and health status, especially since mood stabilizers and antipsychotics commonly cause metabolic side effects such as weight gain. Periodically monitor laboratory tests for renal and thyroid function for patients taking lithium and hematology and liver function for patients taking

Patient Encounter Part 4: Outcome Evaluation

After an initial psychiatric assessment, including evaluation of potential suicidality, support systems, and need for inpatient versus outpatient treatment, the patient was hospitalized briefly and then referred for follow-up in the community. Patient's school performance and grades are improving, although she remains on academic probation. While hospitalized, she was stabilized on lithium carbonate 900 mg by mouth daily and quetiapine 400 mg by mouth every night. Recent lithium level was 1 mEq/L (mmol/L). She now returns to the clinic for routine follow-up. Patient initially reported a mild bilateral hand tremor secondary to lithium, but this has resolved with the addition of propranolol 20 mg by mouth daily. She denies other medication side effects but asks how long she must continue the medication since she is feeling "completely like my old self."

How would you assess therapeutic and adverse effects of treatment for this patient?

How would you educate the patient regarding the need for continued maintenance treatment?

Patient Care Process

Collect information:

- Assess the patient's symptoms.
- Review the family history, including the history of response to treatment by family members.
- Obtain an initial medical evaluation to rule out other causes of mood episodes.
- Evaluate physiologic parameters that may influence pharmacokinetics.
- Obtain a thorough medication use history, including present and past prescription and nonprescription drugs, the patient's self-assessment of response and side effects, alcohol, tobacco, caffeine, illicit substances, herbal products, dietary supplements, allergies, and adherence.

Assess the Information:

- Assess potential drug–disease, drug–drug, and drug–food interactions.

Develop a Care Plan:

- Develop a plan for monitoring therapeutic outcomes, focusing on the individual symptom profile and level of function of the patient. Include a plan for dosage adjustments or alternate therapy if the patient fails to respond adequately. Include serum drug concentration monitoring for efficacy if a therapeutic level is established (eg, lithium therapeutic level 0.6–1.2 mEq/L [mmol/L]).
- Develop a monitoring plan for drug side effects. Include measures to prevent side effects as well as management if they occur. Include appropriate laboratory measures.
- Determine the role of nonpharmacologic therapy and how it is to be integrated with drug therapy.

Implement the Care Plan:

- Educate the patient on the nature of bipolar disorder, its treatment, and what to expect regarding response and side effects and stress the need for adherence to treatment even when feeling well.
- Encourage a healthy lifestyle, including eliminating or stopping substance abuse, smoking cessation, and encouraging proper nutrition and exercise.

Follow-up: Monitor and Evaluate:

- Monitor the patient daily if hospitalized or every 1 to 4 weeks depending on presentation and symptom severity if outpatient to assess efficacy and safety until stabilized. Utilize the clinical interview, physical examination, and laboratory tests.
- Once stabilized, follow-up at decreased frequency, every 1 to 6 months with decreasing follow-up the longer someone is stabilized. Use the same parameters and check for new drugs or drug–drug interactions as necessary.

carbamazepine or divalproex. More specific discussion of side effect monitoring of patients taking SGAs is provided in Chapter 38.

Patient Education

KEY CONCEPT Educate the patient regarding benefits and risks of drug therapy, and the importance of adherence must be integrated into treatment plans. Discuss the nature and chronic course of bipolar disorder and risks of repeated relapses. Help patients understand treatment is not a cure but that many patients enjoy symptom-free or nearly symptom-free function. Educate patients and their family about the purpose of medication, common adverse effects, management of adverse effects, and when to seek medical attention.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Dr. Brian Crabtree in the first through fifth editions of this book.

Abbreviations Introduced in This Chapter

5-HT	5-Hydroxytryptamine
ACE	Angiotensin-converting enzyme
ARB	Angiotensin receptor blocker
BDNF	Brain-derived neurotrophic factor
CBC	Complete blood count
CBT	Cognitive-behavioral therapy
CNS	Central nervous system
DA	Dopamine
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders*, 5th edition
ECG	Electrocardiogram
ECT	Electroconvulsive therapy
FDA	Food and Drug Administration
FGA	First-generation antipsychotic
fMRI	Functional magnetic resonance imaging
FOI	Flight of ideas
GABA	γ-Aminobutyric acid
GI	Gastrointestinal
HAM-D	Hamilton Depression Rating Scale
β-HCG	Beta-human chorionic gonadotropin
HIV	Human immunodeficiency virus
LMP	Last menstrual period
MDD	Major depressive disorder
MRI	Magnetic resonance imaging
NE	Norepinephrine
PET	Positron emission tomography
SGA	Second-generation antipsychotic
THC	Tetrahydrocannabinol
VPA	Valproic acid
YMRS	Young Mania Rating Scale

Anxiety and Trauma-Related Disorders

Bridget Bradley

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying anxiety disorders.
2. Recognize common presenting symptoms of generalized anxiety disorder (GAD), panic disorder (PD), social anxiety disorder (SAD), and posttraumatic stress disorder (PTSD).
3. List treatment goals for patients with GAD, PD, SAD, and PTSD.
4. Identify appropriate lifestyle modifications and over-the-counter medication use in these patients.
5. Compare the efficacy and tolerability profiles of psychotherapy and pharmacotherapy interventions for anxiety disorders.
6. Design a patient-specific pharmacotherapy treatment plan for patients with GAD, PD, SAD, and PTSD.
7. Develop a monitoring plan for patients with anxiety disorders.
8. Formulate appropriate educational information to be provided to a patient receiving pharmacotherapy for anxiety disorders.

INTRODUCTION

Anxiety disorders are among the most frequent mental disorders encountered by clinicians.[1,2] All anxiety disorders are highly comorbid and share features of fear and anxiety that differ from developmentally typical fear or anxiety by being excessive, persistent, and resulting in behavioral disturbances.[1] Anxiety disorders are associated with significant patient and family burden, functional impairment, and increased risk of developing comorbid major depressive disorder (MDD).[1-4]

Initial detection and diagnosis generally falls to primary care clinicians, to whom most patients present in the context of other complaints.[4] Anxiety disorders are often missed or attributed incorrectly to other medical illnesses, and most patients are treated inadequately.[4] Untreated anxiety disorders are associated with increased healthcare utilization, morbidity and mortality, and a poorer quality of life.[1-4]

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

▶ *Prevalence*

Data from the National Comorbidity Survey, Replication not revised (NCS-R) estimate the lifetime prevalence of anxiety disorders in adults (18-64), collectively is 33.7%.[3] This estimate includes PTSD and OCD, although the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) recategorized it to a trauma and stressor-related disorders and obsessive-compulsive and related disorders, respectively.[1] The estimated lifetime prevalence for each anxiety disorder is specific phobia 13.8%, social anxiety disorder 13%, generalized anxiety disorder 6.2%, panic disorder 5.2%, and posttraumatic stress disorder 8%.[3]

Anxiety disorders are more prevalent among women than men (2:1).[2] Prevalence rates across the anxiety spectrum increase from the younger age group (18–29 years) to older age groups (30–44 and 45–59 years); however, rates are substantially lower for those older than age 59 years.[5]

▶ *Course of Illness*

PTSD, PD, and GAD have median ages of onset of 23, 24, and 31 years, respectively, whereas SAD develops earlier, 13 years.[6] It is likely that anxiety disorders are underdiagnosed and that symptoms are present for years prior to diagnosis.

Anxiety disorders are chronic, and symptoms tend to wax and wane, with fewer than one-third of patients experiencing spontaneous symptom remission.[7] As such, the risk for relapse and recurrence of symptoms is high. In a 12-year follow-up study of anxiety disorders, recurrence rates ranged from 39% for SAD, 56% for PD without agoraphobia, and 45% for GAD.[8] The rate of remission for PTSD is estimated to be lower; one study found only a 20% remission rate over a 15-year follow-up.[9]

Remission, if achieved with treatment, is most likely to occur within the first 2 years of an index episode.[7] Similarly, the highest rates of relapse are within the same time frame. This suggests that many patients need ongoing maintenance treatment. Rates of remission and relapse do not appear to vary by sex.[7] Patients with anxiety disorders spend a significant portion of time “being ill” during a particular episode, ranging from 41% to 80% of the time.[8] Appropriate treatment improves overall quality of life and psychosocial functioning.[10]

▶ *Comorbidity*

More than 90% of individuals with an anxiety disorder have a lifetime history of one or more other psychiatric disorder(s).[10] Depression is the most common comorbidity, followed by alcohol and substance use disorders, as well as other co-occurring anxiety disorders.[10]

Etiology

Both genetic and psychosocial factors appear to play a role in the initiation and expression of anxiety disorders.[11] Moderate genetic risk has been identified for all anxiety disorders. Family and twin epidemiologic studies support familial aggregation of anxiety disorders (odds ratio [OR] 4–6) with heritability of 30% to 50%.[11] Twin studies further suggest that anxiety disorders share genetic risk factors that may help to explain the pattern of comorbidity. Candidate gene studies as well as genome-wide association sequence (GWAS) studies seeking to identify genes contributing to risk have been inconclusive to date.[11]

Genetic factors may create a vulnerable phenotype for anxiety disorders, but environmental factors (eg, stressful life events, illness, parental relationships, trauma) contribute to the development and persistence of the disorder.[11] Others factors that may increase risk of anxiety disorder diagnosis include positive family history of anxiety disorders, female sex, loneliness, low education, adverse parenting, and chronic somatic illness (cardiovascular disease, diabetes, asthma, obesity).[12] A 2018 analysis of the National Epidemiological Survey on Alcohol and Related Conditions found that adverse life events (death of family or friend, illness/injury of family or friend, victim of a crime, financial crisis, job loss, and ending of relationship) have a role in the onset of panic, generalized, and social anxiety disorders.[13] PTSD requires an exposure to a traumatic event(s), either intentional or unintentional. Approximately 80% of the US population will experience at least one traumatic event and 13% of women and 6% of men will develop PTSD.[14] Symptoms can occur soon after or years after the trauma.[1]

PATHOPHYSIOLOGY

The thalamus, amygdala, nucleus accumbens, hippocampus, hypothalamus, and prefrontal cortex are key components of the neurocircuitry of fear response[15] and may play a central role in most anxiety disorders (Figure 41–1). Sensory data from environmental threats are first processed by the thalamus. Information is simultaneously passed on to cortical centers for finer processing and to the amygdala for rapid assessment of highly charged emotional information. The amygdala provides emotional valence or importance of the information and enables quick action or response to an ambiguous but vital threat. The cortex performs a more detailed analysis and sends updates to the amygdala for comparison and any needed course corrections.

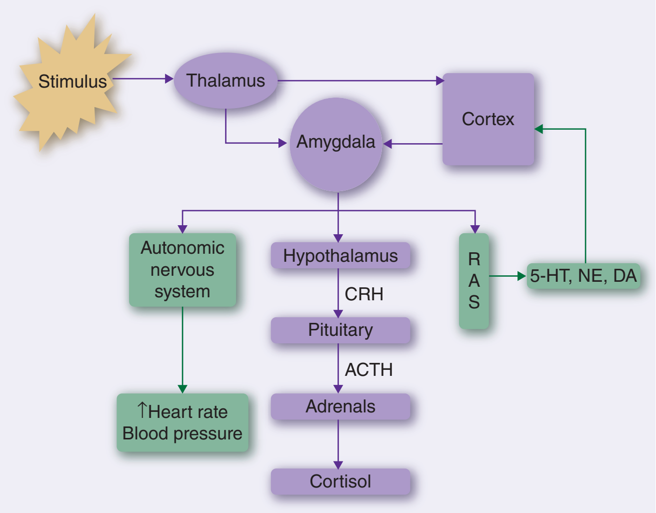

FIGURE 41–1. Neurocircuitry and key neurotransmitters involved in mediating anxiety disorders. (ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; DA, dopamine; 5-HT, serotonin; NE, norepinephrine; RAS, reticular activating system.)

Anxiety disorders develop when the fear-response system leads to maladaptive behavior or distress. Anxiety occurs independent of stimuli (eg, PD), is associated with benign stimuli (eg, phobias), or continues beyond the stimulus duration (eg, GAD). Direct and indirect connections to the reticular activating system (RAS), a region spanning the medulla, pons, and midbrain, help to regulate arousal, vigilance, and fear. These connections are modulated by serotonin (5-HT) and norepinephrine (NE), which have their primary origins in the RAS.[16] The amygdala sends projections to the hypothalamus, thus influencing the autonomic nervous system to affect heart rate, blood pressure, and stress-associated changes. It also influences the hypothalamic–pituitary–adrenal (HPA) axis, leading to a cascade of stress hormones.[16] Elevation of stress hormones, such as cortisol, for prolonged periods can damage the brain and other organs.[16]

Noradrenergic System

Norepinephrine-producing cells reside primarily in a region of the brain called the locus ceruleus (LC). Increased activity in this region is associated with an increase in arousal, anxiety, and panic. Drugs such as yohimbine that increase activity in the LC can be anxiogenic; drugs that decrease activity in the LC appear to improve anxiety. Furthermore, dysregulation of this region is implicated by elevated levels of NE or its metabolites in subjects with GAD, PD, and specific phobias.[17]

Serotonergic System

The raphe nuclei and the resident cell bodies of 5-HT-producing neurons have a complicated role related to anxiety symptoms. Activity of 5-HT cells in the raphe nuclei over time inhibits firing of noradrenergic cells in the LC. Other influences include their ability to regulate cells in the prefrontal cortex and amygdala. Perhaps the strongest evidence for the involvement of the serotonergic system is the success of serotonin reuptake inhibitors in treatment of anxiety disorders.[15]

γ-Aminobutyric Acid

γ-Aminobutyric acid (GABA) plays a complex role as an inhibitory neurotransmitter with nonspecific effects. GABA-ergic drugs reduce anxiety, but the lack of a specific target for their effect leads to multiple undesirable effects. Current research is focused on defining receptor subtypes that may allow for greater specificity in targeting anxiety symptoms.[15]

Hypothalamic–Pituitary–Adrenal Axis

The HPA axis provides a critical mechanism for regulation of the stress response and its effects on the brain and other organ systems. Several important hormones, including corticotropin-releasing hormone and cortisol, are involved in this pathway. These hormones regulate the effects of anxiety on the body and provide positive feedback to the brain.[14] A cycle of anxiety and sensitization by such feedback could, if unchecked, result in escalation of symptoms. Neuropeptides may provide one mechanism to balance positive and negative feedback, helping to minimize such escalation.

Patient Encounter 1, Part 1

A 34-year-old man presents to his primary care team with complaints of nausea, diarrhea, abdominal pain, and fatigue. He recently had a full workup for his gastrointestinal complaints which came back negative. He continues to be worried that something more is wrong medically. He is also worried that he is not performing well at his job. He becomes very upset thinking he will lose his job and then will be homeless, and his wife will leave him. He is an accountant and has been employed with the same firm for the last 10 years but is concerned that he is having trouble concentrating at work. He has recently increased his caffeine as his sleep has been poor. He has one to two beers every evening and denies use of tobacco or other illicit drug use. His medical history is positive for hypertension.

What manifestations described above are suggestive of an anxiety disorder?

What additional information do you need to establish a diagnosis and develop a treatment plan?

What other diagnoses should be considered in your differential diagnosis?

Neuropeptides

Several neuropeptides (eg, neuropeptide Y [NPY], corticotropin-releasing factor, and cholecystokinin) have been investigated for their role in anxiety disorders.[18]

CLINICAL PRESENATION AND DIAGNOSIS

Anxiety disorders share common etiology and risk factors yet have distinct clinical presentation, diagnostic criteria, and treatment recommendations and thus will be discussed separately. Treatment guidelines recommend screening for the presence of anxiety symptoms using general questions such as "During the past 2 weeks, how much have you been bothered by the following: (1) feeling nervous, anxious, frightened, worried, or on edge, (2) feeling panic or being frightened, (3) avoiding situations that make you anxious."[1,19] Positive responses should result in further assessment. Suicide risk assessment is recommended for all anxiety disorders as the risk of suicide attempts is increased irrespective of the presence of a comorbid mood disorder.[19,20]

TREATMENT: GENERALIZED ANXIETY DISORDER

Desired Outcomes

The goals of therapy for GAD are to acutely reduce the severity and duration of anxiety symptoms and restore overall functioning. The long-term goal is to achieve and maintain remission.

General Approach to Treatment

KEY CONCEPT Patients with GAD may be managed with psychotherapy, pharmacotherapy, or both. Treatment should be individualized based on symptom severity, comorbid illnesses, medical status, age, access to care, cost, and patient preference. Patients with severe symptoms resulting in functional impairment should receive an antianxiety medication.

Clinical Presentation and Diagnosis of GAD

General

Onset is typically in early adulthood. The intensity and duration of anxiety is out of proportion to the likelihood or impact of the anticipated event. Laboratory evaluation usually is reserved for later onset, atypical presentation, or poor response to treatment.

Symptoms[1]

- Essential feature is excessive anxiety or worry involving multiple events or activities occurring more days than not for at least 6 months
- Difficulty controlling worry
- Anxiety and worry associated with at least three of the following (unless assessing children):
  - Restlessness
  - Easily fatigued
  - Poor concentration or mind going blank
  - Irritability
  - Muscle tension
  - Insomnia or unsatisfying sleep
- The anxiety or worry causes significant distress or functional impairment and is *not* attributable to another substance, medical, or psychiatric condition

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 41–1 and 41–2)

Laboratory Evaluation

- Urine drug screen
- Basic metabolic panel and HbA1c
- Thyroid-stimulating hormone
- Electrocardiogram

Table 41–1

Medical Conditions That Can Cause Anxiety[1,12]

Psychiatric Disorders
Mood disorders, hypochondriasis, personality disorders, alcohol or substance use, alcohol or substance withdrawal, other anxiety disorders

Neurologic Disorders
CVA, seizure disorders, dementia, stroke, migraine, encephalitis, vestibular dysfunction

Cardiovascular Disorders
Angina, arrhythmias, congestive heart failure, mitral valve prolapse, myocardial infarction

Endocrine and Metabolic Disorders
Hypothyroidism or hyperthyroidism, hypoglycemia, Cushing disease, Addison disease, pheochromocytoma, hyperadrenocorticism, hyponatremia, hyperkalemia, vitamin B_{12} deficiency

Respiratory Disorders
Asthma, COPD, pulmonary embolism, pneumonia, hyperventilation

Other
Carcinoid syndrome, anemias, SLE

COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident; SLE, systemic lupus erythematosus.

Table 41–2

Medications Associated with Anxiety Symptoms[1,6,29]

Category	Examples
Anticonvulsants	Carbamazepine, ethosuximide
Antidepressants	Bupropion, SSRIs, SNRIs, TCAs
Antihypertensives	Felodipine
Antimicrobials	Cephalosporins, ofloxacin, isoniazid
Antiparkinson drugs	Levodopa
Bronchodilators	Albuterol, isoproterenol, theophylline
Corticosteroids	Prednisone, methylprednisolone
Decongestants	Pseudoephedrine, phenylephrine
Herbals	Ma huang, St. John's wort, ginseng, guarana, belladonna
NSAIDs	Ibuprofen, indomethacin
Stimulants	Amphetamines, caffeine, cocaine, methylphenidate, nicotine
Thyroid hormones	Levothyroxine
Toxicity	Anticholinergics, antihistamines, digoxin
Withdrawal of CNS depressants (abrupt)	Alcohol, barbiturates, benzodiazepines

CNS, central nervous system; NSAID, nonsteroidal anti-inflammatory drug; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Nonpharmacologic Therapy

Nonpharmacologic therapy includes psychoeducation, exercise, stress management (eg, applied relaxation), and psychotherapy (eg, cognitive-behavioral therapy, mindfulness-based). Psychoeducation should provide information on GAD and its management. Patients should be instructed to avoid stimulating agents, for example, caffeine, decongestants, diet pills, and excessive alcohol use. Regular exercise is also recommended, and higher-intensity exercise may have more benefit than lower-intensity exercise.[21] Cognitive-behavioral therapy (CBT) is the most effective psychological therapy for GAD patients. It helps patients to recognize and alter patterns of distorted thinking and dysfunctional behavior. Treatment gains with CBT may be maintained for 1 year[6] and up to 3 years.[19] CBT may be delivered in individual or group settings.[19,21] Internet-based CBT (iCBT) that is supported by a therapist was found to be effective and may offer an alternative to face-to-face therapy for patients with access barriers.[22] The effect sizes of trials with CBT are comparable to those of pharmacologic therapies, although benefit may be seen earlier with therapy.[6,12] CBT is effective for children with anxiety disorders and combined with medication may be superior to either treatment alone.[23]

Patient Encounter 1, Part 2

After reviewing the negative GI workup and the patient's presenting symptoms, he is diagnosed with GAD.

PMH: Hypertension

FH: Mother treated for GAD; father, hypertension

SH: One to two beers every evening; lives with spouse and two children

Meds: Amlodipine 10 mg PO daily for hypertension

What are first-line treatment options for this patient?

What factors should be considered in selecting the patient's treatment?

What is the role of benzodiazepines for this patient?

How should the patient be monitored when receiving an antidepressant?

Pharmacologic Therapy

Antidepressants, benzodiazepines, pregabalin, buspirone, hydroxyzine, and the second-generation antipsychotics (SGAs) have controlled clinical trial data supporting their use in GAD. **KEY CONCEPT** Antidepressants are the drugs of choice for chronic GAD because of tolerable side effect profiles, no risk for dependency, and efficacy in common comorbid conditions, including major depression, panic disorder, obsessive-compulsive disorder (OCD), and SAD. Benzodiazepines remain the most effective and commonly used treatment for short-term management of anxiety when immediate relief of symptoms is desired. They may be used for intermittent or adjunctive treatment during GAD exacerbation or for sleep disturbance during the initiation of antidepressant treatment.[6,12] Buspirone and pregabalin are alternative agents for patients with GAD without depression. Hydroxyzine is usually adjunctive and is less desirable for long-term treatment because of side effects such as sedation and anticholinergic effects.

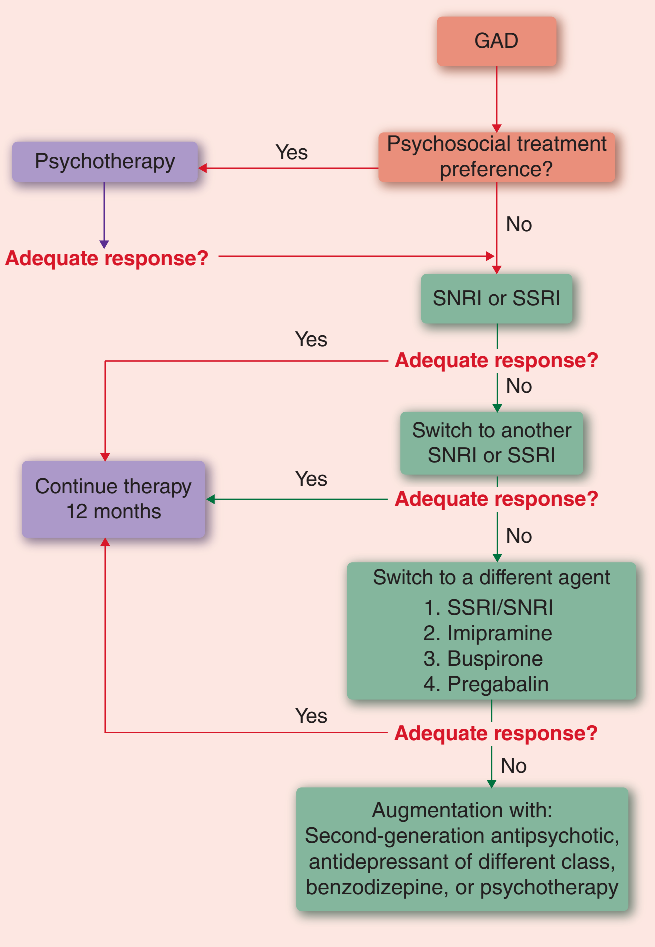
Patients with GAD should be treated to symptom remission. Continuation of antidepressant therapy after acute response significantly decreases the risk of relapse (OR 0.2 [0.15–0.26]).[24] Guidelines vary on how long to continue treatment after remission, and the duration varies from at least 6 months and up to 12 months.[6,12,21,25] An algorithm for the pharmacologic management of GAD is shown in Figure 41–2.

▶ *Antidepressants*

Antidepressants (Table 41–3) reduce the psychic symptoms (eg, worry and apprehension) of anxiety with a modest effect on autonomic or somatic symptoms (eg, tremor, rapid heart rate, and/or sweating). All antidepressants provide a similar degree of anxiety reduction. The onset of antianxiety effect is 2 to 4 weeks. Selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) are preferred over tricyclic antidepressants (TCAs) because of improved safety and tolerability. Selection of a specific antidepressant generally is based on history of prior response, side effect and drug interaction profile (see Chapter 39), cost, or formulary availability.

Antidepressants modulate synaptic 5-HT, NE, and/or dopamine (DA) reuptake and receptor-activated neuronal signal transduction. These intracellular changes modify the expression of genes and proteins important in stress response (eg, glucocorticoid receptors, brain-derived neurotrophic factor, corticotropin-releasing hormone).[26] Activation of these "stress-adapting" pathways may improve both somatic and psychic symptoms of anxiety.[26]

Selective Serotonin Reuptake Inhibitors The SSRIs paroxetine, escitalopram, and sertraline have been shown to be significantly more effective than placebo in reducing anxiety symptoms in adults with GAD. Response rates range from 56% to 68% during acute treatment, with remission achieved in approximately one-third of patients.[6,12,25,27] Common side effects include somnolence, headache, nausea, dry mouth (paroxetine), diarrhea (sertraline), sweating (sertraline), decreased libido, ejaculation disorder, anorgasmia, and asthenia.



GAD
Psychosocial treatment preference?
Yes
Psychotherapy
No
Adequate response?
SNRI or SSRI
Yes
Adequate response?
No
Switch to another SNRI or SSRI
Continue therapy 12 months
Yes
Adequate response?
No
Switch to a different agent
1. SSRI/SNRI
2. Imipramine
3. Buspirone
4. Pregabalin
Yes
Adequate response?
No
Augmentation with: Second-generation antipsychotic, antidepressant of different class, benzodizepine, or psychotherapy

FIGURE 41–2. Treatment algorithm for generalized anxiety disorder (GAD). (SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.) (Data from Refs. 12, 20, 25, 29.)

The SSRIs are better tolerated than TCAs, and tolerability is similar to that of SNRIs. Sertraline, fluoxetine, and fluvoxamine have demonstrated benefits in children and adolescents with GAD and are the preferred pharmacologic treatment in this population.[21]

Serotonin-Norepinephrine Reuptake Inhibitors Venlafaxine and duloxetine alleviate anxiety with or without comorbid depression and maintain response with extended treatment.[6,12,25,27] Venlafaxine and duloxetine are effective for GAD in children and adolescents.[21] Common side effects reported in patients with GAD are nausea, somnolence, dry mouth, dizziness, sweating, constipation, and anorexia.

Tricyclic Antidepressants Imipramine demonstrated similar rate of remission of anxiety symptoms as treatment with trazodone or diazepam.[6] TCAs are limited by bothersome adverse effects (eg, sedation, orthostatic hypotension, anticholinergic effects, and weight gain). TCAs have narrow therapeutic indices and are lethal in overdose due to atrioventricular block.

Novel Antidepressants The efficacy of mirtazapine, an α_2-adrenergic antagonist and postsynaptic 5-HT$_2$ and 5-HT$_3$ receptor antagonist, for anxiety disorders has been limited to small sample sizes.[28] It is not associated with sexual dysfunction but is associated with sedation and weight gain. Bupropion, a DA and NE reuptake inhibitor, lacks the common antidepressant side effects of weight gain and sexual dysfunction. Bupropion has not been studied or used extensively in anxiety disorders. However, a small controlled trial comparing bupropion XL with escitalopram found bupropion to have comparable anxiolytic efficacy and tolerability.[6,12] Vortioxetine, a multimodal SSRI with blockade of serotonin reuptake transporter, antagonist activity at 5-HT$_{1D}$, 5-HT$_3$, and 5-HT$_7$ receptors and partial agonist activity at 5-HT$_{1A}$ and 5-HT$_{1B}$ receptors has been evaluated in the treatment of GAD with conflicting results.[28] Vilazodone, a SSRI and 5-HT$_{1A}$ receptor partial agonist, has shown benefit compared to placebo in several short-term randomized controlled trials in GAD.[29] Neither of these two agents appear to have advantages over generically available SSRIs/SNRIs.[28]

▶ *Benzodiazepines*

KEY CONCEPT Benzodiazepines are recommended for acute treatment of GAD when short-term relief is needed, as an adjunct during initiation of antidepressant therapy, or patients who have three treatment failures.[6,12,27] Benzodiazepines should be used for short-term treatment with scheduled dosing, as opposed to as-needed.[6,12] They are more effective for somatic symptoms than psychic symptoms.[20] Major benzodiazepine disadvantages are lack of effectiveness for depression; risk for withdrawal and potential need for taper; and potential interdose rebound anxiety, especially with short-acting benzodiazepines. They are cautioned in older adults due to fall and fracture risk.[12] Benzodiazepines have a risk for dependency and abuse and should be avoided in patients with current or past substance use disorder(s).[6,12,27]

Benzodiazepines enhance transmission of the inhibitory neurotransmitter GABA through interaction with the GABA$_A$-receptor complex.[6,29] All benzodiazepines are expected to provide equivalent benefit when given in comparable doses. They differ substantially in their pharmacokinetic properties and potency for the GABA$_A$-receptor (Table 41–4).

Benzodiazepines are metabolized by hepatic oxidation (CYP3A4) and glucuronide conjugation. Because lorazepam and oxazepam bypass hepatic oxidation and are conjugated only, they are preferred agents for patients with reduced hepatic function secondary to aging or disease (eg, cirrhosis). Many benzodiazepines are metabolized to long-acting metabolites (Table 41–4) that provide long-lasting anxiety relief. Drugs that either inhibit or induce CYP450 isozymes or glucuronidation can cause drug interactions.

The most common side effects of benzodiazepine therapy include central nervous system (CNS) depressant effects (eg, drowsiness, sedation, psychomotor impairment, and ataxia) and cognitive effects (eg, poor recall and anterograde amnesia). Anterograde amnesia is more likely with high-potency benzodiazepines such as alprazolam.[30] Some patients may be disinhibited and experience confusion, irritability, aggression, and excitement.[20,29] Discontinuation of benzodiazepines may be associated with withdrawal, rebound anxiety, and recurrence of anxiety symptoms.[20] Higher doses of benzodiazepines and a longer duration of therapy increase the severity of withdrawal and risk of seizures after abrupt or rapid discontinuation. Patients should be tapered to avoid withdrawal symptoms. The duration of the taper should increase with extended duration of benzodiazepine therapy.[6,29] A general approach to the taper is to reduce the dose by 25% every 5 to 7 days until reaching half the original dose and then decreasing by 10% to 12% per week until discontinued. Patients should expect minor withdrawal symptoms and discomfort even when tapering. Rebound symptoms (eg, return of original symptoms at increased intensity) are transient. The patient should be educated that rebound anxiety is not a relapse.

Table 41–3

Pharmacotherapy for the Treatment of Generalized Anxiety Disorder[19,46]

Medication Class Drug Name (Brand Name)	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)	Hepatic Insufficiency	Renal Insufficiency
Antidepressants				
SSRIs				
Citalopram[a] (Celexa)	20	20–40	Maximum, 20 mg/day	
Escitalopram[b] (Lexapro)	10	10–20	Maximum, 10 mg/day	
Fluoxetine (Prozac)	20	20–80	Titrate with caution	
Fluvoxamine (Luvox)	50	100–300	Titrate with caution	
Paroxetine (Paxil)[b]	20	20–50	Titrate with caution	
Paroxetine CR (Paxil CR)	25	25–62.5	Maximum, 50 mg/day	Maximum, 50 mg/day
Sertraline (Zoloft)	50–100	50–200	Reduce dose	
SNRIs				
Venlafaxine XR[b] (Effexor XR)	75	75–225	Reduce dose by 50%	Reduce dose 25%–50%
Desvenlafaxine (Pristiq)	50	50–100	Maximum, 100 mg/day	Maximum, 50 mg/day; CrCl < 30 mL/min (0.50 mL/s), dose once every other day
Duloxetine[b,c](Cymbalta)	30	60–120	Use not recommended	CrCl < 30 mL/min (0.50 mL/s) Use not recommended
TCAs				
Imipramine (Tofranil)	50	75–200	Titrate with caution	
Other Agents				
Hydroxyzine (Atarax)	25–50 four times daily	200–400		Reduce dose by 50% GFR < 50 mL/min (0.83 mL/s)
Azapirones				
Buspirone (Buspar)	7.5 mg twice daily	15–60	Not recommended in severe hepatic impairment	Not recommended in severe renal impairment
Anticonvulsants				
Pregabalin (Lyrica)	150	150–600		Reduce dose[c]
Second-Generation Antipsychotic				
Quetiapine XR (Seroquel XR)	50	150–300		

[a]Maximum daily dose of citalopram is 20 mg/day when used in the elderly or when given concomitantly with CYP2C19 inhibitors.

[b]Food and Drug Administration approved for use in generalized anxiety disorder.

[c]Dose reduction recommended for CrCl < 60 mL/min (1 mL/s) and again for CrCl, 30 mL/min (0.50 mL/s) and 15 mL/min (0.25 mL/s).

CR, controlled release; CrCl, creatinine clearance; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; XR, extended release.

▶ *Pregabalin*

Pregabalin is a calcium channel modulator, and its anxiolytic properties are attributed to its selective binding to the α_2-delta subunit of voltage-gated calcium channels. Pregabalin reduces anxiety with a similar onset to alprazolam.[12,27,31] Compared with venlafaxine and placebo, pregabalin was safe, well tolerated, and efficacious in GAD, and results were seen 1 week sooner than with venlafaxine.[12] Pregabalin reduces the risk of relapse during maintenance treatment.[12,27,31] It has a short elimination half-life and must be dosed two to three times daily. It is excreted renally with a low risk of drug–drug interactions. Pregabalin is a schedule V controlled substance owing to a propensity to cause euphoria and may cause withdrawal symptoms if discontinued abruptly. It should be used cautiously in patients with a current or past history of substance use.

▶ *Alternative Agents*

Hydroxyzine, buspirone, and SGAs are alternative agents. Hydroxyzine may be effective for acute reduction of somatic symptoms of anxiety[6] but not for psychic features of anxiety, depression, or other common comorbid anxiety disorders. Buspirone, a 5-HT$_{1A}$ partial agonist, is thought to exert its anxiolytic effects by reducing presynaptic 5-HT firing.[32] Unlike benzodiazepines, it does not have abuse potential, cause withdrawal symptoms, or potentiate alcohol and sedative-hypnotic effects. It has a gradual onset of action (ie, 2 weeks) and does not provide immediate anxiety relief. Data are inconsistent regarding its efficacy in chronic GAD or GAD with comorbid depression.[6,12,27,31] It may be less effective in patients who have been treated previously (4 weeks–5 years) with benzodiazepines.[6]

Buspirone is well tolerated, and most common side effects include dizziness, nausea, and headaches. Buspirone elimination is affected significantly by drugs that inhibit (eg, verapamil, diltiazem, itraconazole, fluvoxamine) or induce (eg, rifampin) CYP3A4.[33] Buspirone may increase blood pressure when coadministered with a monoamine oxidase inhibitor (MAOI).

The SGA quetiapine XR has demonstrated benefit in GAD. In three large placebo-controlled trials, quetiapine in daily doses

Table 41–4

Comparison of Benzodiazepines[46-48]

Drug Name (Brand Name)	Metabolite	Time to Peak Concentration (hours)	Half-Life Range (hours)	Approved Dosage Range (mg/day)	Dose Equivalent (mg)
Alprazolam[a,b] (Xanax)		1–2	12–15	1–4 (GAD) 1–10 (PD)	0.5
Chlordiazepoxide[a] (Librium)	*Desmethyldiazepam* *Desmethylchlordiazepoxide* *Demoxepam* *Oxazepam*	1–4	5–30 40–120 18 14–95 5–15	25–100	10
Clonazepam[b] (Klonopin)		1–4	18–50	1–4	0.25
Clorazepate[a] (Tranxene)	*Desmethyldiazepam*[c] *Oxazepam*	1–2	40–120 5–15	7.5–60	7.5
Diazepam[a] (Valium)	*Desmethyldiazepam*[c] *Oxazepam* *Temazepam*	0.5–2	20–80 40–120 5–15 8–15	2–40	5
Lorazepam[a] (Ativan)		2–4	10–20	0.5–10	0.75–1
Oxazepam[a] (Serax)		2–4	5–15	30–120	15

[a] Food and Drug Administration (FDA) approved for use in generalized anxiety disorder.

[b] FDA approved for use in panic disorder.

[c] CYP2C19 genetic polymorphisms resulting in little or no enzyme activity are present in 15% to 20% of Asians and 3% to 5% of Black and White patients, resulting in reduced clearance of desmethyldiazepam.[33]

GAD, generalized anxiety disorder; PD, panic disorder.

of 50 to 300 mg resulted in 26% greater likelihood of treatment response (effect size, ~0.3).[34] Quetiapine had similar outcomes paroxetine 20 mg/day and escitalopram 10 mg/day.[34] Quetiapine is still considered a second-line option for GAD due to safety concerns.[12] The SGAs quetiapine, risperidone, olanzapine, and aripiprazole have limited evidence as adjunctive treatment in patients with inadequate response to initial pharmacotherapy.[12] SGAs are associated with a risk of weight gain, glucose intolerance, sedation, fatigue, and extrapyramidal symptoms that limit their use.

Clinical Presentation and Diagnosis of PD

General

Typically presents in late adolescence or early adulthood. Onset in older adults should prompt investigation of medical or substance-induced causes. Laboratory evaluation would be driven by any positive findings during the patient history and physical examination.

Symptoms[1]

Recurrent, unexpected panic attacks. A panic attack is an abrupt surge of intense fear or discomfort peaking within minutes and with four or more of the following symptoms:

- Palpitations or rapid heart rate
- Sweating
- Trembling or shaking
- Sensation of shortness of breath or smothering
- Feeling of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy or light-headed
- Chills or hot flushes
- Paresthesias
- Derealization or depersonalization
- Fear of dying
- Fear of losing control or "going crazy"

At least one of the attacks has been followed by 1 month or more of one or both:

- Persistent concern or worry about additional attacks
- Significant maladaptive change in behavior related to the attacks (eg, avoidance)

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 41–1 and 41–2)

Laboratory Evaluation

- Urine drug screen
- Basic metabolic panel and HbA$_{1C}$
- Thyroid-stimulating hormone
- Electrocardiogram

OUTCOME EVALUATION

Assess patients for improvement of anxiety symptoms and return to baseline of occupational, social, and interpersonal functioning. Brief questionnaires like the Generalized Anxiety Disorder 7-Item (GAD-7) may be used to monitor changes in symptoms and measure response to treatment.[35] With effective treatment, patients should have no or minimal symptoms of anxiety or depression. With initiation of drug therapy, evaluate patients frequently for tolerability and response. Monitor for suicidal ideation and behaviors for children, adolescents, and young adults (24 years of age or less) initiated on antidepressants.[21,36,37] Increase the dose in patients exhibiting a partial response after 2 to 4 weeks on an antidepressant or 2 weeks on a benzodiazepine. Individualize the duration of treatment as some patients require up to 1 year of treatment.[6,12,27]

TREATMENT: PANIC DISORDER

Desired Outcomes

The goals of therapy for PD are to reduce the severity and frequency of panic attacks, reduce anticipatory anxiety and avoidant behavior, and minimize symptoms of depression or other comorbid disorders.[38] The long-term goal is to achieve and maintain remission and restore overall functioning.

General Approach to Treatment

Treatment options include medication, psychotherapy, or a combination of both. In some cases, pharmacotherapy will follow psychotherapy treatments when full response is not realized. Patients with panic symptoms without comorbid agoraphobia may respond to pharmacotherapy alone. Agoraphobic symptoms generally take longer to respond than panic symptoms. **KEY CONCEPT** The acute phase of PD treatment lasts about 12 weeks and should markedly reduce or eliminate panic attacks and minimize anticipatory anxiety and phobic avoidance. Treatment should be continued to prevent relapse for an additional 12 to 24 months before attempting discontinuation.[6,12,38] For patients who relapse after discontinuation, therapy should be resumed.[38]

Nonpharmacologic Therapy

Patients with PD should avoid stimulating agents (eg, decongestants, diet pills, and caffeine) that may precipitate a panic attack. CBT generally includes psychoeducation, self-monitoring, countering anxious beliefs, exposure to fear cues, and modification of anxiety-maintaining behaviors.[6,38] Exposure therapy is useful for patients with phobic avoidance.[8,38] CBT is considered a first-line treatment of PD, with efficacy similar to that of pharmacotherapy. Some studies suggest lower risk of relapse after CBT versus drug therapy.[38] Similarly to GAD, iCBT has shown to be effective for PD with effects maintained up to 6 months.[39] CBT in combination with antidepressant treatment is more effective than either treatment alone.[2]

Pharmacologic Therapy

Patients with PD may be treated with SSRIs, SNRIs, TCAs, or MAOIs, as well as benzodiazepines[6,12,38] (Table 41–5) with similar effectiveness, but SSRIs are the treatment of choice. Benzodiazepines often are used concomitantly with antidepressants,

Table 41–5

Antidepressants Used in the Treatment of Panic and Social Anxiety Disorder[6,25,38]

Medication Class	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)	Advantages	Disadvantages
SSRIs/SNRIs			**SSRIs (in General)**	**SSRIs (in General)**
Citalopram	10	20–40	Antidepressant activity; antianxiety activity; single daily dosing (all but fluvoxamine); low toxicity	Activation; delayed onset of action; may precipitate mania; sexual side effects; GI side effects
Escitalopram[b]	5–10	10–20		
Fluoxetine[a]	5–10	20–60		
Fluvoxamine	25	100–300		
Paroxetine[a,b]	10	20–60

FIGURE 41–3. Algorithm for the pharmacotherapy of panic disorder. (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor.) (Adapted from Young AS, Klap R, Sherbourne CD, Wells KB. The quality of care for depressive and anxiety disorders in the United States. Arch Gen Psychiatry. 2001;58:55–61 and Bruce SE, Yonkers SE, Otto MW, et al. Influence of psychiatric comorbidity on recovery and recurrence in generalized anxiety disorder, social phobia, and panic disorder: a 12-year prospective study. Am J Psychiatry. 2005;162:1179–1187, with permission.)

especially early in treatment, or as monotherapy to acutely reduce panic symptoms. Benzodiazepines are not preferred for long-term treatment but may be used when patients fail several antidepressant trials.[6,12,38] Patients with comorbid depression should be treated with an antidepressant. An algorithm for pharmacologic management of PD appears in Figure 41–3.

▶ *Antidepressants*

Antidepressants typically require 4 weeks for onset of antipanic effect, with optimal response at 6 to 12 weeks. Reduction of anticipatory anxiety and phobic avoidance generally follows improvement in panic symptoms. **KEY CONCEPT** Patients with PD are more likely to experience stimulant-like side effects of antidepressants than patients with major depression. Antidepressants should be initiated at lower doses (Table 41–5) in patients with PD than in depressed patients. Target doses are similar to those used for depression. **KEY CONCEPT** Antidepressants should be tapered when treatment is discontinued to avoid withdrawal symptoms, including irritability, dizziness, headache, and dysphoria.

Selective Serotonin and Serotonin-Norepinephrine Reuptake Inhibitors SSRIs and SNRIs are the medications of choice for patients with PD. All SSRIs have demonstrated effectiveness in controlled trials, with 60% to 80% of patients achieving a panic-free state.[6,12,38] Similarly, venlafaxine XR, in dosages of 75 to 225 mg/day, reduced panic and anticipatory anxiety in short-term controlled trials and prevented relapse with extended treatment over 6 months.[12,38] Duloxetine has limited evidence for efficacy and is considered a third-line option.[12] Given lack of head-to-head trials and similar efficacy between agents, drug selection is generally based on pharmacokinetics, drug interactions, side effects, and cost differences (see Chapter 39).

Tricyclic Antidepressants Treatment with imipramine has resulted in 45% to 70% of patients achieving a panic-free state. Clomipramine also has demonstrated effectiveness in PD. TCAs are considered second- or third-line therapeutic options because of poorer tolerability and toxicity upon overdose, which may be fatal.[6,38] Owing to their side effect profile, TCAs are associated with a higher rate of treatment discontinuation than SSRIs.[38] PD patients taking TCAs may experience anticholinergic effects, orthostatic hypotension, sweating, sleep disturbances, dizziness, fatigue, sexual dysfunction, and weight gain.

Monoamine Oxidase Inhibitors MAOIs have not been evaluated systematically for treatment of PD under the current diagnostic classification. In general, they are reserved for patients who are refractory to other treatments.[38] They have significant side effects that limit adherence coupled with restrictions to avoid tyramine-containing foods and sympathomimetic drugs to prevent hypertensive crisis (see Chapter 39).

Other Antidepressants Mirtazapine is considered a second-line option.[17] There is insufficient evidence to support the use of bupropion, trazodone, or nefazodone for treatment of PD.[6,12,38]

▶ *Benzodiazepines*

Benzodiazepines are effective antipanic agents with significant effects on anticipatory anxiety and phobic behaviors. Alprazolam, the most studied benzodiazepine for PD, is associated with significant panic reduction after 1 week of therapy (eg, 55%–75% panic free).[38,39] Benzodiazepines achieve outcomes similar to antidepressants over extended treatment, but benzodiazepine-treated patients are more likely to relapse when the drugs are discontinued.[38] The risk for dependence and withdrawal and lack of efficacy for depression are significant concerns for long-term treatment of patients with PD. There is no evidence that tolerance to therapeutic effect occurs. Patients with PD experience greater rebound anxiety and relapse when discontinuing benzodiazepines than do patients with GAD.[6,38] Tapering should be done at a slower rate and over a longer period of time compared to other anxiety disorders.[6,38]

Alprazolam and diazepam, when given in equivalent doses, produce similar treatment benefits.[6,38] Doses should be titrated to response (see Table 41–4). The use of extended-release alprazolam or clonazepam may minimize breakthrough panic symptoms that are sometimes observed with immediate-release alprazolam.[40]

▶ *Adjunctive Treatment*

Pindolol, a mixed β-adrenergic/serotonergic medication, has limited evidence as adjunctive treatment with an SSRI (fluoxetine) for treatment resistant PD.[2] Propranolol, a nonselective β-blocker, is not effective for acute treatment of PD and is not recommended.[2]

Clinical Presentation and Diagnosis of SAD

General

Individuals have marked fear or anxiety about one or more social situations where they are exposed to possible scrutiny or negative evaluation (eg, common social interactions, conversation, eating, drinking, or performing). In children, the anxiety must be present in peer settings, not just in interactions with adults.

Symptoms[1]

- The individual fears acting in a way or showing anxiety that will be negatively evaluated (ie, they will be humiliated or embarrassed, others will be reject them, others will be offended))
- Social situations almost always provoke fear or anxiety and are avoided or endured with intense fear or anxiety. Children may express fear or anxiety by crying, tantrums, freezing, clinging, or failing to speak in social situations.
- The fear or anxiety is
  - Out of proportion to the actual threat posed by the social situation
  - Persistent, typically lasting for 6 months or more
  - Causes clinically significant distress or impairment in social, occupational, or other areas of functioning
  - Not attributable to physiologic effects of a substance or another medical condition
  - Not better explained by the symptoms of another mental disorder (eg, panic disorder, body dysmorphic disorder, or autism spectrum disorder)

Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (see Tables 41–1 and 41–2).

Laboratory Evaluation

Laboratory investigation is of limited value and should be pursued only in context of other history or physical examination findings.

Outcome Evaluation

Monitor patients weekly during acute treatment (eg, initiation and titration of pharmacotherapy) and monthly once stabilized. With effective therapy, patients should experience significant reductions in the frequency and intensity of panic attacks, anticipatory anxiety, and phobic avoidance with resumption of normal activities. Rating scales, such as the Panic Disorder Symptom Scale (PDSS), can be useful in measuring symptom change over time. Assess patients for comorbidities (eg, depression) as well as suicidal ideation. Alter the therapy of patients who do not achieve a significant reduction in panic symptoms after 6 to 12 weeks on an adequate dose of antidepressant or 3 weeks on a benzodiazepine. Regularly evaluate patients for adverse effects and medication adherence, and educate them about appropriate expectations of drug therapy.

When significant response to drug therapy is achieved, continue treatment for at least 1 year. Evaluate for symptom relapse and adverse effects that may emerge with continued treatment (eg, weight gain and sexual dysfunction). During drug discontinuation, monitor frequently for withdrawal symptoms, rebound anxiety, and relapse.

TREATMENT: SOCIAL ANXIETY DISORDER

Desired Outcomes

Social anxiety disorder is a chronic disorder that begins in adolescence and occurs with significant functional impairment and high rates of comorbidity. The goal of therapy for SAD is to reduce physiologic symptoms of anxiety, fear of social situations, and phobic behaviors. Patients with comorbid depression should have a significant reduction in depressive symptoms. The long-term goal is to restore social functioning and improve the patient's quality of life.

General Approach to Treatment

Patients with SAD may be managed with pharmacotherapy or psychotherapy. There is insufficient evidence to recommend one treatment over the other, and data are lacking on the benefits of combining treatment modalities. Pharmacotherapy often is the first choice of treatment owing to relative greater access and reduced cost compared with psychotherapy.[41,42] Children with SAD should be offered psychotherapy first.[12,41,42] Many patients will not achieve a full response.

Nonpharmacologic Therapy

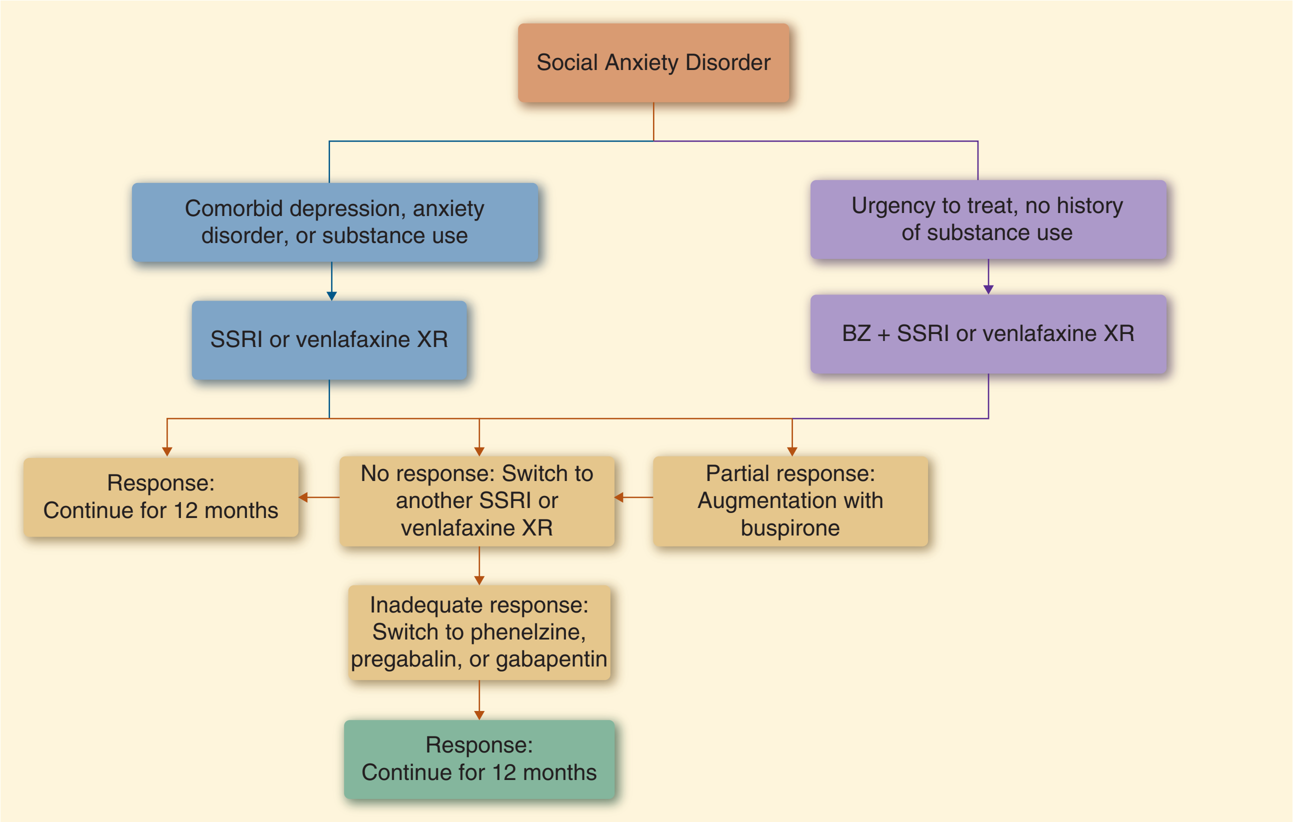
Patient education on disease course, treatment options, and expectations is essential. CBT is effective for reducing anxiety and phobic avoidance, and may lead to a greater likelihood of maintaining response after treatment discontinuation than does pharmacotherapy.[12,41] CBT targets avoidance-learning and negative-thinking patterns associated with social anxiety. iCBT- or CBT-based supported self-help are alternatives when access to face-to-face CBT is a barrier or declined.[12,42]

Pharmacologic Therapy

Several pharmacologic agents have demonstrated effectiveness in SAD, including the SSRIs, venlafaxine, phenelzine, benzodiazepines, gabapentin, and pregabalin (Table 41–5). **KEY CONCEPT** The SSRIs are considered first line based on their tolerability and efficacy for SAD and comorbid depression, if present. The onset of response for antidepressants may be as long as 8 to 12 weeks.[6,43] Patients responding to medication should be continued on treatment for at least 1 year.[6,12,42] Many patients relapse when medication is discontinued, and there are no clear predictive factors for who will maintain response.[43] Some patients may elect more long-term treatment owing to fear of relapse. A suggested treatment algorithm is shown in Figure 41–4.

▶ *Selective Serotonin Reuptake Inhibitors and Venlafaxine*

The efficacy of paroxetine, sertraline, escitalopram, fluvoxamine, and venlafaxine was established in large controlled trials.[6] SSRIs and SNRIs improve social anxiety and phobic avoidance and reduce overall disability. Approximately 50% of patients achieve response during acute treatment. SSRIs reduce the risk of relapse with extended treatment.[44] Limited data support the effectiveness of citalopram and fluoxetine in SAD.[44]



Social Anxiety Disorder
Comorbid depression, anxiety disorder, or substance use
Urgency to treat, no history of substance use
SSRI or venlafaxine XR
BZ + SSRI or venlafaxine XR
Response: Continue for 12 months
No response: Switch to another SSRI or venlafaxine XR
Partial response: Augmentation with buspirone
Inadequate response: Switch to phenelzine, pregabalin, or gabapentin
Response: Continue for 12 months

FIGURE 41–4. Algorithm for the pharmacotherapy of social anxiety disorder. (BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor; XR, extended release.) (Adapted from Melton ST, Kirkwood CK. Anxiety disorders I: generalized anxiety, panic and social anxiety disorders. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill; 2011:1209–1227, with permission.)

The initial dose of SSRIs and venlafaxine is similar to that used in depression. Patients should be titrated as tolerated to response. Patients with comorbid PD should be started on lower doses (see Table 41–6). When discontinuing SSRI/SNRIs, the dose should be tapered slowly to avoid withdrawal symptoms. Relapse rates may be as high as 50%, and patients should be monitored closely for several weeks.[42] Side effects of SSRI/SNRIs in SAD are similar to those seen in depression.

▶ *Monoamine Oxidase Inhibitors*

Phenelzine is generally reserved for treatment-refractory patients owing to dietary restrictions, drug interactions, and side effects.[12]

▶ *Alternative Agents*

Benzodiazepines Benzodiazepines may be useful for acute relief of physiologic symptoms of anxiety when used concomitantly with antidepressants or psychotherapy.[6] Benzodiazepines can also be used as second-line options if the patient does not have a history of substance use.[12] Long-term treatment is not desirable for many SAD patients because of the risk of withdrawal and difficulty with discontinuation, cognitive side effects, and lack of effect on depressive symptoms.

Anticonvulsants Gabapentin and pregabalin, structurally similar anticonvulsants, have each demonstrated modest benefit in a randomized, placebo-controlled trial.[6,12,44] Gabapentin was titrated to a maximum dose of 3600 mg/day and pregabalin to 600 mg/day. While both medications have good tolerability, they should be considered for patients with inadequate response to SSRI/SNRIs, due to better efficacy for comorbid conditions.[17]

β-Blockers β-Blockers decrease the physiologic symptoms of anxiety and are useful for reducing performance anxiety (eg, speech, interview). Propranolol or atenolol should be administered 1 hour before a performance situation. β-Blockers are not useful for management of SAD.[43,44]

Patient Encounter 2, Part 1

A 39-year-old woman experienced a motor vehicle accident about 4 months ago. After the accident she was in the hospital for 1 week with a broken leg. She does not remember much of the accident, except seeing headlights heading straight to her and then paramedics removing her from the car. Since the accident, she has not been able to drive. She has had nightmares for the past few months almost every night. Since the accident, she hasn't volunteered at her daughter's school or attended her weekly book club meeting. She has struggled at work, missing multiple deadlines due to trouble finishing tasks.

Med:

Levothyroxine 75 mcg one tablet daily

Her medical workup is noncontributory, and she is diagnosed with PTSD and recommended to start fluoxetine 20 mg daily.

What symptoms are consistent with a PTSD diagnosis?

What psychotherapy treatment would you recommend for her?

Clinical Presentation and Diagnosis of PTSD

General

Individuals have exposure to a traumatic event (actual or threatened death, serious injury, sexual violence). The patient's exposure to the event can be through direct experience, witnessing, learning about an event to a close family or friend, or repeated exposure or extreme exposure (eg, first responders).

Symptoms[1]

- Intrusion symptoms
  - Recurrent, intrusive distressing memories of the trauma
  - Recurrent, disturbing dreams related to the trauma
  - Reliving the traumatic event (eg, dissociative reaction)
  - Reminders of the trauma result in a physiologic reaction and/or psychological distress
- Stimuli avoidance
  - Memories, thoughts, or feelings related to the trauma
  - External reminders that trigger memories, thoughts, or feelings related to the trauma
- Persistent negative alterations in thinking and mood
  - Inability to remember key features of the traumatic event
  - Inability to feel pleasurable emotions (eg, happiness, love)
  - Isolating from others
  - Loss of interest in activities
  - Negative thoughts about the world or oneself
  - Distorted beliefs about traumatic event resulting in blaming self or others
  - Negative emotions (eg, fear, anger, guilt)
- Hyperarousal symptoms
  - Irritability or anger outbursts expressed as physical aggression
  - Self-destructive behavior
  - Hypervigilance
  - Startle easily ("jumpy")
  - Difficulty concentrating
  - Sleep disturbances
- Symptoms last more than 1 month
- Causes clinically significant distress or impairment in social, occupational, or other areas of functioning
- Not attributable to physiologic effects of a substance or another medical condition

Differential Diagnosis

Rule out underlying medical (traumatic brain injury) or psychiatric disorders (other trauma and stress-related disorders, psychotic disorders, personality disorders, other anxiety disorders, major depressive disorder) and medications that may cause anxiety (see Table 41–2).

OUTCOME EVALUATION

KEY CONCEPT Pharmacotherapy for patients with SAD should lead to improvement in anxiety and fear, functionality, and overall well-being.[6,42] Many patients will experience significant improvement in symptoms but may not achieve full remission. Monitor patients weekly during acute treatment (eg, initiation and titration of pharmacotherapy) and monthly once stabilized. Inquire about adverse effects, SAD symptoms, suicidal ideation, and symptoms of comorbid psychiatric conditions at each visit. Ask patients to keep a diary to record fears, anxiety levels, and behaviors in social situations.[6] Administer the Liebowitz Social Anxiety Scale (LSAS) to rate SAD severity and change, and the Social Phobia Inventory can be used as a "self-assessment" tool.[41] Counsel patients on appropriate expectations of pharmacotherapy in SAD, including gradual onset of effect and the need for extended treatment of at least 6 months following response.

TREATMENT: POSTTRAUMATIC STRESS DISORDER

Desired Outcomes

The goals of therapy for PTSD are to reduce the severity and duration of symptom clusters and restore overall functioning. The long-term goal is to achieve and maintain remission. With a positive response to treatment, comorbid mood or anxiety symptoms should be minimized.

General Approach to Treatment

Patients with PTSD may be managed with pharmacotherapy or psychotherapy. **KEY CONCEPT** Trauma-focused psychotherapy is preferred over pharmacotherapy or other psychotherapy treatments. Pharmacotherapy or non–trauma-focused psychotherapy are both first-line options if trauma-focused psychotherapy is not available.[45]

Nonpharmacologic Therapy

First-line treatment for PTSD is trauma-focused psychotherapy. Trauma-focused therapy involves engaging with the trauma memory for a prolonged period of time and identifying it as benign. This type of therapy includes prolonged exposure (PE), cognitive processing therapy (CPT), and eye movement desensitization and reprocessing (EMDR).[12,45] If trauma-focused psychotherapy is not available, non–trauma-focused therapy is recommended.[45] Treatment effects have been seen for up to 10 years posttreatment.[17]

Pharmacologic Therapy

Several pharmacologic agents have demonstrated effectiveness in PTSD, including some SSRIs, venlafaxine, TCAs, mirtazapine, nefazodone, prazosin, and phenelzine (Table 41–6). **KEY CONCEPT** Sertraline, fluoxetine, and paroxetine are considered the drugs of choice based on their tolerability and efficacy for PTSD and comorbid depression if present.[12,45] Patients responding to medication should be continued on treatment 6 to 12 months.[12,45] A suggested treatment algorithm is shown in Figure 41–5.

▶ *First- and Second-Line Options for Core Symptoms of PTSD*

Antidepressants The efficacy of fluoxetine, paroxetine, sertraline, and venlafaxine has been established in large controlled trials.[6]

The initial dose of first-line agents is similar to that used in depression. Patients should be titrated as tolerated to response. When discontinuing therapy, the dose should be tapered slowly

Table 41–6

Antidepressants for Posttraumatic Stress Disorder[2,12,45]

First-Line Options

Medication	Recommended Starting Dose (mg/day)	Usual Therapeutic Dosage Range (mg/day)
Fluoxetine	10–20	20–80
Paroxetine[a]	10–20	20–60
Sertraline[a]	25	50–200
Venlafaxine XR	37.5	75–225
Second-Line Options		
Phenelzine	15 three times daily	15 mg daily; 60–90 in divided doses
Nefazodone	25–100 twice daily	150–600 in 2 divided doses
Imipramine	25–75	100–300 in 1 or 2 divided doses

[a]Food and Drug Administration approved for use in posttraumatic stress disorder. XR=extended release

to avoid withdrawal symptoms. Side effects of therapy are similar to those seen in depression or anxiety disorders. Limited data support the effectiveness of citalopram, escitalopram, or desvenlafaxine for PTSD.[45]

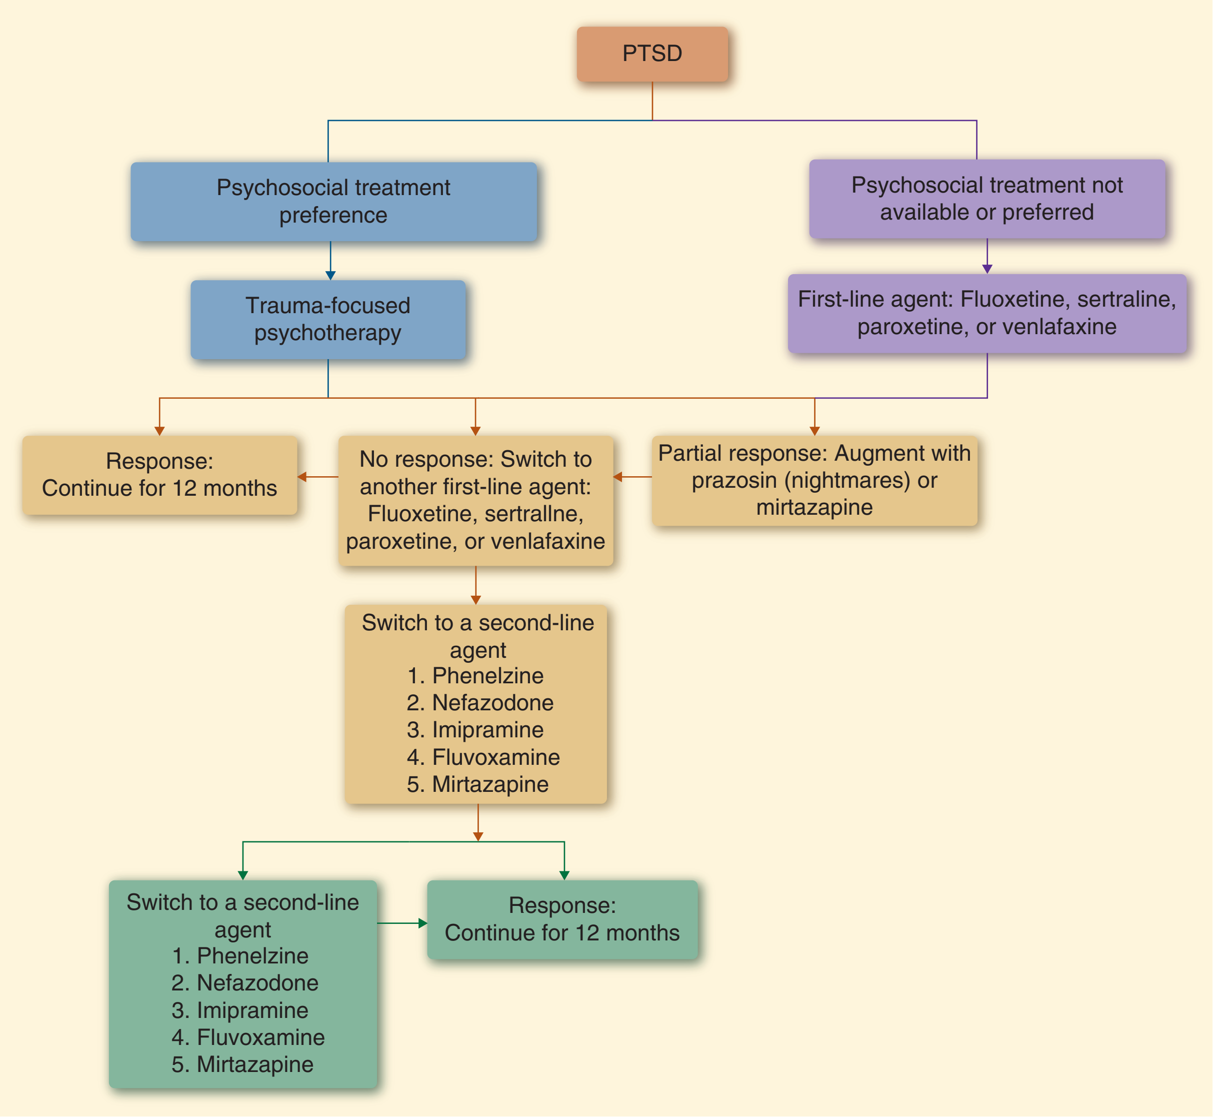
Phenelzine use is limited due to dietary restriction, tolerability, and drug–drug interaction. The effectiveness of phenelzine for PTSD has been demonstrated in small placebo and comparator (imipramine) studies.[6,12]

Imipramine is limited due to tolerability and concern in overdose. Imipramine for PTSD treatment has shown effectiveness versus placebo and equal efficacy to phenelzine in trials.[6,12]

Effectiveness of mirtazapine as monotherapy and combination therapy with sertraline have been shown in randomized trial and open label trials.[6,12] Although nefazodone use is limited due to hepatoxicity, it has shown efficacy in older studies[2,45] and is included in Department of Veterans Affairs clinical practice guideline for PTSD.[45]

▸ *Adjunctive Therapy for Symptoms of PTSD*

Prazosin has historically been used for the treatment of nightmares associated with PTSD based on limited effectiveness data.



PTSD
Psychosocial treatment preference
Psychosocial treatment not available or preferred
Trauma-focused psychotherapy
First-line agent: Fluoxetine, sertraline, paroxetine, or venlafaxine
Response: Continue for 12 months
No response: Switch to another first-line agent: Fluoxetine, sertrallne, paroxetine, or venlafaxine
Partial response: Augment with prazosin (nightmares) or mirtazapine
Switch to a second-line agent 1. Phenelzine 2. Nefazodone 3. Imipramine 4. Fluvoxamine 5. Mirtazapine
Switch to a second-line agent 1. Phenelzine 2. Nefazodone 3. Imipramine 4. Fluvoxamine 5. Mirtazapine
Response: Continue for 12 months

FIGURE 41–5. Algorithm for the pharmacotherapy of posttraumatic stress disorder (PTSD). (Data from Refs. 2, 12, 45.)

Patient Encounter 2, Part 2

Patient returns to clinic 2 months after starting fluoxetine 20 mg daily. She is currently on fluoxetine 60 mg daily with no response to treatment. Her symptoms have persisted for the last 2 months. She continues to take levothyroxine 75 mcg daily.

What change in treatment is needed for this patient?

What tool could be used to monitor her response to treatment?

It continues to be included in guidelines for this use, although the newest Veteran's Administration guidelines for PTSD could not recommend for or against its use.[2,6,12,45]

The SGAs, risperidone, aripiprazole, and quetiapine have limited evidence for intrusion symptoms associated with PTSD and refractory PTSD. Prior to initiating SGA therapy for PTSD symptoms, the benefit of treatment needs to be weighed against the adverse effects associated with their use.[12]

Benzodiazepines have limited evidence for PTSD symptoms and are not recommended for the symptoms specific to PTSD.[7,12,45]

Outcome Evaluation

Pharmacotherapy for patients with PTSD should lead to improvement in PTSD symptoms, functionality, and overall well-being. Monitor patients weekly during acute treatment (eg, initiation and titration of pharmacotherapy) and monthly once stabilized. Inquire about adverse effects, PTSD symptoms, suicidal ideation, and symptoms of comorbid psychiatric conditions at each visit. Administer the PTSD Checklist for *DSM-5* (PCL-5) to rate PTSD severity and treatment response.[45] Counsel patients on appropriate expectations of pharmacotherapy in PTSD and the need for extended treatment of at least 6 months following response. If pharmacotherapy is being discontinued, educate patient about tapering medication and how to return for treatment in the future if needed.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Drs. Sheila Botts, Sallie Charles, and Douglas Newton, authors of this chapter in the first through fifth editions of this book.

Patient Care Process

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements. Identify allergies to medications.
- Review medical history and physical examination findings.
- Review mental status examination and screen for depression, anxiety, and substance use.
- Interview the patient and review records to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect treatment access or preference.

Assess the Information:

- Determine whether the patient is taking any medication or substance that could cause or worsen anxiety (Table 41–2).
- Review relevant laboratory tests (eg, urine toxicology, thyroid-stimulating hormone).
- Document pertinent family medical and mental health history (eg, depression, anxiety, substance use, suicide).
- Based on clinical presentation, mental status examination, and screening tools (eg, GAD-7), determine whether the patient is experiencing symptoms of sufficient intensity and duration to warrant treatment.
- Document current symptom severity using a valid measurement-based tool (eg, GAD-7, LSAS, PDSS).
- Identify comorbidities that will affect treatment choice (eg, depression, substance use).
- Assess the efficacy, safety, and adherence of current pharmacotherapy, if applicable.
- Identify any significant adverse drug effects or drug interactions.

Develop a Care Plan:

- Select lifestyle modifications and antianxiety medications that are likely to be effective and safe.
- Use shared decision making for selection of behavioral and pharmacotherapy treatment intervention(s).
- Choose medications and doses that are optimal for the patient based on age, anxiety disorder, and comorbid conditions (see Tables 41–3, 41–4, and 41–6).

Implement the Care Plan:

- Educate the patient about antianxiety medication effectiveness, onset and expected time to benefit, administration, and common adverse effects.
- Address any patient concerns about anxiety and its management.
- Discuss the importance of lifestyle modifications to reduce anxiety (eg, social support, substance use, exercise).
- Determine whether the patient has access to recommended medication or behavioral treatment (eg, insurance, medication on formulary, CBT provider nearby).

Follow-up: Monitor and Evaluate:

- Follow up at monthly intervals or more frequently during acute treatment to assess effectiveness and tolerability until treatment goal achieved.
- Review medication adherence and anxiety symptom control.
- Use appropriate rating scales to assess symptom change over time.
- Once anxiety is controlled and baseline function restored, determine the appropriateness of treatment beyond 1 year based on the patient's previous treatment and comorbid conditions.

Abbreviations Introduced in This Chapter

CBT	Cognitive-behavioral therapy
CNS	Central nervous system
DA	Dopamine
FDA	Food and Drug Administration
GABA	γ-Aminobutyric acid
GAD	Generalized anxiety disorder
HPA	Hypothalamic–pituitary–adrenal
5-HT	Serotonin
iCBT	Internet-based cognitive-behavioral therapy
LC	Locus ceruleus
LSAS	Liebowitz Social Anxiety Scale
MAOI	Monoamine oxidase inhibitor
MDD	Major depressive disorder
NCS-R	National Comorbidity Survey, Replication
NE	Norepinephrine
NPY	Neuropeptide Y
OCD	Obsessive-compulsive disorder
OTC	Over-the-counter
PD	Panic disorder
PDSS	Panic Disorder Symptom Scale
PTSD	Posttraumatic stress disorder
RAS	Reticular activating system
SAD	Social anxiety disorder
SGA	Second-generation antipsychotic
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant

Sleep Disorders

Jessa Marie Koch and Azita Alipour

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the sequelae of undiagnosed or untreated sleep disorders and appreciate the importance of successful treatment of sleep disorders.
2. Describe the pathophysiology and characteristic features of the sleep disorders covered in this chapter, including insomnia, narcolepsy, restless legs syndrome (RLS), obstructive sleep apnea (OSA), and parasomnias.
3. Assess patient sleep complaints, conduct sleep histories, and evaluate sleep studies to recognize daytime and nighttime symptoms and characteristics of common sleep disorders.
4. Recommend and optimize appropriate sleep hygiene and nonpharmacologic therapies for the management and prevention of sleep disorders.
5. Recommend and optimize appropriate pharmacotherapy for sleep disorders.
6. Describe the components of the patient care process to implement and assess safety and efficacy of pharmacotherapy for common sleep disorders.
7. Educate patients about preventive behavior, appropriate lifestyle modifications, and drug therapy required for effective treatment and control of sleep disorders.

INTRODUCTION

Individuals with normal sleep patterns sleep up to one-third of their lives and spend more time sleeping than in any other single activity. Despite this, our understanding of the full purpose of sleep and the mechanisms regulating sleep homeostasis remain incomplete. Sleep is necessary to allow one to maintain wakefulness and good health. Disruption of normal sleep is a major cause of societal morbidity, lost productivity, reduced quality of life, and contributes to the development and progression of comorbid medical conditions.[1]

Sleep is governed and paced by the suprachiasmic nucleus in the brain that regulates circadian rhythm. There are two main types of sleep: rapid eye movement (REM) sleep, during which eye movements and dreaming occur, but the body is mostly paralyzed, and nonrapid eye movement (NREM) sleep, which consists of three substages (stages 1–3). Stage 1 serves as a transition between wake and sleep and is NREM sleep. This stage of sleep typically lasts several minutes. Most of the time being asleep is spent in stage 2 NREM sleep and is a period of light sleep. Stage 3 is referred to as *deep sleep*, or *delta sleep*, because prominent delta waves are seen on the electroencephalogram (EEG) during this stage of sleep. Stage 3 is considered to be restorative sleep and is needed to feel refreshed in the morning. REM sleep occurs about every 90 minutes upon falling asleep.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 50% of adults will report a sleep complaint over the course of their lifetime.[2] In general, sleep disturbances increase with age and may vary among genders. The full extent and impact of disordered sleep on our society is not known because many patients' sleep disorders remain undiagnosed. Normal sleep, by definition, is "a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment."[3] Individuals with sleep disorders exhibit or complain about consequent symptoms (eg, excessive daytime sleepiness [EDS]) or a bed partner often observes hallmark characteristics of the sleep disorder. Insomnia, restless legs syndrome (RLS), and sleep-related breathing disorders are the most common sleep disorders.

Insomnia

Nearly one-third of all adults report symptoms of insomnia with around 10% of those individuals meeting *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) criteria for insomnia disorder. The prevalence of insomnia is greater among females compared to males. In females, onset of insomnia is often associated with the birth of a child as well as with menopause.[4] **KEY CONCEPT** Diagnostic criteria for insomnia specify that difficulty initiating sleep, maintaining sleep or early morning awakenings occur at least three times per week for a minimum duration of at least 3 months. It is estimated that 50% to 75% of individuals with comorbid psychiatric (eg, depression, anxiety) and/or chronic pain disorders have accompanying insomnia.[2] Insomnia is frequently triggered by acute stress and resolves when the stress resolves. Numerous coexisting medical conditions (eg, pain, thyroid abnormalities, asthma, gastroesophageal reflux) and medications (eg, selective serotonin reuptake inhibitors [SSRIs], steroids, stimulants, diuretics, β-agonists) can lead to secondary insomnia.

Narcolepsy

In comparison to insomnia, narcolepsy is much less prevalent. It is estimated that 0.02% to 0.04% (or about 1 in 2000) of the population have narcolepsy. The onset of narcolepsy symptoms generally occurs in childhood and adolescence with diagnosis taking 5 to 15 years.[4] Narcolepsy is further classified into type 1 (narcolepsy with cataplexy and low orexin levels) and type 2 (narcolepsy without cataplexy and normal orexin levels).[5,6] Around 75% of patients with narcolepsy have narcolepsy type 1.[7]

Restless Legs Syndrome

The prevalence of RLS ranges from 5% to 15% of which around 2.5% of individuals require medical treatment.[4,8] Prevalence increases with age and in various medical conditions, such as end-stage renal disease, pregnancy, and iron deficiency.[9] RLS appears to be more common in women than in men and has a genetic link in a majority of patients.[10]

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) affects between 2% and 15% of adults who are middle-aged, with risk increasing with older age to greater than 20%. There is a higher prevalence of OSA in males, with a male: female ratio of up to 4:1. This ratio decreases in older age, possibly due to the frequency increasing in females after menopause. In addition, there is a strong association between OSA and obesity.[4]

Individuals with OSA experience repetitive upper airway collapse during sleep, which decreases or stops airflow, with subsequent arousal from sleep to resume breathing. Severity is determined by polysomnography (PSG) or home sleep study and is graded by the number of episodes of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) experienced during sleep. Severity is expressed as the respiratory disturbance index (RDI), quantified in events per hour.

Parasomnias

NREM parasomnias have variable prevalence rates depending on patient age and comorbid diagnoses. Sleep talking, bruxism, sleepwalking, sleep terrors, and enuresis occur more frequently in childhood than in adulthood. For instance, sleepwalking occurs at least once in 10% to 30% of children and has a lifetime prevalence in adults of 29.2%.[4] Nightmares appear to occur with similar frequency in adults and children whereas sleep terror episodes occur in 36.9% in individuals of 18 months of age as opposed to 2.2% in adults.[4] REM sleep behavior disorder (RBD), a REM sleep parasomnia, has a reported prevalence of 0.5%, is more common in elderly men and is frequently associated with concomitant neurologic conditions.[4,11]

PATHOPHYSIOLOGY

Although the neurophysiology of sleep is complex, certain neurotransmitters promote sleep and wakefulness in different areas of the central nervous system (CNS). Whereas serotonin is thought to control NREM sleep, cholinergic and adrenergic transmitters mediate REM sleep. Dopamine, norepinephrine, hypocretin (also referred to as orexin), substance P, and histamine all play a role in wakefulness. Perturbations of various neurotransmitters are responsible for some sleep disorders and explain why various treatments are beneficial.

Insomnia

There is no single pathophysiologic explanation for the manifestations of insomnia. Current hypotheses focus on a combination of possible models that incorporate physiologic, cognitive, and cortical arousal. Most models focus on hyperarousal and its interference with the initiation or maintenance of sleep.

Narcolepsy

The exact pathophysiology of narcolepsy is not entirely known. Although individuals with type 1 or type 2 narcolepsy share phenotypic features of the disorder, the underlying cause is believed to differ between the two types. Type 1 narcolepsy is caused by a loss of neurons in the hypothalamus that produce orexin. Type 2 narcolepsy may also be caused by injury or damage to these neurons, but to a much lesser degree due to the normal levels of orexin seen in type 2.[5,6] Genetics also play a significant role in type 1 narcolepsy with 98% of individuals with this subtype carrying HLA-DQB1∗06:02 compared to about 50% of those with type 2 narcolepsy.[12] Another interesting aspect to the disease is onset of symptoms. Symptoms more commonly present in the late spring, which may suggest an autoimmune process from infection such as group A streptococcal infection or influenza that then triggers the attack to the orexin-producing neurons.[13]

Restless Legs Syndrome

RLS is a neurologic medical condition characterized by an irresistible desire to move the limbs. The two main theories surrounding the pathophysiology of RLS center around iron and dopamine pathologies.[8] Dopaminergic dysfunction in individuals with RLS is supported by the dopaminergic medications that reduce RLS symptoms in patients. Likewise, individuals with RLS have been found to have reduced serum ferritin levels. Iron and H-ferritin concentrations, along with transferrin receptor and iron transporter numbers, have been found to be reduced in the substantia nigra of patients with RLS.[14] It is hypothesized that iron abnormalities lead to dysfunction of dopaminergic transmission in the substantia nigra.[15]

Obstructive Sleep Apnea

At least 20 muscles and soft tissue structures control patency of the upper airway. Patients with OSA may have differences in upper airway muscle activity during sleep and may have smaller airways, predisposing them to upper airway collapse and consequent apneic episodes during sleep. The inability of the upper airway to contend with factors that promote collapse, including fat deposition in the neck, negative pressure in the airway during inspiration, and a smaller lower jawbone, also may play a role in the pathogenesis of OSA. Patients with sleep apnea often are obese and may be predisposed to weight gain.

Poor sleep architecture and fragmented sleep secondary to OSA can cause EDS and neurocognitive deficits. These sequelae can affect quality of life and work performance and may be linked to occupational and motor vehicle accidents. OSA is also associated with systemic disease such as hypertension, arrhythmias, heart failure, stroke, and ischemic heart disease.[16,17] Hypertension frequently occurs in OSA and may be a contributing cause of increased cardiovascular conditions found in this population.[18] Furthermore, when hypertension is present, it is often resistant to antihypertensive therapy. Breathing against a closed upper airway during sleep causes intermittent and repetitive episodes of hypoxemia and hypercapnia, dramatic changes in intrathoracic pressure, and activation of the sympathetic nervous system. These responses can produce acute hemodynamic and humoral responses.[19]

Parasomnias

The pathogenesis of both NREM and REM parasomnias (eg, sleepwalking, enuresis, sleep talking) is variable, poorly described, and involves state dissociation, whereby two states of being overlap

Clinical Presentation and Diagnosis

KEY CONCEPT Patients with sleep complaints should have a careful sleep history performed to assess their possible sleep disorder in order to guide diagnostic and therapeutic decisions.

Daytime Symptoms and Associated Characteristics

EDS is the primary symptom described by patients with sleep disorders. It is usually described as not waking up refreshed in the morning or falling asleep or fighting the urge to sleep during the day despite a night of sleep. Other daytime characteristics of sleep disorders include:

- Irritability, fatigue, or depression
- Confusion or impaired performance at work or school
- Cataplexy
- Hypertension

Nighttime Sleep Complaints

Depending on the sleep disorder, patients may exhibit or experience various nocturnal complaints during sleep. Some complaints can be uncovered by clinical history alone (eg, hallucinations, RLS, snoring), but others can be diagnosed during sleep studies (eg, OSA, nighttime awakenings, somnambulism [sleepwalking], etc). Frequent complaints include:

- Inability to fall asleep, nighttime awakenings
- Sleepwalking (somnambulism), sleep talking (somniloquy)
- Cessation of breathing (apnea), snoring
- Sleep paralysis or hallucinations when waking or falling asleep
- Restlessness and periodic limb movements of sleep

simultaneously. For example, abnormal activation of the central pattern generator of the spinal cord that produces motor movements is hypothesized to underlie sleepwalking behavior. In RBD, active inhibition of motor activity in the perilocus coeruleus region is lost, resulting in loss of paralysis and dream enactment.

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT Although the clinical history guides diagnosis and therapy, only PSG, home sleep studies, and/or multiple sleep latency tests (MSLTs) can definitively diagnose and guide therapy for OSA and narcolepsy. All patients presenting with sleep complaints should have a thorough interview and history to inventory their sleep habits and sleep hygiene.

Sleep Diagnostics

Complete PSG is the "gold standard" for diagnosing and identifying sleep-disordered breathing, parasomnias, and nocturnal sleep irregularities related to narcolepsy. Sleep is observed and monitored in a controlled setting, recording sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, heart rhythm, airflow, respiratory effort, and oxygen desaturations. Home sleep studies are increasingly used to diagnose sleep apnea due to their reduced cost and increased patient convenience.[1,4,16]

The MSLT is a commonly performed test to assess daytime sleepiness. During the MSLT, the patient attempts to take a 20-minute nap every 2 hours during the day beginning 2 hours after morning awakening (after a normal night's sleep) to evaluate physiologic sleepiness. The patient is instructed not to resist the urge to fall asleep. Sleep latency of less than 5 minutes is considered pathologic hypersomnolence. The occurrence of a REM onset period during two naps with short sleep latency is indicative of a diagnosis of narcolepsy.[1,4]

Insomnia

Insomnia is often characterized by difficulty falling asleep, frequent nocturnal awakenings, and early morning awakenings, which may result in daytime impairments in concentration and school or work performance. In some situations, social factors (eg, family difficulties, bereavement), medications (eg, antidepressants, β-agonists, corticosteroids, decongestants), and coexisting medical or psychiatric conditions (eg, depression, bipolar disorder) may help to explain difficulties in initiating and maintaining sleep.

Narcolepsy

The hallmark of narcolepsy is EDS and may also include disrupted nighttime sleep. Many patients with narcolepsy experience a tetrad of symptoms: EDS, cataplexy, sleep paralysis, and hypnagogic/hypnopompic hallucinations (dream-like images that appear at sleep–wake transitions).

Restless Legs Syndrome

Although RLS symptoms can vary, patients commonly report "creepy-crawly," burning, tingling, or achy feelings in the legs or arms. These sensations create a desire to move the limbs and may produce motor agitation. Symptoms begin to get worse in the evening and are almost exclusively present at rest, with temporary relief with movement.[4] Symptoms also can occur during sleep and often lead to semirhythmic periodic limb movements of sleep. Periodic limb movements of sleep are objective findings during PSG recorded by leg electrodes and present in most patients with RLS but may occur independently.

Obstructive Sleep Apnea

Common characteristics of OSA include snoring, choking, gasping for air, nocturnal reflux symptoms, and morning headaches.[4] A bed partner or roommate may observe these apneic episodes where the patient stops breathing. Patients with large neck sizes (> 45 cm [~18 in] neck circumference) and a body mass index (BMI) of 30 kg/m^2 or greater are at higher risk for OSA. OSA should always be considered and evaluated in hypertensive patients who are resistant to therapy.

Parasomnias

Parasomnias are characterized by undesirable physical or behavioral phenomena that occur during sleep (eg, sleepwalking, sleep eating, sleep talking, bruxism [grinding of teeth], enuresis, night terrors, and RBD). People with RBD act out their dreams during sleep, often in a violent manner.

TREATMENT

Desired Outcomes and General Approach to Treatment

KEY CONCEPT Treatment goals vary among different sleep disorders but generally include restoration of normal sleep patterns, elimination of daytime sequelae, improved quality of life, and prevention of complications and adverse effects from therapy.[1,4]

Table 42–1

Nonpharmacologic Therapies for Insomnia

Sleep Hygiene
- Keep a regular sleep schedule.
- Exercise frequently but not immediately before bedtime.
- Avoid alcohol and stimulants (caffeine, nicotine) in the late afternoon and evening.
- Maintain a comfortable sleeping environment that is dark, quiet, and free of intrusions.
- Avoid consuming large quantities of food or liquids immediately before bedtime.

Stimulus Control
- Go to bed only when sleepy.
- Avoid daytime naps.
- If you cannot sleep within approximately 20 minutes, get out of bed and go to another room—only return to your bed when you feel the need to sleep.
- Bed is for sleep and intimacy only (no eating or watching TV on bed).
- Always wake up at the same time each day.

Relaxation Training
- Reduce somatic arousal (muscle relaxation).
- Reduce mental arousal (eg, attention-focusing procedures, imagery training, meditation).
- Use biofeedback (visual or auditory feedback to reduce tension).

Cognitive Therapy
- Alter beliefs, attitudes, and expectations about sleep.

Insomnia

KEY CONCEPT Psychological and behavioral interventions for insomnia are effective for adults of all ages. First-line therapy for the treatment of insomnia is nonpharmacological: cognitive-behavioral therapy for insomnia (CBT-I).[2] A number of nonpharmacologic interventions for insomnia are outlined in Table 42–1. Sleep hygiene should be reinforced in all patients; however, insufficient evidence supports its use alone.[2] Rather, good sleep hygiene principles should be combined with behavioral, cognitive, and stimulus-control interventions. Pharmacologic treatment with short-term hypnotic use should be adjunctive to nonpharmacologic therapies.[2] An algorithm for the initial assessment and first treatment step of EDS is provided in Figure 42–1.

In referring to pharmacologic treatment for insomnia, the ideal hypnotic medication would be effective at reducing sleep latency, maintaining sleep, increasing total sleep time, and would be free of unwanted adverse effects. **KEY CONCEPT** Pharmacologic treatment of insomnia is considered a second-line intervention. Treatment guidelines vary slightly regarding which medication is recommended for what primary complaint or patient population. In general, intermediate-acting NBRAs, eszopiclone or zolpidem, or the benzodiazepine, temazepam, may be preferable in patients with complaints of sleep onset difficulty as well as difficulty with sleep maintenance.[2] In individuals solely with sleep onset difficulty, zaleplon, ramelteon, or triazolam may be the best options to consider due to their improvement in reducing sleep latency.[2] For those with complaints of difficulty maintaining sleep, doxepin or suvorexant may be best given evidence to support reduction in time spent awake after sleep onset, improvement in total sleep time, and sleep efficiency.[2] Guidelines are not clear on duration of treatment but will vary depending on pharmacologic medication selected. Eszopiclone, zolpidem CR, and ramelteon have been studied for use up to a 6-month duration whereas zaleplon use should be limited to 30 days.[20-24]

Patient Encounter, Part 1

A 58-year-old woman with a history of chronic insomnia complains of worsened symptoms over the last 2 months: excessive daytime sleepiness, difficulty falling asleep (sleep latency of 2 hours), and frequent nighttime awakenings. She has been followed by a therapist for CBT-I and taking melatonin 3 mg nightly. She reports doing well for 2 months following this treatment plan. Her other medications include sertraline 100 mg daily, furosemide 20 mg daily, lisinopril 10 mg daily, and carvedilol 6.25 mg twice daily.

What additional information do you need to know in your assessment of this patient?

What could contribute to worsening insomnia in this patient?

▶ *Benzodiazepines*

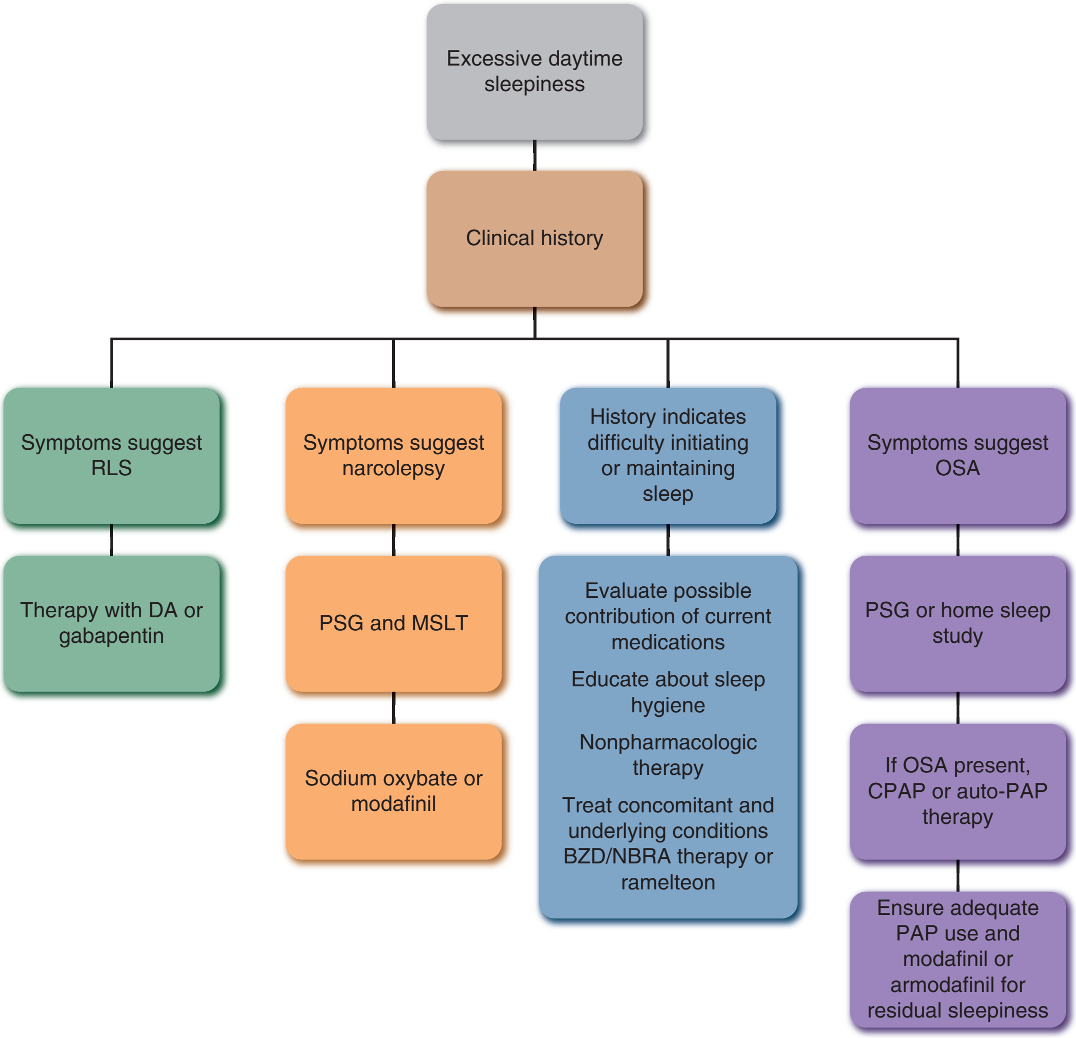
Although all benzodiazepines have sedative-hypnotic properties, only five are FDA approved for the treatment of insomnia: estazolam, temazepam, triazolam, flurazepam, and quazepam. Key pharmacokinetic differences between these five agents help to guide selection, depending on patient considerations and specific sleep complaints (Table 42–2). The benzodiazepines work by binding to a site on the γ-aminobutyric acid (GABA) type A receptor complex, resulting in opening of chloride channels that facilitate GABA inhibition and promote sleepiness.[25] In turn, benzodiazepines decrease sleep latency, increase stage 2 sleep, reduce delta sleep and REM sleep, and some may increase total sleep time.[25]

▶ *Nonbenzodiazepine Receptor Agonists*

NBRAs have a very similar mechanism of action to the BZDs with some subtle differences in exact binding affinities, limiting their efficacy as sedative-hypnotics only.[25] One way in which the NBRAs differ from the BZDs is selectivity for the α_1 subtype of the α subunit on GABA_A. This subtype is known to produce sedation. The BZDs are not as selective and bind to four of the α subtypes on the α subunit on GABA_A.[25] The three NBRAs include eszopiclone, zaleplon, and zolpidem.

Patients should be instructed to take BZDs/NBRAs at bedtime and avoid activities requiring alertness after ingestion. Although BDZs and NBRAs are generally well-tolerated, mild-to-moderate adverse effects can occur, and precautions are warranted.

Precautions and Safety The most common adverse effects associated with BZDs and NBRAs include residual sedation into the waking hours after sleep, grogginess, and psychomotor impairment.[25] Selection of a hypnotic with a duration of action matching the patient's budgeted sleep time can help minimize the risk of residual sedation. BZDs and NBRAs should be initiated at low doses and should ideally be avoided in elderly patients for a number of reasons, but one being an increased risk for falls.[26,27] BZDs may cause anterograde amnesia, defined as memory loss of activities and interactions after ingestion of the drug.[27] Additionally, the BZDs carry a black box warning regarding concomitant use with opioids. The use of BZDs with opioids may result



Excessive daytime sleepiness
Clinical history
Symptoms suggest RLS
Therapy with DA or gabapentin
Symptoms suggest narcolepsy
PSG and MSLT
Sodium oxybate or modafinil
History indicates difficulty initiating or maintaining sleep
Evaluate possible contribution of current medications
Educate about sleep hygiene
Nonpharmacologic therapy
Treat concomitant and underlying conditions BZD/NBRA therapy or ramelteon
Symptoms suggest OSA
PSG or home sleep study
If OSA present, CPAP or auto-PAP therapy
Ensure adequate PAP use and modafinil or armodafinil for residual sleepiness

FIGURE 42–1. Primary assessment and initial treatment for complaint of excessive daytime sleepiness. (BZD, benzodiazepine; CPAP, continuous positive airway pressure; DA, dopamine agonist; MSLT, multiple sleep latency test; NBRA, nonbenzodiazepine receptor agonist; PSG, polysomnography; OSA, obstructive sleep apnea; PAP, positive airway pressure; RLS, restless legs syndrome.)

Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Test

The patient undergoes further evaluation for her worsening insomnia symptoms.

PMH: Chronic insomnia × 10 years, major depressive disorder × 2 years, generalized anxiety disorder × 1 year, congestive heart failure × 4 years

FH: Noncontributory

SH: Married, no children. No tobacco or alcohol intake

Meds:

- Melatonin 3 mg nightly (patient purchases over the counter)
- Sertraline 100 mg daily
- Furosemide 20 mg daily
  - Of note, this medication was started about 3 months ago. Patient takes at bedtime to minimize bathroom use during the day
- Lisinopril 10 mg daily
- Carvedilol 6.25 mg twice daily

ROS: (+) daytime sleepiness; (+) symptoms of anxiety (Generalized Anxiety Disorder 7-Item Scale score: 19 out of 21, indicating severe symptoms of anxiety)

PE: Complete physical examination was unremarkable

VS: BP 122/68 mm Hg, P 72 beats/min, RR 16 breaths/min, T 37°C (98.6°F); BMI 21 kg/m^2

Labs: All within normal limits

Given this additional information, summarize what is occurring with this patient.

Identify your treatment goals and therapy recommendations for the patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient?

Table 42–2

Pharmacokinetics and Dosing of Prescription Medications[a] Approved to Treat Insomnia

Generic Name (Brand)	Class	Parent t½ (hours)	Daily Dose Range (mg)	Recommended Daily Dose in Elderly (mg)[b]	Dose or Action in Hepatic Impairment	Comments
Doxepin (Silenor)	Antidepressant	15.3	3–6	3	3 mg	Effective for sleep maintenance difficulties only. Noncontrolled substance
Estazolam (Prosom)	BZD	2	1–2	0.5[e]	Dose ↓ may be needed	Moderate duration. CIV
Eszopiclone (Lunesta)	NBRA	6	2–3	1–2[e]	1 mg in severe impairment	Can be used up to 6 months for chronic insomnia. CIV
Flurazepam (Dalmane)	BZD	8	15–30	15[e]	No change necessary	High risk of hangover and residual effects. CIV
Lemborexant (Dayvigo)	Orexin receptor antagonist	17–19	5–10	5	5 mg maximum in moderate hepatic impairment	Novel mechanism of action. CIV
Quazepam (Doral)	BZD	2	7.5–15	7.5–15[e]	Dose ↓ may be needed	High risk of hangover and residual effects. CIV
Ramelteon (Rozerem)	Melatonin receptor agonist	1–2.6	8	No specific recommendations	Do not use in severe hepatic impairment	Noncontrolled substance; may be useful in patients with a history of substance abuse
Suvorexant (Belsomra)	Orexin receptor antagonist	12	10–20	No specific recommendations	No change necessary	Novel mechanism of action. CIV.
Temazepam (Restoril)	BZD	10–15	7.5–30	7.5	No change necessary	Moderate duration, well-tolerated, inexpensive. CIV
Triazolam (Halcion)	BZD	2	0.125–0.25	0.125[e]	0.125 mg	Short acting; little residual hangover. CIV
Zaleplon (Sonata)	NBRA	1	5–10	5[e]	5 mg	Short acting; only for difficulty falling asleep. CIV
Zolpidem (Ambien)	NBRA	2–2.6	5–10[d]	5[e]	5 mg	Short-to-moderate duration; no effects on sleep architecture. CIV
Zolpidem CR (Ambien CR)	NBRA	2.8	6.25–12.5[d]	6.25[e]	6.25 mg	Longer duration of action than regular-release zolpidem. CIV
Zolpidem sublingual (Intermezzo)	NBRA	2.5	1.75–3.5[d]	1.75[e]	1.75 mg	Approved for middle-of-the-night insomnia taken more than 4 hours before awakening. CIV

[a] In 2007, the Food and Drug Administration required additional information added to the safety labeling of sedative–hypnotic drugs concerning potential risks, including severe allergic reactions and complex sleep-related behaviors, which may include sleep driving. Sleep driving is defined as driving while not fully awake after ingestion of a sedative–hypnotic product with no memory of the event.

[b] If a dosing range is displayed, the first dose listed should be the starting dose.

[c] Data not available.

[d] For zolpidem, recommended dose for women is 5 mg, 6.25 mg for zolpidem CR, and 1.75 mg for sublingual zolpidem.

[e] These agents are all included on the updated 2019 Beers criteria and should be avoided in the elderly when possible.

BZD, benzodiazepine; CIV controlled substance schedule IV, CR, controlled release; NBRA, nonbenzodiazepine receptor agonist

in greater levels of sedation, respiratory depression, coma, and death. BZDs should not be used in conjunction with other sedating medications or alcohol due to concern for increased CNS depression.

On discontinuation of BZDs and NBRAs, patients may experience rebound insomnia that may last for a few nights. Rebound insomnia occurs more frequently after discontinuation of shorter-acting BZDs and NBRAs compared with longer-acting BZDs and NBRAs. Intermittent hypnotic therapy with the lowest dose possible reduces the likelihood of tolerance, dependence, and withdrawal when therapy is stopped. Patients should be counseled that rebound insomnia is not necessarily a return of their original symptoms, and it may take a few nights for rebound symptoms to subside. In general, eszopiclone, zaleplon, and zolpidem appear to be associated with lower risk of tolerance, rebound insomnia, and withdrawal than traditional benzodiazepines.[28] The NBRAs, however, are associated with complex sleep-related behaviors (eg, sleep eating, sleep driving, etc), and all carry a boxed warning regarding this risk. Female patients have reduced zolpidem clearance compared to males, and the maximum dose of zolpidem is 5 mg for female patients.[22]

► *Sedating Antidepressants*

Sedating antidepressants (eg, trazodone, amitriptyline, mirtazapine, doxepin) are commonly used for insomnia and may be an appealing option in patients with concomitant depression. However, at the doses frequently used for sleep, only mirtazapine exhibits significant antidepressant activity. Furthermore, quality clinical studies demonstrating efficacy for insomnia are lacking.[2,29] Adverse effects from antidepressants can be frequent, including next day sedation, grogginess, anticholinergic effects, and weight gain. Tricyclic antidepressants (TCAs; eg, amitriptyline, doxepin) should be used with caution in the elderly and patients with cardiovascular and hepatic impairment. Doxepin is approved for treatment of sleep maintenance insomnia at low doses (3–6 mg). Mirtazapine can cause daytime sedation, dizziness, and weight gain; trazodone can cause orthostatic hypotension and dizziness.

▶ *Miscellaneous Agents*

Ramelteon, a melatonin receptor agonist, is indicated for insomnia characterized by difficulty with sleep onset. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse.[30] Suvorexant and lemborexant, orexin receptor antagonists, are the first medications that turn off wakefulness mechanisms instead of stimulating pathways that induce sleepiness. Suvorexant and lemborexant are both indicated for insomnia characterized by both difficulty initiating and maintaining sleep, and like BZD and NBRA are classified as Schedule IV controlled substances.[31,32] Both suvorexant and ramelteon have documented safety in those with mild-to-moderate chronic obstructive pulmonary disease and OSA while evidence for lemborexant in this population is limited at this time.[31-34]

▶ *Over-the-Counter Agents*

Over-the-counter first-generation antihistamines, such as diphenhydramine and doxylamine, are frequently used for difficulty sleeping. Diphenhydramine and doxylamine are FDA approved for the treatment of insomnia and can be effective at reducing sleep latency. However, first-generation antihistamine medications produce undesirable anticholinergic effects and carryover sedation that limit their use, especially in the elderly. Additionally, rapid tolerance can develop to antihistamines, thus use beyond 10 days is not recommended.[35]

Melatonin is an endogenous hormone that is secreted by the pineal gland to regulate the body's circadian rhythm and is available exogenously as a supplement. Doses of 8 mg or less seem to be safe for use for up to 6 months; however, there is limited evidence to support its use for insomnia in individuals.[36] Valerian root is a herb that has inconsistent effects on sleep but may reduce sleep latency and increase efficiency at commonly used doses of 400 to 900 mg valerian extract.[37]

Patient Encounter, Part 3: Modifying the Treatment Plan

The patient returns to the clinic 3 months later. The provider previously decided to increase the dose of the patient's sertraline to better control her symptoms of anxiety and changed the furosemide schedule to morning. She was also started on zolpidem 5 mg to take nightly as needed if insomnia persists. At the visit today, the patient reports that her anxiety is well-controlled and she is no longer having nighttime awakenings to use the restroom. She takes the zolpidem about five nights/week with benefit but is very concerned about staying on the zolpidem. She requests a different sleep aid that is not controlled and may be safer to take as she ages.

Based on the information presented, recommend therapy and a plan for the patient.

Narcolepsy

Therapy for narcolepsy involves two key principles: (a) treatment of EDS with scheduled naps, CNS stimulants or sodium oxybate and (b) suppression of cataplexy and REM sleep abnormalities with aminergic signaling drugs or sodium oxybate.

▶ *Excessive Daytime Sedation*

Modafinil/or sodium oxybate are the first-line treatments recommended for EDS due to narcolepsy.[38] Modafinil and armodafinil (the active R-isomer of modafinil) are Schedule IV medications, and these may have fewer peripheral and cardiovascular effects than traditional stimulants due to a slightly different mechanism of action. Most recently, solriamfetol was FDA approved as an additional medication to improve wakefulness in individuals with EDS secondary to narcolepsy. Solriamfetol is a dopamine and norepinephrine reuptake inhibitor and is also a Schedule IV medication.[39] Pitolisant is a histamine-3 receptor antagonist/inverse agonist that works to increase histamine levels and thereby increasing wakefulness; it has been FDA approved for EDS and is not a controlled substance.[40]

Sodium oxybate is a first-line treatment indicated for both EDS and cataplexy. The exact mechanism of action for sodium oxybate is not known but is believed to improve nocturnal sleep via CNS depression and GABA-B agonist activity. The improvement in nocturnal sleep thereby decreases EDS and improves alertness. Due to illicit use and abuse, sodium oxybate is Schedule III and only dispensed by one pharmacy in the nation. Sodium oxybate has a short duration of action, requiring patients to take two doses per night, one at bedtime and one follow-up dose taken 2.5 to 4 hours later.[41]

▶ *Cataplexy*

The most effective medication for the treatment of cataplexy is sodium oxybate. Other treatment options consist of aminergic signaling antidepressants.[38] These include TCAs and certain selective serotonin reuptake inhibitors (eg, sertraline) and serotonin norepinephrine reuptake inhibitors (eg. venlafaxine).

Restless Legs Syndrome

KEY CONCEPT RLS treatment involves suppression of abnormal sensations and leg movements and consolidation of sleep. Dopaminergic medications are prescribed commonly to treat RLS. Dopamine agonists (DAs) offer many advantages over levodopa–carbidopa, including longer half-lives to cover overnight symptoms, flexible dosing, and a reduced incidence of symptom augmentation. Up to 80% of patients who take levodopa–carbidopa will experience symptom **augmentation**: RLS symptoms appear earlier in the day, previously unaffected body parts become involved, duration of relief gets shorter, and higher doses of medication are required to control symptoms.[42] Augmentation should be managed by tapering and discontinuing dopaminergic medications, repleting body iron stores (if low), and switching to alternative medications such as gabapentin. Additionally, use of longer-duration DAs may reduce symptom augmentation.[43] Ropinirole, pramipexole, and rotigotine are FDA approved for the treatment of RLS and are available in sustained-release products. Treatment guidelines recommend pramipexole and rotigotine as first-line therapy with ropinirole as an alternative option.[44]

Table 42–3

Frequently Used Medications for Restless Legs Syndrome

Generic Name (Brand Name)	Half-Life (hours)	Dose Range (mg/day)[a]	Potential Side Effect or Disadvantage
Dopaminergic Agents[b]			
Levodopa–carbidopa (Sinemet)	1.5–2	100–200 of levodopa	Nausea or vomiting; high incidence of symptom augmentation
Pramipexole (Mirapex)	8–12[c]	0.125–0.5	Nausea or vomiting; risk of compulsive behaviors[d]
Ropinirole (Requip)	6[e]	0.25–3	Nausea or vomiting; risk of compulsive behaviors[d]
Rotigotine (Neupro)	5–7	1–3	Application site reactions with patch; risk of compulsive behaviors[d]
Anticonvulsants			
Gabapentin (Neurontin, Horizant)	5–7[c]	300–3600	Dizziness, ataxia, weight gain
Pregabalin (Lyrica)	5–6.5[c]	50–300	Weight gain, daytime sedation

[a] Usual range.

[b] Dopaminergic agents are frequently given at bedtime or 2 hours before bedtime or the anticipated onset of RLS symptoms.

[c] May be longer in patients with renal dysfunction.

[d] Compulsive behaviors such as gambling, shopping, sexual behaviors, and eating have been reported in patients taking dopamine agonists.

[e] May be longer in patients with hepatic dysfunction.

Gabapentin is an effective treatment for RLS, particularly in patients with painful symptoms.[8] The gabapentin prodrug (gabapentin enacarbil) is FDA approved for RLS at a recommended dose of 600 mg taken with food at dinnertime.[45,46] Although not FDA approved for RLS, pregabalin has demonstrated similar or greater efficacy compared to DAs for RLS treatment.[47] Low iron levels may exacerbate RLS symptoms. Iron supplementation should be prescribed in patients who are iron deficient. Iron supplementation in patients with serum ferritin concentrations of less than 50 to 75 mcg/L (ng/mL; 112–169 pmol/L) have been shown to improve RLS symptoms. Medications frequently used for RLS are shown in Table 42–3.[44]

Obstructive Sleep Apnea

KEY CONCEPT The main therapy for OSA is nasal continuous positive airway pressure **(CPAP)** therapy, which alleviates sleep-disordered breathing by producing a positive pressure column in the upper airway using room air. A flexible tube connects the CPAP machine to a mask that covers the nose. CPAP therapy has a favorable impact on blood pressure and attenuates some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.[16,18]

Not all individuals tolerate CPAP therapy, in part because patients must wear a mask during sleep, and therapy can dry and irritate the upper airway. In some individuals, these barriers for adherence may be reduced by properly fitting the mask, adding humidity to therapy, using bilevel positive airway pressure (BiPAP) or autotitrating continuous positive airway pressure (AutoPAP) therapy. BiPAP therapy applies a variable pressure into the airway during the inspiratory phase of respiration but, unlike CPAP, reduces the applied pressure during the expiratory phase. AutoPAP machines are set for a pressure range and individualize the pressure based on breath-to-breath analysis of the necessary pressure to keep the airway open.[16,48]

Obesity can worsen sleep apnea; thus weight management should be implemented for all overweight patients with OSA. In obese patients with mild OSA, weight loss alone can be effective, with studies showing reduced severity of OSA following bariatric surgery.[16,18] For patients who cannot tolerate CPAP, oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. For individuals who have OSA only when on their backs during sleep, positional therapies may be effective.[16]

Medication is not first- line for OSA but may be considered in select patients. Modafinil, armodafinil, and solriamfetol are wake-promoting medications approved by the FDA to treat EDS due to OSA. Initiation of these medications should be attempted only after patients are using optimal CPAP therapy to alleviate sleep-disordered breathing. The need for treating residual sleepiness in this population is not clear because it may not be related to the OSA and is similar to sleepiness in the general population.[49]

Parasomnias

NREM parasomnias usually do not require treatment. If needed, low-dose BZDs such as clonazepam can be prescribed for bothersome episodes. Clonazepam reduces the amount of sleep time spent in stage 3 of NREM sleep, when most NREM parasomnias occur. For treating RBD, clonazepam 0.5 to 2 mg at bedtime is the drug of choice, although melatonin 3 to 12 mg at bedtime also may be effective.[50] Patients with RBD also should have dangerous objects removed from the bedroom and environmental accommodations made to reduce the chance of injury from breakthrough episodes.

Drug–Disease and Drug–Drug Interactions

KEY CONCEPT It is important to review medication profiles for drugs that may aggravate sleep disorders. Patients should be monitored for adverse drug reactions and potential drug–drug interactions and assessed for treatment adherence. Pharmacotherapy for sleep disorders should be individualized. Often medications can treat several concomitant sleep disorders. Conversely, medication therapy may be effective for one sleep disorder and exacerbate another. For example, antidepressants may alleviate depressive symptoms but exacerbate symptoms of RLS. Medications that block dopaminergic transmission may worsen RLS symptoms. The orexin receptor antagonists are contraindicated in patients with narcolepsy. Alcohol and CNS depressants, including opioids,

Patient Care Process

Collect Information:

- Perform a detailed history of prescription, nonprescription, and complementary or alternative medication use.
- Based on patient nighttime and daytime complaints and bed partner report, determine the suspected sleep problem and its consequences.
- Review objective and subjective data regarding sleepiness, nighttime sleep quality and limb movements, sleep disordered breathing, and parasomnias.
- Evaluate concomitant sleep and medical conditions that influence therapy decisions.

Assess the Information:

- Evaluate effectiveness, safety, adherence, and adverse effects of therapy.
- Assess whether patient is taking any medications that may contribute to sleep complaint and/or daytime complaints.
- Determine whether the patient has insurance coverage for prescribed medications.
- Review relevant laboratory parameters for sleep (eg, serum thyroid-stimulating hormone [TSH], ferritin).

Develop a Care Plan:

- If patient requires sedative-hypnotic medication therapy, determine best agent based on timing of sleep complaint (difficulty initiating and/or maintaining sleep).
- For treatment of insomnia, try to ensure the lowest possible doses are prescribed and used for the shortest possible time period.
- If patient complaints are not entirely improved, consider increasing dose or adding a complementary agent.
- Ensure sleep hygiene (see Table 42–1) and drug therapy are appropriate for each sleep complaint.
- Determine if medication doses are optimal for treatment of various sleep disorders (see Tables 42–2 and 42–3).
- For insomnia, select medications whose duration of action matches the timing of the difficulty sleeping (eg, difficulty initiating or maintaining sleep).

Implement the Care Plan:

- Educate patient about medication changes, sleep hygiene, and importance of proper medication use and adherence.
- Address patient concerns about the sleep medication and possible adverse effects.

Follow-up: Monitor and Evaluate:

- Evaluate improvement in the specific sleep complaint (eg, how therapy affected sleep latency or sleep maintenance).
- Monitor daytime sleepiness, sleep diaries, and diaries of sleep events (periodic limb movements of sleep [PLMS], hallucinations, snoring, apneas, etc) and monitor cataplexy and other daytime symptoms to determine if therapy is effective.
- Make appropriate changes to therapy to address inadequately controlled symptoms and reported adverse effects.

sedatives (such as BZDs), and muscle relaxants, can worsen OSA, even in small doses, by reducing respiratory drive and relaxing the upper airway muscles responsible for maintaining patency. CNS depressants should be avoided, and if they are necessary, they should not be administered before sleep. Medication therapy for sleep disorders should be patient specific, and careful consideration should be given to coexisting diseases, concomitant medications, and potential drug–drug and drug–disease interactions to optimize patient care and treatment.

OUTCOME EVALUATION

Evaluate whether the treatment plan restored normal sleep patterns, reduced daytime sequelae, and improved quality of life without causing adverse effects. Schedule patients for follow-up within 3 weeks for insomnia and within 3 months for other sleep disorders. Perform a detailed clinical history to determine the patient's perception of treatment progress and symptoms along with medication effectiveness and adverse effects.[2,16,38,44,50]

Instruct patients to keep sleep diaries (number of hours, number of awakenings, and worsening or improved sleep) and daytime symptoms, along with documentation of episodes such as cataplexy or RBD. Increase medication to effective doses, and if necessary, start additional therapy to control symptoms. Perform a detailed history of prescription, nonprescription, and complementary or alternative medications and review the patient's sleep diary, daytime symptoms, and nonpharmacologic therapies on a regular basis.[2,16,38,44,50]

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Dr. John M. Dopp and Dr. Bradley G. Phillips, authors of this chapter in the first through fifth editions of this book.

Abbreviations Introduced in This Chapter

AutoPAP	Autotitrating continuous positive airway pressure
BiPAP	Bilevel positive airway pressure
BMI	Body mass index
BZD	Benzodiazepine
CBT-I	Cognitive-behavioral therapy for insomnia
CNS	Central nervous system
CPAP	Continuous positive airway pressure
CRD	Circadian rhythm disorder
DA	Dopamine agonist
EDS	Excessive daytime sleepiness
EEG	Electroencephalogram
ESS	Epworth sleepiness scale
FDA	Food and Drug Administration
GABA	γ-Aminobutyric acid
MSLT	Multiple sleep latency test
NBRA	Nonbenzodiazepine receptor agonist
NREM	Nonrapid eye movement
OSA	Obstructive sleep apnea
PLMS	Periodic limb movements of sleep
PSG	Polysomnography
RBD	REM sleep behavior disorder

RDI	Respiratory disturbance index
REM	Rapid eye movement
RLS	Restless legs syndrome
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant

43 Attention-Deficit/Hyperactivity Disorder

Kevin W. Cleveland, Julia Boyle, and
Renee F. Robinson

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain accepted criteria necessary for the diagnosis of attention-deficit/hyperactivity disorder (ADHD).
2. Recommend a therapeutic plan, including drug selection, initial doses, dosage forms, and monitoring parameters, for a patient with ADHD.
3. Differentiate among the available pharmacologic agents used for ADHD with respect to pharmacology and pharmaceutical duration of action.
4. Recommend alternative agents and/or adjunctive agents as clinically indicated.
5. Address potential cost–benefit issues associated with pharmacotherapy of ADHD.
6. Recommend strategies for minimizing adverse effects of ADHD medications.

INTRODUCTION

Attention-deficit/hyperactivity disorder (ADHD) is characterized by a persistent pattern of inattention and/or hyperactivity–impulsivity. It can have a severe impact on a patient's ability to function in both academic and social environments. Early diagnosis and appropriate treatment are essential to compensate for areas of deficit.

EPIDEMIOLOGY AND ETIOLOGY

KEY CONCEPT This disorder usually begins in young children and must occur before 12 years of age to meet current diagnostic criteria. In the United States, ADHD is the most common neurobehavioral disorder that affects children.[1] ADHD has been diagnosed in approximately 11% of school-aged children.[2] ADHD occurs more than twice as often in school-aged boys than girls.[3]

Although ADHD generally is considered a childhood disorder, symptoms can persist into adolescence and adulthood. The prevalence of adult ADHD is estimated to be 2.5%; majority of adults with ADHD have symptoms that manifested in childhood.[3,4] Furthermore, problems associated with ADHD (eg, social, marital, academic, career, anxiety, depression, smoking, and substance abuse problems) increase with the transition of patients into adulthood. Untreated adults with ADHD have high rates of psychopathology, substance abuse, and social and occupational dysfunction.

PATHOPHYSIOLOGY

KEY CONCEPT The exact pathologic cause of ADHD has not been identified. ADHD is generally thought of as a disorder of self-regulation or **response inhibition** and **cognitive deficits**.[5] Patients who meet the diagnostic criteria for ADHD have difficulty maintaining self-control, resisting distractions, concentrating on ideas, and often alternate between inattentiveness to overexcitement.[3,6]

KEY CONCEPT Dysfunction of the **neurotransmitters** is thought to key in the pathology of ADHD. Norepinephrine is responsible for maintaining alertness and attention; dopamine is responsible for regulating learning, motivation, goal setting, and memory. Both of these neurotransmitters predominate in the frontal subcortical system, an area of the brain responsible for maintaining attention and memory. Genetics is a risk factor for developing ADHD with children having a 50% chance of developing ADHD if a parent has ADHD. An association has been made between the development of ADHD and fetal alcohol syndrome, lead poisoning, maternal smoking, and hypoxia.[3,6]

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT ADHD is often misdiagnosed and is generally associated with comorbid conditions.[1] Males are more likely to have oppositional defiant disorder and conduct disorders, where females are more likely to have anxiety and depression.[6] It is important to identify and appropriately treat coexisting conditions in patients with ADHD.

According to most recent diagnostic guidelines, all patients 4 to 18 years of age presenting with inattention, hyperactivity, impulsivity, academic, and/or behavioral problems should be evaluated for ADHD. Additional behavior information from various settings should be gathered from the patient, family, and teachers. The age of onset, frequency, severity, and duration of symptoms should be documented.[3,6]

The most useful diagnostic criteria for ADHD is the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*).[3] The *DSM-5* defines three presentations of ADHD: (a) predominately inattentive; (b) predominantly hyperactive–impulsive; and (c) combined, in which both inattentive and hyperactive or impulsive symptoms are evident.[3,6] It is recommended that parents and teachers complete a standardized rating scale based on the *DSM-5* criteria.[3] Rating scales (Vanderbilt, Conners) are not by themselves diagnostic but are diagnostic aids when added to a careful history and interview.[7]

Clinical Presentation and Diagnosis of ADHD Based on DSM-5 Criteria

General

Patients with ADHD can present with inattention, hyperactivity–impulsivity, or both. ADHD is typically encountered with comorbid conditions.

Symptoms

- A persistent pattern of inattention and/or hyperactivity–impulsivity that interferes with functioning or development, as characterized by inattention and/or hyperactivity and impulsivity:
  - Inattention: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:
    - Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (eg, overlooks or misses details, work is inaccurate.)
    - Often has difficulty sustaining attention in tasks or play activities (eg, has difficulty remaining focused during lectures, conversations, or lengthy reading).
    - Often does not seem to listen when spoken to directly (eg, mind seems elsewhere, even in absence of any obvious distraction).
    - Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workspace (eg, starts tasks but quickly loses focus and is easily sidetracked).
    - Often has difficulty organizing tasks and activities (eg, difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
    - Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (eg, schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
    - Often loses things necessary for tasks or activities (eg, school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).
    - Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
    - Is often forgetful in daily activities (eg, doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).
  - Hyperactivity and impulsivity: Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities: Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or a failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.
    - Often fidgets with or taps hands or feet or squirms in seat.
    - Often leaves seat in situations when remaining seated is expected (eg, leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
    - Often runs about or climbs in situations where it is inappropriate. (Note: In adolescents or adults, may be limited to feeling restless.)
    - Often unable to play or engage in leisure activities quietly.
      - Is often "on the go," acting as if "driven by a motor" (eg, is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
    - Often talks excessively.
    - Often blurts out an answer before a question has been completed (eg, completes people's sentences; cannot wait for turn in conversation).
    - Often has difficulty waiting his or her turn (eg, while waiting in line).
    - Often interrupts or intrudes on others (eg, butts into interrupts conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).

Diagnostic Criteria

- Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.
- Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).
- There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
- The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

TREATMENT

Desired Outcomes

KEY CONCEPT The primary therapeutic objectives in ADHD are to (1) improve behavior; (2) increase attention; or (3) response inhibition. The secondary goals of treatment are to (1) improve interpersonal relationships and academic performance; (2) decrease disruptive behavior; (3) increase independence; and (4) minimize adverse effects of therapy.

Nonpharmacologic (Behavioral) Therapy

Behavioral therapy can be useful; however, it is generally not recommended as first-line monotherapy except in preschool-aged children (4–5 years of age).[3,6] KEY CONCEPT Studies have demonstrated pharmacotherapy alone is superior to behavioral intervention alone in improving attention. However, combined behavioral and stimulant therapy is better at improving opposition and aggression in school-aged children.[8] Behavioral modification involves training caregivers and teachers to change environmental factors and establish a reward/consequence system.[6] Success of behavioral modifications depends on the cooperation of the caregivers and teachers.

Pharmacologic Therapy

The proposed mechanism of ADHD pharmacotherapy is to modulate neurotransmitter function in order to improve academic and social functioning. Pharmacotherapy can be divided into two categories—stimulants and nonstimulants.

▶ *Stimulants*

KEY CONCEPT Psychostimulants (eg, methylphenidate and amphetamines) are the most effective agents in treating ADHD. Following a diagnosis of ADHD, a stimulant medication should be considered first-line therapy in patients 6 years of age or older. Stimulants theoretically exert their primary effect by blocking the reuptake of dopamine and norepinephrine. In preschool-aged children, methylphenidate can be added to the patient's treatment if behavioral modification monotherapy is not sufficient.[6] Generally, a trial of at least 3 months on a stimulant is appropriate, and this includes dose titration to response as tolerated.[6] **KEY CONCEPT** If treatment with the first stimulant formulation fails, it is recommended to switch to a different stimulant class.[3,6] For example, if the patient was started on methylphenidate but could not tolerate the side effects, switching to dextroamphetamine with or without amphetamine is appropriate. Most patients who fail one stimulant will respond to an alternative stimulant medication.[6] **KEY CONCEPT** If the patient fails two adequate trials of different stimulant medications, a third stimulant formulation or second-line nonstimulant such as atomoxetine, guanfacine, or clonidine can be considered. The diagnosis of ADHD should be revalidated as well.

Stimulants should be initiated at recommended starting doses and titrated up using a consistent dosing schedule until appropriate response, minimizing side effects (Table 43–1). Stimulant medications have been shown to decrease fidgeting and finger tapping, increase on-task classroom behavior and positive interactions at home and in social environments, and ameliorate conduct and anxiety disorders.[9] Generally, stimulants should not be used in patients who have glaucoma, severe hypertension or cardiovascular disease, hyperthyroidism, severe anxiety, or previous illicit or stimulant drug abuse.

Stimulant drug formulations can be divided into short-, intermediate-, and long-acting preparations (see Table 43–1). Initial response to short-acting stimulant formulations (eg, methylphenidate and dextroamphetamine) is seen within 30 minutes and can last for 4 to 6 hours.[6] Thus short-acting stimulant formulations must frequently be dosed at least twice daily, increasing the chance of missed doses and nonadherence. Patients using any stimulant formulation, but especially short-acting formulations, can experience a rebound effect of ADHD symptoms as the stimulant wears off.[9]

Most intermediate-acting stimulants release the medication in a slow, continuous fashion without any early release (except Dexedrine Spansules). The onset of action for this category of stimulants (typically 60–90 minutes) may be inadequate for some patients. Some practitioners prescribe a short-acting stimulant concurrently with an intermediate-acting stimulant to curtail the delay in onset of action of the intermediate-acting stimulant. However, this practice can increase patient copay costs.

To minimize rebound symptoms associated with short-acting formulations and still achieve early stimulant release, long-acting formulations with rapid onsets have been developed. These formulations release medications early and deliver a delayed release of stimulant in either a pulsed (Adderall XR, Focalin XR, Metadate CD, Quillivant XR, and Ritalin LA) or continuous manner (Concerta). Formulations available as capsules contain coated beads that can be opened and sprinkled on semisolid food. Concerta tablets have an immediate-release overcoat and an oral osmotic controlled release that delivers methylphenidate in an extended manner. Patients should be educated that the empty tablet shell of Concerta can be seen in the stool.

Three long-acting stimulants, Daytrana, Vyvanse, and Jornay PM, have slower onsets of action than the other long-acting stimulants with a rapid release. Daytrana transdermal patches have a delayed onset of 2 hours and are to be applied for only 9 hours per day; their effects persist for 3 hours after being removed. Some patients report skin sensitization and irritation. Vyvanse is a prodrug that is hydrolyzed to its active form, dextroamphetamine, after oral ingestion. Inhalation or injection abuse potential is minimized because of impeded hydrolysis by these routes. Onset of action for Vyvanse has been reported to be 2 hours.[10] Jornay PM beads are formulated with two different coatings, the first is a delayed-release coating which prevents release of medication for 8 to 10 hours after ingestion, the second coating is an extended-release coating which allows for release of medication throughout the day.[11]

Adverse effects of stimulants can be generalized to the whole class (Table 43–2). Most side effects can be managed by changing the dosing routine (ie, giving with food, dividing daily dose, or giving the dose earlier in the day). Serious side effects (eg, hallucinations and abnormal movements) require discontinuation of medication.[9] To avoid potential drug–food interactions and absorption issues, stimulants should be given 30 to 60 minutes before eating.

Patient Encounter, Part 1

An 11-year-old boy who described is reported to having difficulties with focusing and sitting still in class. He often has difficulty sustaining his attention at school. His parents and teacher indicate that he is restless, and often requires reminders to help him stay on task. He is described as "constantly running around" and presenting with difficulties listening and following instructions. His teacher indicates that he often blurts out answers and interrupts other students in the classroom. He recognizes this tendency in himself but says that he can't stop in spite of his best intentions. The patient is diagnosed with ADHD using the Vanderbilt scale.

Wt: 47.2 kg or 104 lb (90th percentile)

Allergies: None known

Ht: 152 cm or 5′0″ (90th percentile)

BP: 95/63 mm Hg

P: 100 beats/min

Which of the patient's symptoms are suggestive of ADHD?

What other information should be collected before recommending therapy for ADHD?

What treatment recommendations could you make for this patient?

Table 43–1

Selected Medications for ADHD[a]

Drug, Generic (Brand Name)	Initial Dose	Titration Schedule Increments	Typical Dosing Range (Maximum Dose)	Cost[e]
Stimulants				
Short Acting				
Methylphenidate[b] (Methylin, Ritalin)	5 mg twice daily	5–10 mg/day in weekly intervals	5–20 mg two to three times daily (60 mg/day)	Brand—$$ Generic—$
Dexmethylphenidate[b] (Focalin)	2.5 mg twice daily	2.5–5 mg/day in weekly intervals	5–10 mg twice daily (20 mg/day)	Brand—$ Generic—$
Dextroamphetamine[b] (Zenzedi)	2.5–5 mg every morning	2.5–5 mg/day in weekly intervals	5–20 mg twice daily (40 mg/day)	Brand—$ Generic—$
Intermediate Acting				
Methylphenidate[b,f] (Methylin ER)	10 mg once daily	10 mg/day in weekly intervals	20–40 mg every morning (60 mg/day)	Generic—$
Dextroamphetamine–amphetamine[b] (Adderall)	2.5–5 mg once to twice daily	2.5–5 mg/day in weekly intervals	10–30 mg every morning or 5–20 mg twice daily (40 mg/day)	Brand—$$$ Generic—$
Dextroamphetamine[b,f] (Dexedrine Spansule)	5 mg every morning	5 mg/day in weekly intervals	5–30 mg daily or 5–15 mg twice daily (40 mg/day)	Generic—$$
Long Acting				
Methylphenidate[b]				
(Concerta[f])	18 mg every morning	9–18 mg/day in weekly intervals	18–54 mg every morning (54 mg/day in children)	Brand—$$$ Generic—$
(Daytrana[f])	10 mg every morning (2 hours before effect needed)	Patch dosage strength in weekly intervals	30–60 mg every morning	Brand—$$$
(Metadate CD)	20 mg every morning	10–20 mg/day in weekly intervals	20–40 mg daily every morning (60 mg/day)	Brand—$$$ Generic—$
(Ritalin LA[f])	20 mg every morning	10 mg/day in weekly intervals	20–40 mg every morning (60 mg/day)	Brand—$$$ Generic—$
(Quillivant XR)[c]	20 mg every morning	10–20 mg/day in weekly intervals	20–40 mg every morning (60 mg/day)	Brand—$$$
(Aptensio XR[f])	10 mg every morning	10 mg/day in weekly intervals	10–60 mg every morning (60 mg/day)	Brand—$$$ Generic—$$
(Cotempla XR-ODT)	17.3 mg every morning	8.6–17.3 mg/day in weekly intervals	17.3–51.8 mg every morning (51.8 mg/day)	Brand—$$$
(Adhansia XR[f])	25 mg every morning	10–15 mg/day in ≥ 5 day intervals	25–85 mg every morning (85 mg/day)	Brand—$$$
(Jornay PM[f])	20 mg every evening between 6:30 and 9:30 PM	20 mg/day in weekly intervals	20–100 mg every evening (100 mg/day)	Brand—$$$
Dextroamphetamine/amphetamine[b] (Adderall XR[f])	5–10 mg every morning (children); 20 mg once daily (adults)	5–10 mg/day in weekly intervals	10–30 mg every morning or 5–15 mg twice daily (30 mg/day, children) (60 mg/day, adult)	Brand—$$$ Generic—$
Dexmethylphenidate[b] (Focalin XR[f])	5 mg every morning (children); 10 mg every morning (adults)	5 mg/day in weekly intervals	10–20 mg daily in the morning (20 mg/day)	Brand—$$$ Generic—$$
Lisdexamfetamine[b] (Vyvanse[f])	30 mg every morning (children and adults)	10–20 mg/day in weekly intervals	30–70 mg every morning (70 mg/day)	Brand—$$$
Amphetamine[b]				
(Dyanavel XR)	2.5–5 mg every morning	2.5–10 mg/day every 4–7 days	2.5–20 mg every morning (20 mg/day)	Brand—$$$
(Adzenys XR-ODT)	6.3 mg every morning	3.1–6.3 mg/day in weekly intervals	6.3–18.8 mg every morning depending on age (ages 6–12 years—18.8 mg/day; ages 13–18 years—12.5 mg/day)	Brand—$$$
(Evekeo)	2.5 mg every morning (3–5 years) or 5 mg every morning or twice daily (6 years or older)	2.5 mg/day (3–5 years) or 5 mg/day (6 years or older) in weekly intervals	2.5–40 mg daily in a single morning or twice daily divided dose (40 mg/day)	Brand—$$$ Generic—$$
(Mydayis[f])	12.5 mg every morning (13-17 years of age)	12.5 mg/day at weekly intervals	12.5–25 mg every morning (25 mg/day)	Brand—$$$

Table 43–1

Selected Medications for ADHD[a] (*Continued*)

Drug, Generic (Brand Name)	Initial Dose	Titration Schedule Increments	Typical Dosing Range (Maximum Dose)	Cost[e]
Clonidine (Catapres)	0.05 mg once daily	0.05 mg/day every 3–7 days	0.1 mg 1 to 4 times daily (0.4 mg/day)	Brand—$$
(Kapvay)[b,f]	0.1 mg at bedtime	0.1 mg/day in weekly intervals	0.1–0.2 mg twice daily (0.4 mg/day)	Generic—$
Guanfacine (Tenex)	0.5 mg at bedtime	0.5 mg every 3–14 days	1.5–3 mg/day divided into 2–3 doses (4 mg/day)	Generic—$
(Intuniv)[b,f]	1 mg once daily	No more than 1 mg/week	1–4 mg daily (4 mg/day)	

[a] Pediatric dosing except when adult dosing specified.

[b] Approved by the US FDA for the treatment of ADHD.

[c] Oral extended-release suspension.

[d] Dose adjustment required in patients with hepatic insufficiency.

[e] Cost based on brand regimen specified without a dispensing fee or discount for a 30-day supply.

[f] Do not crush, chew, or cut.

CD, extended release (biphasic immediate release with extended release); ER, extended release; LA, long acting; ODT, orally disintegrating tablet; SR, sustained release; XL, extended release; XR, extended release.

(From GoodRx.com or various online State Maximum Allowable Costs [SMAC]); $, less than $60; $$, $60–$140; $$$, greater than $140.

Table 43–2

Patient Monitoring and Management of Selected Adverse Effects of ADHD Medications

Drug	Adverse Effects	Management	Monitoring
Stimulants			
Methylphenidate Dexmethylphenidate Dextroamphetamine Amphetamine Lisdexamfetamine	GI upset, nausea, decreased appetite, potential growth delay	Administer after breakfast and lunch Encourage high-calorie meals/beverages and snacks after dinner Divide dose Change to shorter-acting stimulant Discontinue on weekends and during holidays	Height, weight, blood pressure, pulse ECG if warranted Eating and sleeping patterns Evaluate every 2–4 weeks until stable dose is achieved; then evaluate every 3 months
	Insomnia	Move dose(s) earlier in the day and discontinue later day dose if problem persists Change to a shorter-acting stimulant Consider adjunct hypnotic (eg, melatonin) or alternate medication (eg, guanfacine)	
	Headache	Decrease dose Change to longer-acting stimulant or nonstimulant (eg, atomoxetine) Consider analgesic (eg, acetaminophen)	
	Irritability, dysphoria, agitation	Early onset (peak related): Decrease dose or change to longer-acting stimulant Late onset (withdrawal related): Change to longer-acting stimulant Evaluate for comorbidity and treat if present	
	Tics	Decrease dose if stimulant caused Change to a different stimulant or a nonstimulant (eg, guanfacine, atomoxetine) Add an antipsychotic (eg, risperidone)	
Nonstimulants			
Atomoxetine	Increased blood pressure and pulse, nausea, vomiting, fatigue, and insomnia	Decrease dose or change to another medication (eg, guanfacine)	Same as above but with baseline and routine liver function tests for hepatotoxicity
	Hepatotoxicity, suicidal thoughts	Discontinue, reevaluate patient and consider a change to another medication	
Clonidine and guanfacine	Sedation	Decrease dose Administer closer to bedtime	Same as above

ECG, electrocardiogram; GI, gastrointestinal.

Growth suppression or delay is a major concern for parents of children taking stimulants. Height appears to be decreased by 1 to 2 cm; these effects are diminished after 3 years of treatment and do not appear to rebound.[12] Another concern is risk of substance abuse with stimulant use. A diagnosis of untreated ADHD increases the risk of substance abuse in adolescents and adults.[13] Two prospective observational studies concluded that ADHD treatment in children does not increase or decrease the likelihood of developing substance abuse in adulthood.[14,15]

The choice of ADHD medication should be made based on the patient's symptoms, prescriber's familiarity with the medications, ease of administration, and cost. Stimulants should be used as first-line agents in most ADHD patients, although studies in groups of patients have shown no clear advantage of one stimulant over another.[4]

▶ *Nonstimulants*

Atomoxetine Atomoxetine is approved for the treatment of ADHD in both children and adults. In clinical studies it demonstrated superior efficacy over placebo and either equivalent efficacy compared with a suboptimal immediate-release methylphenidate dose or inferior to Concerta.[16] **KEY CONCEPT** Atomoxetine may be used first line if there are concerns with using stimulant medications; however, atomoxetine is less effective than stimulants in treatment of ADHD.

Atomoxetine selectively inhibits the reuptake of adrenergic neurotransmitters, principally norepinephrine.[16] Atomoxetine is metabolized through the cytochrome P450 (CYP) 2D6 pathway. Concurrent use of CYP2D6 inhibitors may necessitate slower dose titration of atomoxetine. Approximately 5% to 10% of the population are CYP2D6 poor metabolizers, and atomoxetine's half-life is increased significantly in this population.[17] The recommended dosing for atomoxetine depends on patient weight and is given once or twice daily[17] (see Table 43–1). In poor metabolizers, atomoxetine should be dosed once daily at 25% to 50% of the dose typically used in normal metabolizers.[17] Onset of therapeutic effect of atomoxetine may take up to 2 to 8 weeks, significantly longer than with stimulants.[18] Common side effects (headache, decreased appetite) of atomoxetine are similar to those of stimulants.[16] It can slow growth rate and cause weight loss; thus, height and weight should be monitored routinely in children[16] (see Table 43–2). Atomoxetine's labeling includes warnings about severe hepatotoxicity and increased association with suicidal thinking.

Atomoxetine can be given once daily in many patients. It appears to lack any abuse potential and is not a controlled substance.[19] One big disadvantage of atomoxetine is cost compared with other ADHD medications, despite a generic being approved by the FDA in May 2017 (see Table 43–1).

Because of the high cost, lack of long-term efficacy data, and few comparison studies with stimulants, atomoxetine should be advocated only if the patient has failed or is intolerant to stimulant therapy or has history or risk factors for substance use.

Clonidine and Guanfacine Clonidine and guanfacine are central α_2-adrenergic agonists that inhibit the release of norepinephrine presynaptically. Both of these agents are less effective than stimulants in treating ADHD but typically are used as adjuncts to stimulants to control disruptive or aggressive behavior and alleviate insomnia.[20] The effects of immediate-release guanfacine typically last 3 to 4 hours longer than immediate-release clonidine, and the drug requires less frequent dosing. Extended-release formulations of guanfacine (Intuniv) and clonidine (Kapvay) were developed to minimize dosing frequency and improve treatment of anger, hostility, and irritability in patients with ADHD. Similar to other nonstimulants, these two dosage forms can also be used in patients who are intolerant to stimulants. However, use of these dosage forms is limited because of a lack of comparative trials to stimulants. Common side effects with clonidine and guanfacine are low blood pressure and sedation. Sedation generally subsides after 2 to 3 weeks of therapy.[21,22] Rarely, severe side effects such as bradycardia, rebound hypertension, irregular heartbeats, and sudden death have been reported.

Patient Encounter, Part 2

He has been on Focalin (dexmethylphenidate) 5 mg BID for the past 3 months with only a moderate change in symptoms. He has also lost 10 lb (4.5 kg) (currently 76th percentile for weight) in the last 3 months and reports trouble sleeping.

What changes to the patient's ADHD medication therapy would you recommend?

What important education points would you discuss with the patient and his caregivers about his ADHD medications?

Pharmacoeconomic and Treatment Adherence Considerations

Annual healthcare costs for people with ADHD was almost 60% higher than people without ADHD.[20] The financial burden of ADHD is attributed to the direct cost of pharmacotherapy, office visits, diagnostic measurements, therapy monitoring, and indirect costs (eg, lost work time and productivity). When selecting a treatment, the cost burden to the patient's family should be considered. Short-acting stimulants may be more cost effective compared with longer-acting stimulant formulations (see Table 43–1), but in certain circumstances, longer-acting stimulant formulations may provide a greater benefit owing to increased adherence to the medication and prolonged control of symptoms of ADHD. All intermediate-acting and various long-acting (Concerta, Ritalin LA, Metadate CD, Focalin XR, and Adderall XR) stimulant formulations are now available as generic products, making them potentially more affordable. In addition, some nonstimulant ADHD medications (eg, immediate-release α_2-adrenergic agonists) appear to be less costly than many stimulant formulations; however, these agents have not been consistently proven to have superior efficacy over stimulants. Decisions on selection of

Patient Encounter, Part 3

Patient returns 3 months later having been on Concerta titrated to 36 mg daily. He is reporting being able to focus better, improvement in grades, no reported insomnia, and evening appetite has normalized; however, he still struggles with no appetite in the morning after taking his medication.

What monitoring parameters should be followed in order to assess efficacy and safety of treatment?

What education could you provide to the patient and caregivers regarding his lack of appetite in the morning?

Patient Care Process

Collect Information:

- Current and past medication use including prescription and nonprescription products
- Identify allergies
- Medication history, physical assessment (blood pressure, pulse, height, and weight), ECG (baseline and periodically in children with known or suspected cardiac disease) neurologic assessment, home assessment
- Signs and symptoms of hyperactivity, impulsivity, and/or inattention from patient, parents, teachers, and/or other people spending significant amount of time with the patient utilizing established ADHD rating scales (Vanderbilt, Conners)
- Patient and family lifestyle habits (poor academic performance, poor sleep hygiene, inadequate nutrition), belief system, functional goals, socioeconomic factors (insurance vs ability to pay for prescriptions)

Assess the Information:

- Determine if medications or lifestyle habits could be contributing to signs and symptoms of ADHD
- Evaluate medications for indication, side effects, adherence and effectiveness, interactions, and drug-related problems
- Assess overall health status, signs, and symptoms of ADHD
- Identify patient/family cost effectiveness/burden of therapy and ability to remain adherent to therapy

Develop a Care Plan:

- Address any drug-related problems, interactions, adherence issues
- Patients < 6 years old, consider behavioral modification before pharmacotherapy
- Patients ≥ 6 years old, consider low-dose stimulant (see Table 43–1)
- If initial stimulant therapy is not effective after 2 to 4 weeks, consider switching to a different stimulant medication (see Table 43–1)
- Try at least two stimulant medications before considering nonstimulant pharmacotherapy
- Reevaluate the diagnosis if all pharmacotherapy treatment attempts fail

Implement the Care Plan:

- Initiate medication at appropriate dose (see Table 43–1) and titrate to effect as tolerated (see Table 43–2), while considering cost (see Table 43–1)
- Emphasize medication adherence
- Educate patient/family on effectiveness and safety (see Table 43–2)

Follow-up: Monitor and Evaluate:

- Evaluate effectiveness and safety of stimulant therapy monthly for the first 3 months
- Evaluate every 3 months once on maintenance dose
- Monitor height and weight in children and blood pressure in adults quarterly
- Evaluate for improvement in function, use rating scales for consistent evaluation

specific ADHD medications should not be based solely on cost but also on efficacy and safety along with adherence to the prescribed regimen.

OUTCOME EVALUATION

Carefully document core ADHD symptoms at baseline to provide a reference point from which to evaluate effectiveness of treatment. Improvement in individualized patient outcomes is desired, such as (a) family and social relationships, (b) disruptive behavior, (c) completing required tasks, (d) self-motivation, (e) appearance, and (f) self-esteem. Elicit evaluations of the patient's behavior from family, school, and social environments in order to assess these outcomes. Using standardized rating scales (eg, Conners Rating Scales—Revised, Child Behavior Checklist-Attention Problem scale, and Conners Abbreviated Symptoms Questionnaire, Vanderbilt) leads to favorable diagnostic precision.[23] Assess eating and sleeping patterns, height, weight, pulse, and blood pressure at baseline and after initiation of pharmacotherapy every 2 to 4 weeks to determine efficacy of treatment and potential effects on growth and cardiac system. Use physical examinations or liver function tests as appropriate to monitor for adverse effects. In children with known or suspected cardiac disease obtain baseline and follow-up electrocardiograms (ECGs) to monitor for safety of stimulant therapy.[24] Recent evidence suggests that overall cardiac risk with ADHD pharmacotherapy is low, but presence of risk factors is associated with increased risk of serious cardiac events.[25] Typically, therapeutic benefits will be seen within days of initiating stimulants and within 1 or 2 months of starting atomoxetine. When a maintenance dose has been achieved, schedule follow-up visits every 3 months. At these visits, assess height and weight, and screen for possible adverse drug effects. If a patient has failed to respond to multiple agents, reevaluate for other possible causes of behavior dysfunction. Educate patients and their families that treatment generally is long term. Typically, appropriately treated patients learn to better control their ADHD symptoms as adults.

Diabetes Mellitus

Julie M. Sease and Elizabeth W. Blake

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss the incidence of diabetes mellitus (DM).
2. Distinguish clinical differences in type 1, Latent Autoimmune Diabetes of Adulthood, type 2, and gestational diabetes.
3. List screening and diagnostic criteria for DM.
4. Discuss therapeutic goals for blood glucose (BG) and blood pressure (BP) for a patient with diabetes.
5. Recommend nonpharmacologic therapies, including meal planning and physical activity, for patients with diabetes.
6. Compare oral agents used in treating diabetes by their mechanisms of action, time of action, side effects, contraindications, and effectiveness.
7. Select appropriate insulin therapy based on onset, peak, and duration of action.
8. Discuss the signs, symptoms, and treatment of hypoglycemia.
9. Define *diabetic ketoacidosis* and discuss treatment goals.
10. Develop a comprehensive therapeutic monitoring plan for a patient with diabetes based on patient-specific factors.

INTRODUCTION

Diabetes mellitus (DM) describes a group of chronic metabolic disorders. **KEY CONCEPT** DM is characterized by hyperglycemia that may result in long-term **microvascular** and neuropathic complications that contribute to DM being the leading cause of (a) new cases of blindness among adults, (b) end-stage renal disease, and (c) nontraumatic lower limb amputations. Macrovascular complications (coronary artery disease, peripheral vascular disease, and stroke) are also associated with DM.

EPIDEMIOLOGY

DM affects an estimated 34.2 million persons in the United States, or 10.5% of the population.[1] Although an estimated 23.1 million persons have been diagnosed, another 7.2 million have DM but are unaware they have the disease.[1] DM is characterized by a complete lack of insulin, a relative lack of insulin, or **insulin resistance**, as well as disorders of other hormones. These defects result in an inability to use glucose for energy. The increasing prevalence of DM is partly caused by three influences: lifestyle, ethnicity, and age.

Lifestyle

A sedentary lifestyle coupled with greater consumption of high-fat, high-carbohydrate foods, and larger portion sizes have resulted in increasing rates of obesity. Current estimates indicate that 42.4% of US adults are obese when obesity is defined as body mass index (BMI) of greater than 30 kg/m^2.[2] Over 15% of adults throughout the country report being physically inactive, defined as self-report of no leisure-time physical activity within the past month.[3]

Ethnicity

Certain ethnic groups are at disproportionately high risk for developing type 2 DM (T2DM). Prevalence of DM is 14.7% among American Indian/Alaska Native individuals, 12.5% among persons of Hispanic ethnicity, and 11.7% among non-Hispanic Black individuals, whereas among non-Hispanic White individuals, prevalence is only 7.5%.[1] Socioeconomic status, when examined as a function of education level, also plays a role in development of DM. Rate of DM is 13.3% for persons with less than a high school education versus 7.5% for those with education beyond high school.[1]

Age

The third factor contributing to increased prevalence of T2DM is age. In 2018, it was estimated that 11.5 million Americans aged 65 or older had been diagnosed with DM compared with 3.6 million between the ages of 18 and 44.[1] As the population ages, incidence of T2DM is expected to increase. **KEY CONCEPT** T2DM accounts for approximately 90% to 95% of all diagnosed cases of DM, is progressive in its development, and often preceded by an increased risk for diabetes, known as **prediabetes**. A combination of insulin deficiency, insulin resistance, and other hormonal irregularities, primarily involving **glucagon**, are key problems with T2DM. The majority of people with T2DM are overweight, and an increasing number of cases in children have been observed. Type 1 DM (T1DM) is usually diagnosed before age 30 years but can develop at any age. As a result, patients over 30 years of age who newly develop T1DM may be misdiagnosed as having T2DM.

ETIOLOGY

T1DM is an autoimmune disease in which the insulin-producing β-cells of the pancreas are destroyed, leaving the individual insulin deficient.[4] T1DM develops on a variable, but predictable continuum through three stages. In Stage 1, patients have two or more islet autoantibodies but normal glucose values and no classic symptoms of DM. In Stage 2, β-cell autoimmunity is present, dysglycemia (impaired fasting glucose [IFG] or impaired glucose tolerance [IGT]) has begun, but the patient remains asymptomatic. In Stage 3, classic symptoms including polyuria, polydipsia, weight loss, polyphagia, fatigue, and blurred vision are present. It was once a commonly held belief that, at the time of diagnosis of T1DM, most patients have over 80% loss of β-cell function.[5] This belief has become contested by more recent data suggesting residual β-cell mass up to 40% may be present in those diagnosed in adolescence and may also be variable based on degree and cellular profile of the individual's insulitis. The concept of remaining β-cell function at diagnosis is supported by the observation that, once provided insulin, patients with T1DM may have a temporary and spontaneous partial or even full remission. Duration of this so-called honeymoon period is variable, lasting anywhere from weeks to, in rare cases, years.

Maturity onset diabetes in the young (MODY) is seen in approximately 1.2% to 4% of pediatric diabetes patients.[4] Often misdiagnosed as T1DM and treated with insulin, MODY should be considered in patients presenting without the presence of diabetes-associated islet cell autoantibodies to insulin. Autoantibodies include islet cell cytoplasmic, glutamic acid decarboxylase, and tyrosine phosphatase autoantibodies. C-peptide, a surrogate marker for insulin secretion, may be used to establish or verify diagnosis of T1DM. While variable in MODY, C-peptide will be decreased or absent in T1DM. Diagnosing MODY correctly has implications for the patient as well as their family. Testing for various genetic mutations associated with the disorder is available. The calculator found at https://www.diabetesgenes.org/exeter-diabetes-app/ModyCalculator may be useful in determining which individuals should undergo genetic testing.

KEY CONCEPT Latent autoimmune diabetes in adults (LADA) is a form of autoimmune diabetes hallmarked by a milder autoimmune process and slower progression of β-cell failure as compared with T1DM.[6] Criteria for diagnosis of LADA include adult age at onset, presence of islet autoantibodies, and insulin dependence. Patients with LADA often are mistakenly thought to have T2DM because the person is an adult at onset and exogenous insulin is usually not required during the first 6 to 12 months following diagnosis. The presence of glutamic acid decarboxylase antibodies is a key indicator of LADA as it is more prevalent in LADA than T1DM.

Prediabetes is a commonly used term to describe those at highest risk for development of T2DM and cardiovascular disease. Prediabetes encompasses the following conditions: IFG, IGT, or hemoglobin A_{1c} (A_{1c}) between 5.7% and 6.4% (0.057 and 0.064; 39 and 46 mmol/mol hemoglobin [Hgb]).[7] IFG is defined as having a fasting blood glucose (FBG) level between 100 and 125 mg/dL (5.6 and 6.9 mmol/L).[7] IGT is defined by a postprandial blood glucose (BG) level between 140 and 199 mg/dL (7.8 and 11.0 mmol/L).[7]

T2DM is usually slow and progressive in its development. Risk factors include:[7]

- First-degree family history of DM (ie, parents or siblings)
- Overweight or obese
- Habitual physical inactivity
- Race or ethnicity (Native American, Latino or Hispanic American, Asian American, African American, and Pacific Islander)
- Previously identified IFG, IGT, or A_{1c} between 5.7% and 6.4% (0.057 and 0.064 or 39 and 46 mmol/mol Hgb)
- Hypertension (greater than or equal to 140/90 mm Hg or on therapy for hypertension)
- High-density lipoprotein (HDL) cholesterol less than 35 mg/dL (0.91 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.83 mmol/L)
- History of gestational diabetes
- History of cardiovascular disease
- History of polycystic ovarian syndrome
- Other conditions associated with insulin resistance (eg, acanthosis nigricans)

Gestational DM (GDM) is defined as glucose intolerance in women during pregnancy. Clinical detection of and therapy for GDM are important because blood sugar levels within normal range produces significant reductions in adverse maternal, fetal, and neonatal outcomes.

Diabetes insipidus is unrelated to DM despite the similar nomenclature.[8] Four types of diabetes insipidus exist including central, nephrogenic, dipsogenic, and gestational. Central diabetes insipidus results from damage to a patient's hypothalamus or pituitary causing irregular production, storage and/or release of vasopressin leading to excessive elimination of fluid by the kidneys. Nephrogenic diabetes insipidus occurs when the kidneys no longer respond appropriately to the action of vasopressin. Dipsogenic diabetes insipidus results from hypothalamic dysfunction which causes increased thirst and liquid intake in the affected patient. Gestational diabetes insipidus occurs during pregnancy and results either from placental destruction of the mother's vasopressin or from prostaglandin's action on the kidneys causing them to lose sensitivity to the action of vasopressin.

DM from other causes includes genetic defects in β-cell function and genetic defects in insulin action, both related to neonatal diabetes; diseases of the exocrine pancreas such as cystic fibrosis; and drug- or chemical-induced diabetes.[7] Drugs which have been associated with development of diabetes include those thought to cause insulin resistance/decreased insulin sensitivity such as atypical antipsychotics, glucocorticoids, first-generation protease inhibitors, nicotinic acid, and statins; those that cause insulin deficiency such as β-adrenergic antagonists, didanosine, pentamidine, and thiazide diuretics; and those that cause insulin resistance such as β-adrenergic agonists and megestrol.[9]

PATHOPHYSIOLOGY

Normal Carbohydrate Metabolism

Glucose, the body's fuel source, is required for both aerobic and anaerobic cellular respiration.[10] Cells metabolize glucose through glycolysis and the citric acid cycle, producing energy as adenosine triphosphate (ATP). Glucose is stored in the liver and muscles as glycogen. Glycogenolysis converts stored glycogen back to glucose. Glucose may also be stored in adipose tissue, which subsequently undergoes lipolysis to yield free fatty acids.[11] In the fasting state, free fatty acids supply much of the energy needs for the body except the central nervous system, which requires glucose to function normally. Glucose is primarily supplied to the brain by liver glycogen stores during fasting, though conversion of lactate, alanine, and glycerol to glucose also provides energy for the brain when no exogenous glucose supply is available. During exercise, most glucose is supplied through hepatic gluconeogenesis which is stimulated by the catecholamines epinephrine and norepinephrine.

Insulin and glucagon are produced in the pancreas by cells in the pancreatic islets. β-cells produce insulin and amylin, whereas α-cells produce glucagon. The main function of insulin is to decrease BG, and an elevated BG is necessary for insulin release above basal levels. Glucagon and other counterregulatory hormones such as epinephrine and norepinephrine increase BG levels. Although BG levels vary, the opposing actions of insulin and glucagon, along with the counterregulatory hormones, normally maintain fasting values below 100 mg/dL (5.6 mmol/L).[11]

▶ *Normal Insulin Action*

Insulin is necessary for glucose to move into cells where it can be utilized to create energy. Without adequate insulin, glucose remains extracellular and BG remains high. In persons without diabetes, a constant, lower amount of insulin is produced by the pancreas to maintain fasting BG within normal levels.[12] This is referred to as basal insulin production. After food is consumed, BG levels rise, and the insulin-secretion response occurs in two phases.[13] An initial burst, known as the *first phase,* lasts for only minutes while the *second phase* occurs over the course of an hour or more. The pulsatile release of insulin appears to be particularly important for suppressing hepatic glucose production and stimulating glucose disposal in adipose tissue.

Amylin is a naturally occurring hormone cosecreted from β-cells with insulin. People with T1DM have either a relative or complete lack of amylin. Amylin has three major mechanisms of action: suppression of postmeal glucagon secretion; regulation of the rate of gastric emptying from the stomach to the small intestine, which increases satiety; and stimulation of glycogenolysis and glycolysis in muscle.

▶ *Impaired Insulin Secretion*

A pancreas with normal β-cell function is able to adjust insulin production to maintain normal BG levels.[11] In T2DM, the β-cell becomes less sensitive to glucose and other stimuli,[13] resulting in slowed, insufficient release of insulin and subsequent hyperglycemia, particularly after meals. Additionally, insufficient insulin production results in insufficient suppression of glucose production by the liver as the result of a meal. The typical course of T2DM is characterized by increasing therapy requirements to maintain adequate glucose control. The progressive nature of T2DM is thought to be related to an ongoing loss of both β-cell mass and function.

Table 44–1

Five Components of Metabolic Syndrome[14]

Risk Factor	Defining Level
1. Abdominal obesity	Based on ethnic group[a]
Plus any two of the following:	
2. Triglycerides	≥ 150 mg/dL (1.70 mmol/L) or treated
3. HDL cholesterol	
• Men	< 40 mg/dL (1.03 mmol/L) or treated
• Women	< 50 mg/dL (1.29 mmol/L) or treated
4. Blood pressure	≥ 130 or ≥ 85 mm Hg or treated
5. Fasting glucose	≥ 100 mg/dL (5.6 mmol/L) or diagnosed type 2 diabetes

[a]102 cm (40 in) for males and 88 cm (35 in) for females likely to be used clinically.

HDL, high-density lipoprotein.

▶ *Insulin Resistance*

The initial hyperglycemia which occurs in T2DM causes the body to react with an exaggerated second-phase hyperinsulinemia response. This initial hyperinsulinemia downregulates insulin receptors on the liver, muscles, and adipose tissue,[11,13] resulting in insulin resistance which is the inability of target tissues to respond as expected to circulating insulin. Insulin resistance in the liver is particularly problematic as it results in the liver continuing glucose production even during nonfasting periods.[11] Insulin resistance may exist for years prior to diabetes diagnosis. Attempts by the pancreas to increase insulin production to overcome insulin resistance will eventually result in β-cell exhaustion and decreased insulin production. The combination of insulin resistance and reduced β-cell mass and function results in T2DM.

▶ *Metabolic Syndrome*

Insulin resistance has been associated with a number of other cardiovascular risks. The clustering of these risk factors has been termed the metabolic syndrome. Criteria defining the metabolic syndrome as established by the International Diabetes Federation are summarized in Table 44–1.[14] Patients having these additional risk factors are at much higher cardiovascular risk than would be expected from individual components of the syndrome.

Clinical Presentation and Diagnosis

Characteristic	T1DM	T2DM	LADA
Usual age of onset	Childhood or adolescence	Adult	Over 30
Speed of onset	Abrupt	Gradual	Gradual
Family history	Negative	Positive	Positive
Body type	Thin	Obese	Thin
Metabolic syndrome	No	Often	No
Autoantibodies	Present	Rare	Present
Symptoms	Polyuria, polydipsia, polyphagia, rapid weight loss	Asymptomatic	Polyuria, polydipsia, polyphagia, rapid weight loss
Ketones at diagnosis	Present	Uncommon	Dependent upon β-cell function at time of diagnosis
Acute complications	Diabetic ketoacidosis (DKA)	Rare	DKA possible
Microvascular complications at diagnosis	Rare	Common	Dependent on length of disease at time of diagnosis
Macrovascular complications at or before diagnosis	Rare	Common	Dependent on length of disease at time of diagnosis

▶ *Incretin Effect*

When nutrients enter the stomach and intestines, incretin hormones are released, which stimulate insulin secretion to a greater degree than what is secreted when glucose is administered intravenously.[15,16] This so-called incretin effect is mediated by two hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP). GLP-1 is secreted by the L cells of the ileum and colon primarily, and GIP is secreted by the K cells. GLP-1 secretion is stimulated when nutrients enter the gastrointestinal (GI) tract.[16] Within minutes of food ingestion, GLP-1 levels rise rapidly. A glucose-dependent release of insulin occurs, and the dipeptidyl peptidase-4 (DPP-4) enzyme cleaves GLP-1 rapidly to an inactive metabolite. Much of the research on glucose-lowering products involves prolonging the action of GLP-1. Other glucose-lowering effects of GLP-1 include suppression of glucagon, slowing gastric emptying, and increasing satiety.

▶ *Selective Sodium-Dependent Glucose Cotransporter-2 (SGLT2)*

Rather than allowing glucose to be dumped into the urine to assist with correction of hyperglycemia in the blood, the kidney functions to hold onto glucose. Glucose filtered by the kidneys is completely reabsorbed when blood glucose values are normal, though once blood glucose levels exceed 180 mg/dL (10.0 mmol/L), glucose does begin being spilled into excreted urine.[17] The SGLT2 transporter reabsorbs the majority (80%–90%) of the filtered glucose in the early section of the proximal tubule and the remaining glucose in the more distal portions of the proximal tubule.[17] The SGLT2 transporter has become an important target for newer antidiabetic drug therapy since inhibition of this transporter results in excretion of glucose by the kidney, thereby lowering glucose concentrations in the plasma.

CLINICAL PRESENTATION AND DIAGNOSIS

Screening

Currently, the American Diabetes Association (ADA) recommends routine screening for T2DM every 3 years in all adults starting at 45 years of age.[7] Testing for T2DM should be considered, regardless of age, in adults who have a BMI greater than or equal to 25 kg/m^2 (or BMI greater than or equal to 23 kg/m^2 for Asian Americans) and one or more additional risk factors.[7] The ADA does not currently recommend widespread screening for T1DM, although measurement of islet autoantibodies may be appropriate for high-risk individuals, including those who have relatives with T1DM. See Table 44–2[7] for complete screening guidelines.

Table 44–2

American Diabetes Association (ADA) Screening Recommendations for Diabetes[7]

Asymptomatic Type 1

The ADA does not recommend screening for T1DM because of low incidence in the general population and due to acute presentation of symptoms

Asymptomatic Type 2

1. The ADA recommends screening for T2DM every 3 years in all adults beginning at 45 years of age
2. Testing should be considered for persons younger than 45 years of age or more frequently in individuals who are overweight (BMI ≥ 25 kg/m^2 for the general population and ≥ 23 kg/m^2 for Asian Americans) and have additional risk factors:
   - Habitually inactive
   - First-degree relative with diabetes
   - Member of a high-risk ethnic population (eg, African American, Latino or Hispanic American, Native American, Asian American, Pacific Islander)
   - Previous diagnosis of GDM
   - Hypertensive (≥ 140/90 mm Hg or on therapy)
   - HDL cholesterol level < 35 mg/dL (0.91 mmol/L) and/or triglyceride level > 250 mg/dL (2.83 mmol/L)
   - Polycystic ovary syndrome
   - Previous IGT or IFG or A_{1c} ≥ 5.7% (0.057 or 39 mmol/mol Hgb)
   - Other clinical conditions associated with insulin resistance (eg, acanthosis nigricans)
   - History of cardiovascular disease

Type 2 in Children and Adolescents

Criteria:
- Overweight (BMI ≥ 85th percentile for age and sex) or obesity (BMI ≥ 95th percentile for age and sex)

And one or more of the following risk factors:
- Family history of T2DM in first- or second-degree relatives
- Race or ethnicity (Native American, African American, Latino or Hispanic American, Asian American, Pacific Islander)
- Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary disease, small-for-gestational-age birth weight)
- Maternal history of diabetes or GDM during child's gestation

Age of initiation:
Age 10 years or at onset of puberty, if puberty occurs at a younger age
Frequency of testing:
Every 3 years
Test method: A_{1c}, FPG, or OGTT (FPG or OGTT possibly more suitable than A_{1c})

GDM

1. Screen for undiagnosed T2DM at first prenatal visit in those with risk factors using standard criteria
2. All women not already known to have diabetes should be screened with an OGTT between weeks 24 and 28 of gestation

A_{1c}, hemoglobin A_{1c}; BMI, body mass index; FPG, fasting plasma glucose; GDM, gestational diabetes mellitus; HDL, high-density lipoprotein; Hgb, hemoglobin; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

Gestational Diabetes

All pregnant women who have risk factors for T2DM should be screened for undiagnosed T2DM at their first prenatal visit using standard diagnostic criteria. Any woman found to have diabetes at that early point in pregnancy is considered to have T2DM, not GDM. All other pregnant women not currently known to have DM should be screened for GDM. Two possible strategies exist for GDM screening. They are a "one-step" fasting 2-hour 75-g oral glucose tolerance test (OGTT) and a "two-step" process that include a 1-hour 50-g nonfasting screen followed by a 3-hour fasting 100-g OGTT for those with a 1-hour screening glucose of greater than or equal to 140 mg/dL (7.8 mmol/L). See Table 44–3.[7] The "one-step" test with diagnostic criteria from the International Association of Diabetes and Pregnancy Study Groups is preferred by the ADA given these criteria were based on pregnancy outcomes rather than prediction of subsequent maternal diabetes.[7] Any woman diagnosed with GDM should be retested at four to 12 weeks postpartum using the OGTT with nonpregnant diagnostic criteria.

Table 44–3

One-Step and Two-Step Strategies for Diagnosis of Gestational Diabetes Mellitus[7]

One-Step Strategy		
	Plasma Glucose	
Time	**mg/dL**	**mmol/L**
Fasting	92 or more[a]	5.1 or more[a]
75-g glucose load		
1 hour	180 or more[a]	10.0 or more[a]
2 hours	153 or more[a]	8.5 or more[a]
Two-Step Strategy		
	Plasma Glucose	
Time	**mg/dL**	**mmol/L**
Step 1: Nonfasting		
50-g glucose load		
1 hour	130 or more[b]	7.2 or more[b]
	135 or more[b]	7.5 or more[b]
	140 or more[b]	7.8 or more[b]
Step 2: Fasting		
	95 or more[c]	5.3 or more[c]
100-g glucose load		
1 hour	180 or more[c]	10 or more[c]
2 hours	155 or more[c]	8.6 or more[c]
3 hours	140 or more[c]	7.8 or more[c]

[a] A positive diagnosis of diabetes is made when any of the listed glucose values are exceeded. The test should be done in the morning after an 8-hour fast.

[b] Any threshold could be utilized. Exceeding threshold selected requires follow-up fasting oral glucose tolerance test.

[c] A positive diagnosis of diabetes is made when at least two of the four listed glucose values are exceeded.

Note: These values are based on American Diabetes Association guidelines.

Diagnostic Criteria

Diagnosis of DM includes glycemic outcomes exceeding threshold values with one of three testing options (Table 44–4).[7] For a diagnosis, two abnormal test results are required from either the same sample or two separate samples unless unequivocal symptoms of hyperglycemia exist, such as polydipsia, polyuria, and polyphagia. Either A_{1c}, fasting plasma glucose (FPG), or OGTT are appropriate tests for detecting and confirming DM. Use of the same type of test for initial screening and confirmation is recommended, but diagnostic results from two different testing options can also be used.

The categorization thresholds of glucose status for FPG determination and the OGTT are listed in Table 44–5.[7] IFG and IGT may coexist or may be identified independently. FPG level represents hepatic glucose production during the fasting state, whereas postprandial glucose (PPG) levels in the OGTT may reflect glucose uptake in peripheral tissues, insulin sensitivity, or decreased first-phase insulin response. The OGTT identifies people with either IFG or IGT and, therefore, potentially more people at increased risk for DM and cardiovascular disease. The OGTT is a more cumbersome test to perform than either A_{1c} or

Table 44–4

American Diabetes Association Criteria for Diagnosis of Diabetes[7]

Symptoms of diabetes plus a casual plasma glucose concentration ≥ 200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of day without regard to time since the last meal. Classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

Or

FPG ≥ 126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours.

Or

Two-hour postload glucose ≥ 200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the WHO using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.

Or

A_{1c} ≥ 6.5% (0.065; 48 mmol/mol Hgb). The test should be performed in a laboratory using a method that is NGSP certified to the DCCT assay.

A_{1c}, hemoglobin A_{1c}; DCCT, Diabetes Control and Complications Trial; FPG, fasting plasma glucose; Hgb, hemoglobin; NGSP, National Glycohemoglobin Standardization Program; OGTT, oral glucose tolerance test; WHO, World Health Organization.

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The OGTT is not recommended for routine clinical use.

Patient Encounter Part 1

A 42-year-old African American woman presents to her provider for a follow-up appointment for hypertension. Upon questioning, she states that she has noticed increased fatigue lately. She has occasional headaches which she treats with moderate success with over-the-counter ibuprofen.

PMH: Hypertension for 3 years

FH: Mother has type 2 diabetes, dyslipidemia, and hypertension and is living at age 65; father has hypertension, dyslipidemia, and a previous myocardial infarction resulting in the placement of two stents at age 51. He is living at age 67. She has three siblings, all of whom have hypertension; one older brother has type 2 diabetes, as well. She has two children without chronic health conditions.

SH: Prior history of smoking one-half pack per day for 10 years, but she quit 10 years ago; denies alcohol or illicit drug use; denies physical activity.

Allergies: Amoxicillin

Meds: Hydrochlorothiazide 25 mg daily; ibuprofen 400 mg PRN headache

VS: BP 146/84 mm Hg, P 78 beats/min, RR 16 breaths/min, T 36.5°C (97.7°F), Ht 5′3″ (160 cm), Wt 185 lb (84 kg)

ROS: (+) Fatigue, (–) N/V/D, headache, SOB, chest pain

What risk factors does this patient have for diabetes?

Based on patient presentation, which type of diabetes is more likely?

What additional information is needed to diagnose this patient with diabetes?

Table 44–5

American Diabetes Association Categorization of Glucose Status[7]

	mg/dL	mmol/L
FPG		
Normal	< 100	< 5.6
IFG (prediabetes)	100–125	5.6–6.9
Diabetes	≥ 126	≥ 7.0
2-hour postload plasma glucose (OGTT)		
Normal	< 140	< 7.8
IGT (prediabetes)	140–199	7.8–11.0
Diabetes	≥ 200	≥ 11.1

FPG, fasting plasma glucose; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test.

FPG; however, the efficacy of interventions for primary prevention of T2DM has been demonstrated among patients with IGT, not among those with IFG or specific A_{1c} levels.

TREATMENT

Goals of Therapy

KEY CONCEPT DM treatment goals include reducing, controlling, and managing long-term microvascular, macrovascular, and neuropathic complications; preserving β-cell function; preventing acute complications from high BG levels; minimizing hypoglycemic episodes; and maintaining the patient's overall quality of life. To achieve the majority of these goals, near-normal BG levels are fundamental; thus, glycemic control remains a primary objective in diabetes management. Two landmark trials, the Diabetes Control and Complications Trial (DCCT)[18] and the United Kingdom Prospective Diabetes Study (UKPDS),[19] showed that lowering BG levels decreased the risk of developing chronic complications. A near-normal BG level can be achieved with appropriate patient education, lifestyle modification, and medications.

▶ *Setting and Assessing Glycemic Targets*

KEY CONCEPT Patients and clinicians can evaluate how well a patient's DM is managed by monitoring daily BG values and the A_{1c} quarterly to biannually.[20] Self-monitoring of blood glucose (SMBG) enables patients to obtain their current BG level at any time easily and relatively inexpensively. The A_{1c} test provides a weighted-mean BG level from approximately the previous 3 months.[20]

Self-Monitoring of Blood Glucose SMBG is the standard method for routinely checking BG levels. Most often, a small drop of blood obtained from a fingertip using a lancet device is used for testing. Some home BG meters require very little blood and can be used for alternative site testing, where small samples can be obtained from the palm, forearm, or thigh. Each reading provides a point-in-time evaluation of glucose levels that can vary widely depending on numerous factors including food, exercise, stress, illness, and time of day.

By examining multiple individual points of data, glucose patterns can be established. Therapy can be evaluated from these patterns, and adjustments made to improve overall BG levels. The ADA premeal plasma glucose goals are 80 to 130 mg/dL (4.4–7.2 mmol/L) and peak postprandial plasma glucose goals are less than 180 mg/dL (10.0 mmol/L).[20] For patients using multiple daily insulin injections or insulin pump therapy, SMBG is generally required prior to each meal or snack, at bedtime, prior to exercise, prior to critical tasks like driving, and throughout an episode of hypoglycemia from suspicion of hypoglycemia to restoration of normal glucose levels.[21] Optimal frequency of testing in patients using less frequent insulin injections, noninsulin therapies, or medical nutrition therapy (MNT) is less clear.

Continuous glucose sensors are now available that work with or independently of insulin pumps. These monitors provide BG readings, primarily through interstitial fluid (ISF). A small sterile disposable glucose-sensing device called a sensor is inserted into the subcutaneous tissues. This sensor measures change in glucose in ISF and sends the information to a monitor, which stores the results. Some devices allow analysis of data collected over time to aid in clinical decision-making.

Hemoglobin A_{1c} Glucose interacts spontaneously with Hgb in red blood cells to form glycated derivatives. The most prevalent derivative is A_{1c}. Greater amounts of glycation occur when BG levels increase. Because a red blood cell has a life span of approximately 3 months, levels of A_{1c} provide a marker reflecting the average glucose levels over this timeframe.[20] The ADA goal for persons with DM is less than 7% (0.07; 53 mmol/mol Hgb), whereas the American Association of Clinical Endocrinologists (AACE) supports a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hgb) if achievable without resultant hypoglycemia.[20,22] A less stringent A_{1c} goal of less than 8% (0.08; 64 mmol/mol Hgb) may be utilized in some patients such as those with limited life expectancy, long-standing diabetes that is otherwise difficult to control, and those with multiple comorbid conditions including advanced microvascular and/or macrovascular complications.[20] Testing A_{1c} levels should occur at least twice a year for patients who are meeting treatment goals and four times per year for patients not meeting goals or those with recent changes in therapy.[20] Table 44–6 presents goals for A_{1c} and monitoring parameters for concomitant conditions associated with DM.[20,23,24]

Ketone Monitoring Diabetic ketoacidosis is a particular concern in people with T1DM but can also occur in GDM and even in patients with T2DM.[25] When there is a lack of insulin, peripheral tissues cannot take up and store glucose. This causes the body to think it is starving, and because of excessive lipolysis, ketones, primarily β-hydroxybutyric acid and acetoacetic acid, are produced as byproducts of free fatty acid metabolism in the liver. Glucose and ketones are osmotically active, and when an excessive amount of ketones is formed, the body gets rid of them through urine, leading to dehydration.

Patients prone to ketosis should test for ketones during stressful events such as acute illness.[20] When marked hyperglycemia is accompanied by ketosis, vomiting, or alterations in consciousness, temporary changes to the patient's treatment regimen are needed, and therefore, immediate contact with the diabetes care team is required. Women with preexisting diabetes before pregnancy or with GDM should be prescribed ketone strips and educated on ketoacidosis prevention and detection.[26] Blood ketone testing methods that quantify β-hydroxybutyric acid, the predominant ketone body, are available and preferred to diagnose and monitor ketoacidosis.[25] Home tests for β-hydroxybutyric acid are available. Specific treatment of DKA may include rehydration, correction of electrolyte imbalances, and insulin administration.[27]

General Approach to Therapy

▶ *Type 1 Diabetes Mellitus*

Treatment of T1DM requires providing exogenous insulin to replace the endogenous loss of insulin from the nonfunctional pancreas. Ideally, insulin therapy mimics normal

Table 44–6

American Diabetes Association Recommended Goals of Therapy in Adults[20,23,24]

Area	Goals
Glycemia	
A_{1c}	< 7% (0.07; 53 mmol/mol Hgb) Evaluate every 3 months until in goal; then every 6 months
Preprandial plasma glucose	80–130 mg/dL (4.4–7.2 mmol/L)
Peak postprandial plasma glucose[a]	< 180 mg/dL (10.0 mmol/L)
Blood Pressure	10-year ASCVD risk ≥ 15%: < 130/80 mmHg 10-year ASCVD risk < 15%: < 140/90 mm Hg Evaluate at every visit
Lipids	No lipid-lowering therapy: Evaluate at diagnosis, then every 5 years thereafter Lipid-lowering therapy: At initiation, 4–12 weeks after initiation or dose change, then annually
Monitoring for Complications	
Eyes	Dilated eye examination every 1–2 years
Feet	Yearly comprehensive foot evaluation Feet should be examined at every visit for those with known sensory loss or history of prior ulcerations or amputation
Urinary microalbumin	Yearly

[a] Peak postprandial glucose measurements should be made 1–2 hours after the beginning of the meal.

A_{1c}, hemoglobin A_{1c}; ASCVD, atherosclerotic cardiovascular disease; Hgb, hemoglobin.

insulin physiology. The basal-bolus approach attempts to reproduce basal insulin response using intermediate- or long-acting insulin, whereas short- or rapid-acting insulin replicates bolus release of insulin physiologically seen around a meal in individuals without diabetes. A number of different regimens have been used through the years to more closely follow natural insulin patterns. As a rule, basal insulin makes up approximately 50% of the total daily dose.[28] The remaining half is provided with bolus doses around three daily meals. Exact doses are individualized to the patient and amount of food consumed. Most people with T1DM use between 0.4 and 1 unit/kg/day.[28]

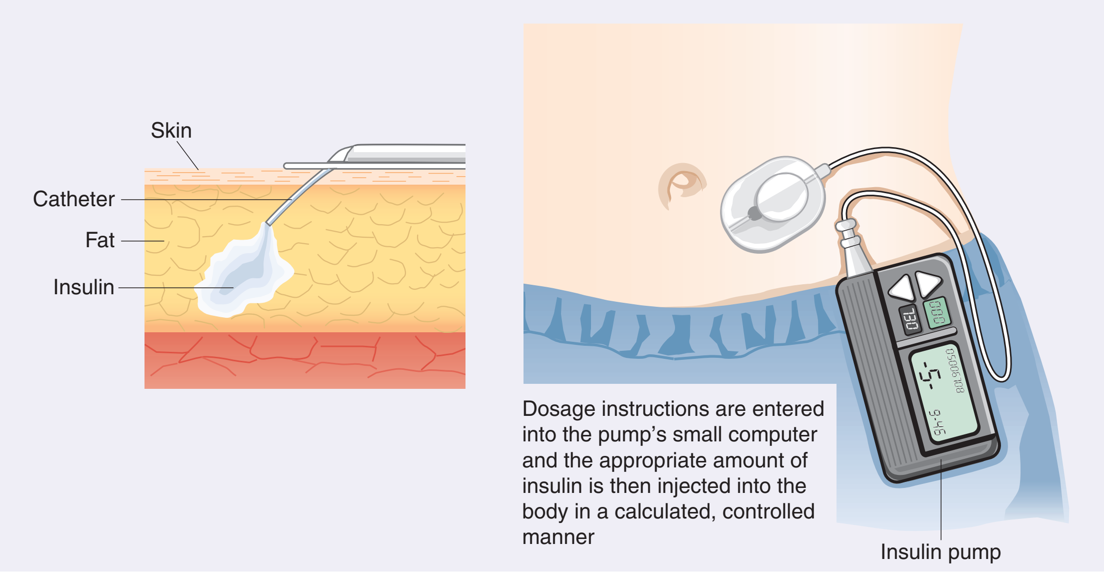
Currently, the most advanced form of insulin delivery is the insulin pump, also referred to as continuous subcutaneous insulin infusion (CSII).[28] See Figure 44–1. Insulin pumps have been linked to improvement in quality of life. Using rapid-acting insulin most often, these pumps are programmed to provide a slow release of small amounts of insulin as the basal portion of therapy, and larger boluses of insulin are administered by the patient to account for consumption of food or correction of hyperglycemia. Insulin pump settings may be adjusted to address exercise, illness, and other factors. Pramlintide, a synthetic analog of the naturally occurring hormone amylin, is another injectable BG–lowering medication that can be used in people with T1DM or in people with T2DM using insulin for treatment.[28] In addition to medication management with insulin, patients with T1DM must also be educated to live a healthy lifestyle including eating a healthy diet and exercising.

▶ *Type 2 Diabetes Mellitus*

Treatment of patients with T2DM has changed dramatically over the past decade with the addition of a number of new drugs and recommendations to maintain tighter glycemic levels.[20,22,28] Technology available to individuals with T1DM can also be used for those with T2DM.[21] However, lifestyle modifications including education, nutrition, and exercise are paramount to managing the disease successfully.[29]

▶ *Gestational Diabetes*

An individualized meal plan consisting of at least 175 g of carbohydrate, 71 g of protein, and 28 g of fiber per day is recommended in all pregnant women.[26] Preventing ketosis, promoting adequate



Dosage instructions are entered into the pump's small computer and the appropriate amount of insulin is then injected into the body in a calculated, controlled manner

FIGURE 44–1. Insulin pump and placement.

growth of the fetus, maintaining satisfactory BG levels, and preventing nausea and other undesired GI side effects are desired goals in these patients. Glucose goals for SMBG for pregnant women as per the ADA include fasting of 95 mg/dL (5.3 mmol/L), 1-hour postprandial of 140 mg/dL (7.8 mmol/L), and 2-hour postprandial of 120 mg/dL (6.7 mmol/L).[26] An abundance of glucose causes excessive insulin production by the fetus, which can lead to development of an abnormally large baby. Infant hypoglycemia at delivery, hyperbilirubinemia, and complications associated with delivery of a large baby also may occur when BG levels are not controlled. The ADA currently advocates for insulin as the primary pharmacotherapeutic choice for GDM.[26] Neither metformin nor glyburide is considered first line owing to the fact that they cross the placenta as well as concerns over inconsistent efficacy data in this population. Insulin should be used when BG levels are not maintained adequately by diet and physical activity. Insulin detemir, insulin aspart, lispro, neutral protamine hagedorn (NPH), and regular insulin all carry the older Food and Drug Administration (FDA) letter category B safety rating which indicates animal studies with the drug have failed to demonstrate risk to a developing fetus.[30]

Nonpharmacologic Therapy

▶ *Medical Nutrition Therapy*

MNT is considered an integral component of DM management and self-management education.[29] People with DM should receive individualized MNT, preferably by a registered dietitian. MNT should be provided as an ongoing dialogue customized to take into account cultural, lifestyle, and financial considerations. The primary focus of MNT for T1DM patients and T2DM patients taking mealtime insulin is matching optimal insulin dosing to carbohydrate consumption while maintaining a healthy balance. In T2DM, the primary focus is portion control and controlling BG, blood pressure (BP), and lipids through individualizing limits of carbohydrates, saturated fats, sodium, and calories.

▶ *Dietary Supplements*

There is insufficient evidence of efficacy for improved BG control for any individual herb or supplement. Herbs and supplements commonly touted to improve glucose control include chromium, curcumin, vitamin D, aloe vera, and cinnamon.[29] Additional information can be found at the National Institutes of Health Office of Dietary Supplements (https://ods.od.nih.gov).

▶ *Weight Management*

Moderate weight loss in patients with T2DM has been shown to reduce cardiovascular risk, as well as delay or prevent onset of DM in those with prediabetes.[31-33] The recommended primary approach to weight loss is therapeutic lifestyle change (TLC), which integrates a 7% reduction in body weight and increase in physical activity.[34] Slow but progressive weight loss of 0.45 to 0.91 kg (1–2 lb) per week is preferred.[34] Individual target caloric goals should be set. In the Diabetes Prevention Program, this was done by estimating daily caloric intake needed to maintain a person's current weight and then subtracting 500 to 1000 Calories per day (about 2100–4200 kJ/day) depending on initial weight.[31] Metabolic surgeries, such as Roux-en-Y gastric bypass, are recommended for patients with T2DM and BMI that is or exceeds 40 kg/m^2 regardless of glycemic control.[35] Metabolic surgery is also recommended in patients with BMI above 35 kg/m^2 but less than 40 kg/m^2 who are unable to achieve sustained weight loss and have comorbidities such as uncontrolled glucose.[35] Four drug therapy options have been approved for weight loss in patients with BMI greater than or equal to 27 kg/m^2 with one or more obesity-related conditions and in patients with BMI greater than or equal to 30 kg/m^2.[35] Options include orlistat (a lipase inhibitor), phentermine/topiramate extended release (a sympathomimetic amine anorectic/antiepileptic combination), naltrexone/bupropion (an opioid antagonist/aminoketone antidepressant combination), liraglutide (a GLP-1 receptor agonist [GLP-1 RA]), and semaglutide (a GLP-1 RA).

▶ *Physical Activity*

Regular physical activity improves BG control by improving insulin sensitivity.[34] Physical activity is associated with long-term maintenance of weight loss and may prevent onset of T2DM in high-risk persons. Before initiating a physical activity program, patients should undergo a detailed physical examination, including screening for microvascular or macrovascular complications that may be worsened by a particular activity.[29] Initiation of physical activities in an individual with a history of a sedentary lifestyle should begin with a modest increase in activity. Walking, swimming, and cycling are examples of low-impact exercises that could be encouraged; gardening and usual housecleaning tasks can be good exercises as well. Recommended physical activity goals for patients with T2DM include 150 min/week of moderate-to-vigorous aerobic exercise spread out during at least 3 days of the week with no more than 2 consecutive days between bouts of aerobic activity and moderate-to-vigorous resistance training at least 2 to 3 days/week.[29] All persons should be encouraged to break up sedentary periods over 30 minutes by getting up to stand, walk, or perform light physical activities.[29]

▶ *Psychological Assessment and Care*

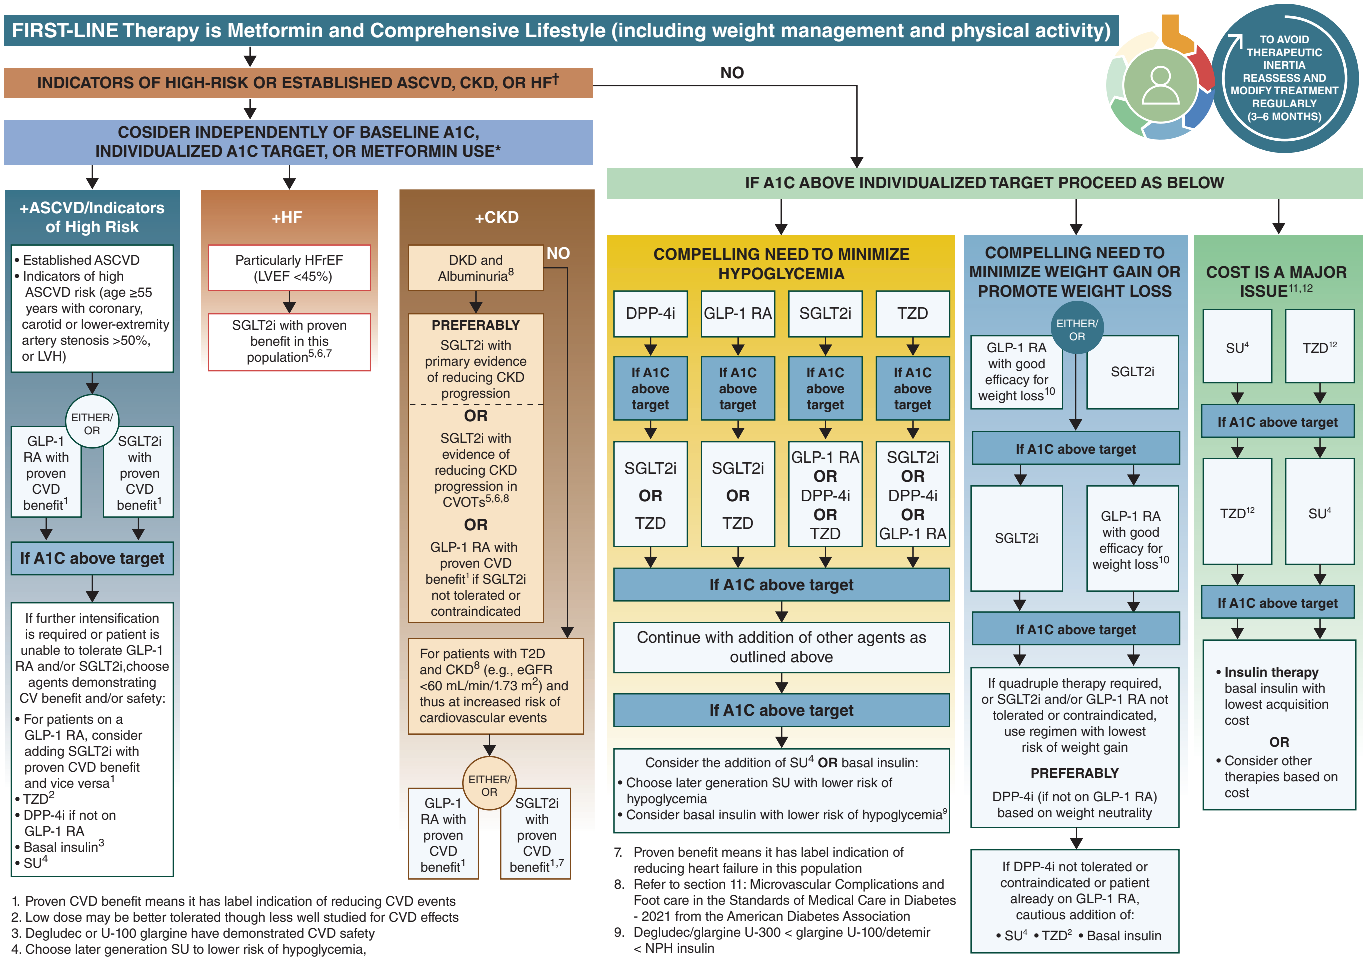
Mental health may impact a patient's ability to carry out DM management care tasks. Clinicians should incorporate psychological assessment and treatment into routine care. The ADA recommends ongoing psychological screening, including determining the patient's attitudes regarding DM; expectations of medical management and outcomes; mood and affect; general and diabetes-related quality of life; and financial, social, and emotional resources.[29] Patients demonstrating poor self-management should be screened for diabetes-related distress, depression, anxiety, an eating disorder, and/or cognitive impairment.[29]

▶ *Immunizations*

Yearly influenza vaccinations are recommended for all patients with DM 6 months of age or older.[36] Pneumococcal vaccination with the 13-valent conjugate vaccine is recommended for children before age 2.[36] The 23-valent polysaccharide vaccine is recommended for patients with DM who are between 2 and 64 years of age as a one-time vaccination.[36] At age greater than or equal to 65 years, patients should receive the pneumococcal polysaccharide vaccine, regardless of prior vaccination history. Whether the patient should receive another dose of the pneumococcal 13-valent conjugate vaccine before receipt of this 23-valent polysaccharide dose should be determined via shared clinical decision making with a healthcare provider. A 2- or 3-dose hepatitis B vaccination series is recommended in unvaccinated patients aged 18 to 59.[36] For those over the age of 60, hepatitis B vaccination may also be considered. Additional vaccinations such as zoster; human papillomavirus; and tetanus, diphtheria, and pertussis are also recommended by the Advisory Committee on Immunization Practices for persons with diabetes as they are for persons without diabetes.

Pharmacologic Therapy

Figure 44–2 summarizes the treatment algorithm for T2DM per the ADA.[28] This algorithm is similar to the AACE algorithm in that both treatment guidelines prioritize treatment options based



FIRST-LINE Therapy is Metformin and Comprehensive Lifestyle (including weight management and physical activity)
TO AVOID THERAPEUTIC INERTIA REASSESS AND MODIFY TREATMENT REGULARLY (3–6 MONTHS)
INDICATORS OF HIGH-RISK OR ESTABLISHED ASCVD, CKD, OR HF†
NO
COSIDER INDEPENDENTLY OF BASELINE A1C, INDIVIDUALIZED A1C TARGET, OR METFORMIN USE*
IF A1C ABOVE INDIVIDUALIZED TARGET PROCEED AS BELOW
+ASCVD/Indicators of High Risk
• Established ASCVD
• Indicators of high ASCVD risk (age ≥55 years with coronary, carotid or lower-extremity artery stenosis >50%, or LVH)
EITHER/ OR
GLP-1 RA with proven CVD benefit1
SGLT2i with proven CVD benefit1
If A1C above target
If further intensification is required or patient is unable to tolerate GLP-1 RA and/or SGLT2i,choose agents demonstrating CV benefit and/or safety:
• For patients on a GLP-1 RA, consider adding SGLT2i with proven CVD benefit and vice versa1
• TZD2
• DPP-4i if not on GLP-1 RA
• Basal insulin3
• SU4
+HF
Particularly HFrEF (LVEF <45%)
SGLT2i with proven benefit in this population5,6,7
+CKD
DKD and Albuminuria8
NO
PREFERABLY
SGLT2i with primary evidence of reducing CKD progression
OR
SGLT2i with evidence of reducing CKD progression in CVOTs5,6,8
OR
GLP-1 RA with proven CVD benefit1 if SGLT2i not tolerated or contraindicated
For patients with T2D and CKD8 (e.g., eGFR <60 mL/min/1.73 m2) and thus at increased risk of cardiovascular events
EITHER/ OR
GLP-1 RA with proven CVD benefit1
SGLT2i with proven CVD benefit1,7
COMPELLING NEED TO MINIMIZE HYPOGLYCEMIA
DPP-4i
GLP-1 RA
SGLT2i
TZD
If A1C above target
SGLT2i OR TZD
SGLT2i OR TZD
GLP-1 RA OR DPP-4i OR TZD
SGLT2i OR DPP-4i OR GLP-1 RA
If A1C above target
Continue with addition of other agents as outlined above
If A1C above target
Consider the addition of SU4 OR basal insulin:
• Choose later generation SU with lower risk of hypoglycemia
• Consider basal insulin with lower risk of hypoglycemia9
COMPELLING NEED TO MINIMIZE WEIGHT GAIN OR PROMOTE WEIGHT LOSS
EITHER/ OR
GLP-1 RA with good efficacy for weight loss10
SGLT2i
If A1C above target
SGLT2i
GLP-1 RA with good efficacy for weight loss10
If A1C above target
If quadruple therapy required, or SGLT2i and/or GLP-1 RA not tolerated or contraindicated, use regimen with lowest risk of weight gain
PREFERABLY
DPP-4i (if not on GLP-1 RA) based on weight neutrality
If DPP-4i not tolerated or contraindicated or patient already on GLP-1 RA, cautious addition of:
• SU4 • TZD2 • Basal insulin
COST IS A MAJOR ISSUE11,12
SU4
TZD12
If A1C above target
TZD12
SU4
If A1C above target
• Insulin therapy basal insulin with lowest acquisition cost
OR
• Consider other therapies based on cost

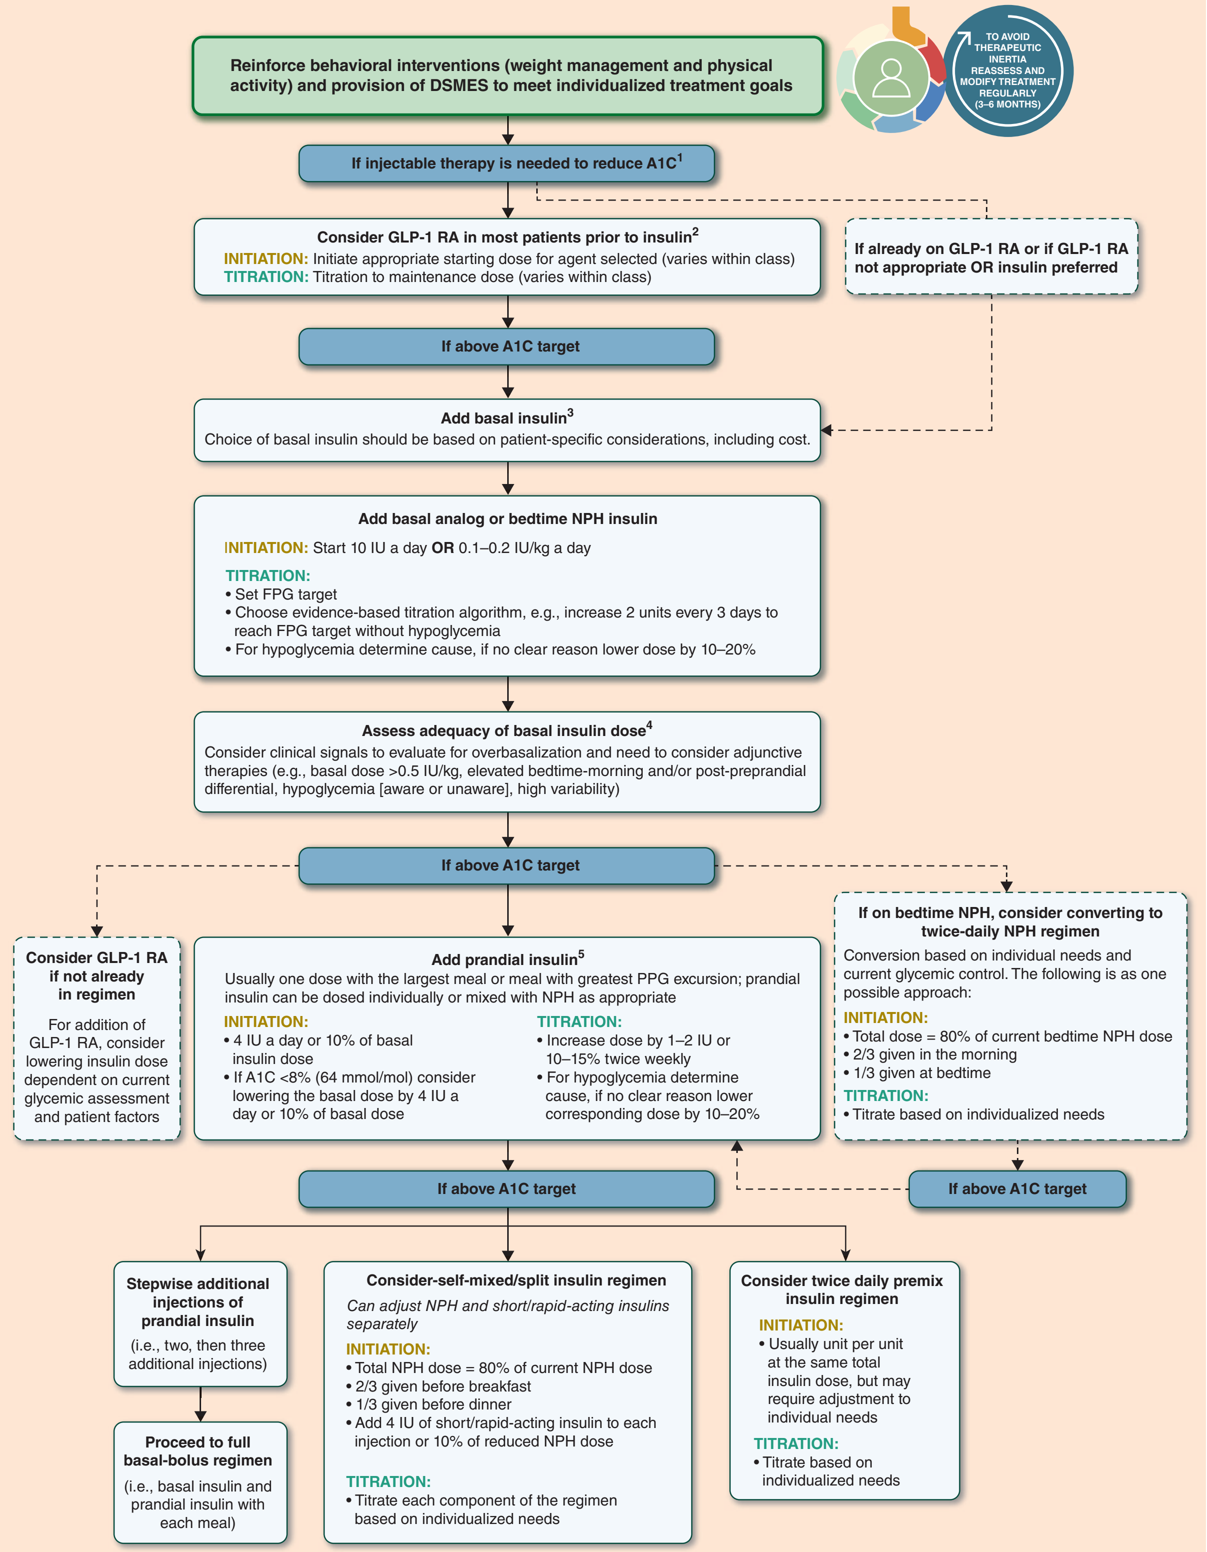
1. Proven CVD benefit means it has label indication of reducing CVD events
2. Low dose may be better tolerated though less well studied for CVD effects
3. Degludec or U-100 glargine have demonstrated CVD safety
4. Choose later generation SU to lower risk of hypoglycemia, glimepiride has shown similar CV safety to DPP-4i
5. Be aware that SGLT2i labelling varies by region and individual agent with regard to indicated level of eGFR for initiation and continued use
6. Empagliflozin, canagliflozin, and dapagliflozin have shown reduction in HF and to reduce CKD progression in CVOTs. Canagliflozin and dapagliflozin have primary renal outcome data. Dapagliflozin and empagliflozin have primary heart failure outcome data.
7. Proven benefit means it has label indication of reducing heart failure in this population
8. Refer to section 11: Microvascular Complications and Foot care in the Standards of Medical Care in Diabetes - 2021 from the American Diabetes Association
9. Degludec/glargine U-300 < glargine U-100/detemir < NPH insulin
10. Semaglutide > liraglutide > dulaglutide > exenatide > lixisenatide
11. If no specific comorbidities (i.e., no established CVD, low risk of hypoglycemia, and lower priority to avoid weight gain or no weight-related comorbidities)
12. Consider country- and region-specific cost of drugs. In some countries TZDs are relatively more expensive and DPP-4i are relatively cheaper.

† Actioned whenever these become new clinical considerations regardless of background glucose-lowering medications.
* Most patients enrolled in the relevant trials were on metformin at baseline as glucose-lowering therapy.

FIGURE 44–2. Glucose-lowering medication in type 2 diabetes: overall approach as per the American Diabetes Association. (A_{1c}, hemoglobin A_{1c}; ASCVD, atherosclerotic cardiovascular disease; CKD, chronic kidney disease; CV, cardiovascular; CVD, cardiovascular disease; CVOTs, cardiovascular outcomes trials; DKD, diabetic kidney disease; DPP-4i, dipeptidyl peptidase 4 inhibitor; eGFR, estimated glomerular filtration rate; GLP-1 RA, glucagon-like peptide 1 receptor agonist; HF, heart failure; HErEF, heart failure with reduced ejection fraction; LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy; SGLT2i, sodium–glucose cotransporter 2 inhibitor; SU, sulfonylurea; T2D, type 2 diabetes; TZD, thiazolidinedione.) (From American Diabetes Association. Pharmacologic approaches to glycemic treatment: Standards of Medical Care in Diabetes – 2021. Diabetes Care. 2021;44(suppl 1):S40–S52., with permission.)

on patient specific factors and treatment benefits, particularly for those patients with cardiovascular disease, heart failure, or chronic kidney disease (CKD).[22,28] The AACE guidelines take a more aggressive approach by advocating for consideration of starting a patient on two medications if presenting A_{1c} is greater than or equal to 7.5% (0.075; 58 mmol/mol Hgb).[22] The ADA, on the other hand, recommends dual therapy when the A_{1c} is greater than or equal to 8.5% (0.085; 69 mmol/mol Hgb).[28] While the ADA guidelines include metformin alone as the first-line therapy option for T2DM, the AACE guidelines include six other noninsulin initial therapy options as possibilities, though SGLT2 inhibitors and GLP-1 RAs are preferred in patients with established or high atherosclerotic cardiovascular disease (ASCVD) risk, heart failure with reduced ejection fraction (HFrEF), and/or CKD.[22,28] Because T2DM generally tends to be a progressive disease, BG levels will eventually increase, making insulin therapy the eventual required therapy in many patients, and therefore, insulin should not be used rhetorically as a prophylactic deterrent as this may result in patient trust issues and/or feelings of failure. This is usually done when several agents have been used with inadequate glucose-lowering results. Addition of GLP-1 RA is recognized by the ADA as an alternative to mealtime insulin in those already receiving maximally titrated basal regimens; in addition to GLP-1 RAs, the AACE guidelines also suggest DPP-4 or SGLT2 inhibitors as options in this scenario. Figure 44–3 is one illustration of a way to start insulin therapy in a patient with T2DM.[28]

KEY CONCEPT Oral and injectable agents are available to treat patients with T2DM who are unable to achieve glycemic control through meal planning and physical activity. Table 44–7[22,28,37-39] lists the oral agents, Table 44–8 lists each noninsulin drug class with site of action and mechanism of action, and Table 44–9 lists the expected A_{1c} reduction for each noninsulin antiglycemic drug class.[28,38-40] Various classes of BG-lowering agents target different organs and have different mechanisms of action. Each of these



TO AVOID THERAPEUTIC INERTIA REASSESS AND MODIFY TREATMENT REGULARLY (3–6 MONTHS)

Reinforce behavioral interventions (weight management and physical activity) and provision of DSMES to meet individualized treatment goals

If injectable therapy is needed to reduce A1C[1]

Consider GLP-1 RA in most patients prior to insulin[2]
INITIATION: Initiate appropriate starting dose for agent selected (varies within class)
TITRATION: Titration to maintenance dose (varies within class)

If already on GLP-1 RA or if GLP-1 RA not appropriate OR insulin preferred

If above A1C target

Add basal insulin[3]
Choice of basal insulin should be based on patient-specific considerations, including cost.

Add basal analog or bedtime NPH insulin

INITIATION: Start 10 IU a day **OR** 0.1–0.2 IU/kg a day

TITRATION:
- Set FPG target
- Choose evidence-based titration algorithm, e.g., increase 2 units every 3 days to reach FPG target without hypoglycemia
- For hypoglycemia determine cause, if no clear reason lower dose by 10–20%

Assess adequacy of basal insulin dose[4]
Consider clinical signals to evaluate for overbasalization and need to consider adjunctive therapies (e.g., basal dose >0.5 IU/kg, elevated bedtime-morning and/or post-preprandial differential, hypoglycemia [aware or unaware], high variability)

If above A1C target

Consider GLP-1 RA if not already in regimen

For addition of GLP-1 RA, consider lowering insulin dose dependent on current glycemic assessment and patient factors

Add prandial insulin[5]
Usually one dose with the largest meal or meal with greatest PPG excursion; prandial insulin can be dosed individually or mixed with NPH as appropriate

INITIATION:
- 4 IU a day or 10% of basal insulin dose
- If A1C <8% (64 mmol/mol) consider lowering the basal dose by 4 IU a day or 10% of basal dose

TITRATION:
- Increase dose by 1–2 IU or 10–15% twice weekly
- For hypoglycemia determine cause, if no clear reason lower corresponding dose by 10–20%

If on bedtime NPH, consider converting to twice-daily NPH regimen

Conversion based on individual needs and current glycemic control. The following is as one possible approach:

INITIATION:
- Total dose = 80% of current bedtime NPH dose
- 2/3 given in the morning
- 1/3 given at bedtime

TITRATION:
- Titrate based on individualized needs

If above A1C target

If above A1C target

Stepwise additional injections of prandial insulin

(i.e., two, then three additional injections)

Proceed to full basal-bolus regimen

(i.e., basal insulin and prandial insulin with each meal)

Consider-self-mixed/split insulin regimen

Can adjust NPH and short/rapid-acting insulins separately

INITIATION:
- Total NPH dose = 80% of current NPH dose
- 2/3 given before breakfast
- 1/3 given before dinner
- Add 4 IU of short/rapid-acting insulin to each injection or 10% of reduced NPH dose

TITRATION:
- Titrate each component of the regimen based on individualized needs

Consider twice daily premix insulin regimen

INITIATION:
- Usually unit per unit at the same total insulin dose, but may require adjustment to individual needs

TITRATION:
- Titrate based on individualized needs

1. Consider insulin as the first injectable if evidence of ongoing catabolism, symptoms of hyperglycemia are present, when A1C levels (>10% [86 mmol/mol]) or blood glucose levels (≥300 mg/dL [16.7 mmol/L]) are very high, or a diagnosis of type 1 diabetes is a possibility.
2. When selecting GLP-1 RA, cosider: patient preference, A1C lowering, weight-lowering effect, or frequency of injection. If CVD, consider GLP-1 RA with proven CVD benefit. Oral or injectable GLP-1 RA are appropriate.
3. For patients on GLP-1 RA and basal insulin combination, consider use of a fixed-ratio combination product (iDegLira or iGlarLixi).
4. Consider switching from evening NPH to a basal analog if the patient develops hypoglycemia and/or frequently forgets to administer NPH in the evening and would be better managed with an AM dose of a long-acting basal insulin.
5. If adding prandial insulin to NPH, consider initiation of a self-mixed or premixed insulin regimen to decrease the number of injections required.

FIGURE 44–3. Initiation and adjustment of insulin regimens. (A$_{1c}$, hemoglobin A$_{1c}$; CVD, cardiovascular disease; DSMES, diabetes self-management education and support; FPG, fasting plasma glucose; GLP-1 RA, glucagon-like peptide-1 receptor agonist; NPH, neutral protamine Hagedorn; PPG, postprandial glucose.) Table 44–7

Oral Agents for the Treatment of Type 2 Diabetes Mellitus (T2DM)[22,28,37–39]

	Drugs					Adjustment for Renal Impairment			
Drug Class	**Trade**	**Generic/ Commercially Available**	**Target Area**	**Blood Glucose Affected**	**Dosing Strategy (All Agents Taken Orally)**	**eGFR 30-50 mL/min (0.50–0.83 mL/s)**	**eGFR < 30 mL/min (0.50 mL/s)**	**Adjustment for Hepatic Impairment**	**Common Adverse Drug Reactions**
α-Glucosidase inhibitors	Precose	Acarbose/Y	Brush border of small intestine	Postprandial	25 mg three times daily with first bite of each main meal Advance at 4–8 week intervals to maximum of 100 mg three times daily	SCr > 2 mg/dL (177 μmol/L): Not recommended	SCr > 2 mg/dL (177 μmol/L): Not recommended	No specific dose adjustment recommended; contraindicated in cirrhosis	GI (flatulence, diarrhea)
	Glyset	Miglitol/Y			25 mg three times daily with first bite of each main meal Advance at 4–8 week intervals to maximum of 100 mg three times daily	SCr > 2 mg/dL (177 μmol/L): Not recommended	SCr > 2 mg/dL (177 μmol/L): Not recommended	No adjustment necessary	GI (flatulence, diarrhea)
Meglitinides (should not be used in combination with other insulin secretagogues)	Prandin	Repaglinide/Y	Pancreas	Postprandial	0.5 mg 15–30 minutes before each meal Double preprandial dose every 7 days to maximum of 4 mg/dose or 16 mg/day (To be taken only if eating)	20–40 mL/min (0.33–0.67 mL/s): Initial dose: 0.5 mg with careful titration	< 20 mL/min (0.33 mL/s): Not studied	Use conservative initial and maintenance doses and use longer intervals between dose adjustments	Hypoglycemia (although less risk than with sulfonylureas)
	Starlix	Nateglinide/Y			120 mg three times daily before meals (To be taken only if eating)	No specific dose adjustment recommended	Use with caution in severe dysfunction	No dose adjustment needed in mild impairment; use with caution in moderate-to-severe dysfunction	Hypoglycemia (although less risk than with sulfonylureas)

(Continued)

Table 44–7

Oral Agents for the Treatment of Type 2 Diabetes Mellitus (T2DM)[22,28,37–39] (*Continued*)

	Drugs					Adjustment for Renal Impairment			
Drug Class	Trade	Generic/ Commercially Available	Target Area	Blood Glucose Affected	Dosing Strategy (All Agents Taken Orally)	eGFR 30-50 mL/min (0.50–0.83 mL/s)	eGFR < 30 mL/min (0.50 mL/s)	Adjustment for Hepatic Impairment	Common Adverse Drug Reactions
Second-generation sulfonylureas	Glynase PresTab	Glyburide micronized/Y	Pancreas	Fasting and postprandial	1.5–3 mg/day with breakfast Increase by 1.5 mg weekly to maximum of 12 mg/day	Not recommended	Not recommended	Use conservative dosing and avoid in severe disease	Hypoglycemia, weight gain
	DiaBeta	Glyburide/Y			2.5–5 mg/day with breakfast Increase by 2.5 mg weekly to maximum of 20 mg/day	Not recommended	Not recommended	Use conservative dosing and avoid in severe disease	Hypoglycemia, weight gain
	Glucotrol	Glipizide/Y			2.5 mg/day 30 minutes before a meal Increase by 2.5–5 mg weekly to maximum of 40 mg/day; divide dose if > 15 mg/day	No specific dose adjustment recommended	No specific dose adjustment recommended	Initial dose: 2.5 mg/day	Hypoglycemia, weight gain
	Glucotrol XL	Glipizide ER/Y			2.5-5 mg once daily before a meal Increase by 5–10 mg weekly to maximum of 20 mg/day	No specific dose adjustment recommended	No specific dose adjustment recommended	No specific dose adjustment recommended	Hypoglycemia, weight gain
	Amaryl	Glimepride/Y			1–2 mg with breakfast Increase by 2 mg every 1–2 weeks to maximum of 8 mg/day	No specific dose adjustment recommended	Initial starting dose should be 1 mg < 15 mL/min (0.25 mL/s): Consider alternative	No specific dose adjustment recommended	Hypoglycemia, weight gain

Biguanides	Glucophage	Metformin/Y	Liver	Fasting and postprandial	500 mg/day to twice daily with meals. Advance weekly to maximum of 2000–2550 mg/day	Do not start or, if already taking, continue cautiously if eGFR 30–45 mL/min/1.73 m^2. Consider 50% of maximum doses and monitoring of renal function every 3 months.	Contraindicated	Avoid or use cautiously in patients at risk for lactic acidosis (renal impairment or alcohol abuse)	GI (diarrhea, abdominal pain)
	Glucophage ER, Glumetza, Fortamet	Metformin, ER/Y							
	Riomet	Metformin, solution/Y			500 mg twice daily; dose may be increased by 500 mg weekly or 850 mg every 2 weeks to maximum of 2000 mg/day				
Thiazolidinediones	Actos	Pioglitazone/Y	Peripheral tissue	Fasting and postprandial	15–30 mg/day Increase after 12 weeks to maximum of 45 mg/day	No adjustment necessary	No adjustment necessary	Clearance lower in Child-Pugh grade B/C; do not start if transaminases > 2.5 × ULN and discontinue if ALT rises to and remains at more than three times ULN	Weight gain
	Avandia	Rosiglitazone/Y	Peripheral tissue	Fasting and postprandial	4 mg/day Increase after 8–12 weeks to maximum of 8 mg/day	No adjustment necessary	No adjustment necessary	Do not initiate if active liver disease or ALT > 2.5 times ULN	Weight gain
Dipeptidyl peptidase-4 inhibitors	Januvia	Sitagliptin/N	GI tract (increases GLP-1)	Fasting and postprandial	100 mg/day	50 mg once daily	25 mg once daily	Child-Pugh class A and B: No dosage adjustment necessary Child-Pugh class C: Not studied	Upper respiratory, diarrhea
	Onglyza	Saxagliptin/N			2.5 or 5 mg/daily	2.5 mg once daily	2.5 mg once daily	No dose adjustment necessary	UTI, headache
	Tradjenta	Linagliptin/N			5 mg/day	No dose adjustment necessary	No dose adjustment necessary	No dose adjustment necessary	Headache, arthralgia, nasopharyngitis
	Nesina	Alogliptin/Y			25 mg/day	> 30 mL/min (0.50 mL/s) but < 60 mL/min (1 mL/s): 12.5 mg/day	> 15 mL/min (0.25 mL/s) but < 30 mL/min (0.50 mL/s): 6.25 mg/day < 15 mL/min (0.25 mL/s): 6.25 mg/day	No dose adjustment necessary Child-Pugh class C: Not studied	Headache, increased ALT greater than three times ULN, nasopharyngitis, upper respiratory

Selective sodium-dependent glucose cotransporter-2 inhibitor	Invokana	Canagliflozin/N	Kidney	Fasting and postprandial	100 mg/day in the morning; may increase to 300 mg/day	> 45 mL/min/1.73 m^2 (0.43 mL/s/m^2) but < 60 mL/min/1.73 m^2 (0.58 mL/s/m^2): 100 mg/day 30 mL/min/1.73 m^2 (0.29 mL/s/m^2) to 45 mL/min/1.73 m^2 (0.43 mL/s/m^2) with urinary albumin excretion > 300 mg/day: 100 mg/day	< 30 mL/min/1.73 m^2 (0.29 mL/s/m^2): contraindicated	Mild-to-moderate (Child-Pugh class A and B): no adjustment necessary Severe (Child-Pugh class C): not recommended	Hyperkalemia, genitourinary infection, hypovolemia, renal insufficiency, hypotension
	Farxiga	Dapagliflozin/N			5 mg/day in the morning; may increase to 10 mg/day	< 45 mL/min/1.73 m^2 (0.43 mL/s/m^2): not recommended for glycemic control >25 mL/min/1.73 m^2 (0.24 mL/s/m^2) but <45 mL/min/1.73 m^2 (0.43 mL/s/m^2) with heart failure or chronic kidney disease: 10 mg/day	< 25 mL/min/1.73 m^2 (0.24 mL/s/m^2): contraindicated	Mild-to-moderate: No adjustment necessary Severe: not studied	Genitourinary infection, hypovolemia/hypotension, dysuria, polyuria, dyslipidemia, mild hypoglycemia, nasopharyngitis
	Jardiance	Empagliflozin/N			10 mg/day in the morning; may increase to 25 mg/day	No dosage adjustment	< 30 mL/min/1.73 m^2 (0.29 mL/s/m^2): contraindicated	No dose adjustment necessary	Genitourinary infection, hypovolemia/hypotension, dysuria, polyuria, mild hypoglycemia
	Steglatro	Ertugliflozin/N			5 mg/day in the morning; may increase to 15 mg/day	< 60 mL/min (1.0 mL/s): not recommended	< 30 mL/min (0.50 mL/s): contraindicated		Genitourinary infection, hypovolemia, mild hypoglycemia, polyuria, increased LDL cholesterol, renal insufficiency

GLP-1 receptor agonist	Rybelsus	Semaglutide/N	GI tract; pancreas	Fasting and postprandial	3 mg/day in the morning with water 30 minutes before first food, beverage, or other oral medications for 30 days; increase to 7 mg/day; may increase to 14 mg/day after 30 days if additional glycemic control needed	No dose adjustment necessary	No dose adjustment necessary	No dose adjustment necessary	GI effects (nausea, diarrhea, flatulence, abdominal pain), risk of pancreatitis, increased heart rate
Dopamine receptor agonist	Cycloset	Bromocriptine mesylate/N	Hypothalamus	Postprandial	0.8 mg once daily within 2 hours of waking; may increase in weekly intervals to 4.8 mg once daily	No dose adjustment necessary	No dose adjustment necessary	No specific dose adjustment recommended, although adjustment may be necessary because of extensive hepatic metabolism	Nausea, headache
Bile acid sequestrant	Welchol	Colesevelam/Y	Intestinal lumen	Fasting	1.875 g twice daily or 3.75 g once daily	No dose adjustment necessary	No dose adjustment necessary	No dose adjustment necessary	Constipation

ALT, alanine aminotransferase; eGFR, estimated glomerular filtration rate; ER, extended release; GI, gastrointestinal; GLP-1, glucagon-like peptide-1; LDL, low-density lipoprotein; SCr, serum creatinine; ULN, upper limit of normal; UTI, urinary tract infection.

Table 44–8

Site and Mechanism of Action for Noninsulin Agents[22,38-40]

Site of Action	Drug Class	Mechanism of Action
Pancreas	Sulfonylureas	Enhances insulin secretion
	Nonsulfonylurea secretagogues	Enhances insulin secretion
	GLP-1 agonists	Enhances insulin secretion and suppresses glucagon secretion
	Pramlintide	Suppresses glucagon secretion
Liver	Biguanide	Decreases hepatic glucose production and increases insulin sensitivity
	Thiazolidinedione	Increases insulin sensitivity
Muscle	Biguanide	Increases insulin sensitivity
	Thiazolidinedione	Increases insulin sensitivity
Adipose tissue	Thiazolidinedione	Increases insulin sensitivity
Intestines	GLP-1 agonists	Increases satiety and regulates gastric emptying
	Pramlintide	Increases satiety and regulates gastric emptying
	Dipeptidyl peptidase-4 inhibitors	Increases endogenous GLP-1
	α-Glucosidase inhibitors	Delays absorption of carbohydrates
Kidney	SGLT2 inhibitors	Inhibits glucose reabsorption in the kidney's proximal tubule

GLP-1, glucagon-like peptide-1; SGLT2, sodium-dependent glucose cotransporter-2.

agents may be used individually or in combination with other medications targeting different organs for synergistic effects. In addition to single agent products, there are many combination products marketed as well.

▶ *Sulfonylureas*

Sulfonylureas enhance insulin secretion by blocking ATP-sensitive potassium channels in the cell membranes of pancreatic β-cells. This action results in membrane depolarization, allowing an influx of calcium to cause the translocation of secretory granules of insulin to the cell surface, and enhances insulin secretion in a non–glucose dependent manner. Insulin is then transported through the portal vein to the liver, suppressing hepatic glucose production. These drugs are classified as being either first- or second-generation agents. The vast majority of patients receiving a sulfonylurea are prescribed a second-generation agent.

All sulfonylureas undergo hepatic biotransformation, with most agents being metabolized by the cytochrome P450 2C9 pathway. First-generation sulfonylureas are more likely to cause drug interactions. All sulfonylureas, except tolbutamide, require dosage adjustment or are not recommended in renal impairment.[38] In elderly patients or those with compromised renal or hepatic function, lower starting dosages are necessary.

The BG-lowering effects sulfonylureas can be observed in both fasting and postprandial levels. Monotherapy with these agents generally produces a 1.5% to 2% (0.015–0.02 or 17–22 mmol/mol Hgb) decline in A_{1c} concentrations and a 60 to 70 mg/dL (3.3–3.9 mmol/L) reduction in FBG levels.[40] Secondary failure with these drugs occurs as a result of continued pancreatic β-cell destruction. One limitation of sulfonylurea therapy is the inability of these products to stimulate insulin release from β-cells at extremely high glucose levels, a phenomenon called glucose toxicity. Common adverse effects include hypoglycemia and weight gain. There may be some cross-sensitivity in patients with sulfa allergy. Patients with glucose-6-phosphate dehydrogenase deficiency may experience an increased risk for hemolytic anemia with sulfonylurea use.[38]

▶ *Nonsulfonylurea Secretagogues (Glinides)*

Although producing the same effect as sulfonylureas, nonsulfonylurea secretagogues, meglitinides, have a much shorter onset and duration of action. Meglitinides produce a pharmacologic effect by interacting with ATP-sensitive potassium channels on the β-cells; however, this binding is to a receptor adjacent to those to which sulfonylureas bind. The primary benefit of

Table 44–9

Expected A_{1c} Reduction for Noninsulin Antiglycemic Drug Classes[22,38-40]

Drug Class	Efficacy	A_{1c} Reduction (%)	A_{1c} Reduction (mmol/mol Hgb)
Biguanides	High	1.5%–2% (0.015–0.02)	17–22 mmol/mol Hgb
Sulfonylureas	High	1.5%–2% (0.015–0.02)	17–22 mmol/mol Hgb
GLP-1 agonists	High	0.78%–1.9% (0.0078–0.019)	8.8–20 mmol/mol Hgb
Thiazolidinedione	High	up to 1.5% (0.015)	17 mmol/mol Hgb
Dipeptidyl peptidase-4 inhibitors	Intermediate	0.7%–1% (0.007–0.01)	8–11 mmol/mol Hgb
SGLT2 inhibitors	Intermediate	0.5%–1% (0.005–0.01)	5–11 mmol/mol Hgb
Nonsulfonylurea secretagogues	Intermediate	0.3%–1% (0.003–0.01)	3–11 mmol/mol Hgb
α-Glucosidase inhibitors	Intermediate	0.3%–1% (0.003–0.01)	3–11 mmol/mol Hgb
Central-acting dopamine agonists	Low	0.3%–0.6% (0.003–0.006)	3–7 mmol/mol Hgb
Pramlintide	Low	0.4%–0.5% (0.004–0.005)	4–5 mmol/mol Hgb
Bile acid sequestrants	Low	0.4% (0.004)	4 mmol/mol Hgb

A_{1c}, hemoglobin A_{1c}; GLP-1, glucagon-like peptide-1; Hgb, hemoglobin; SGLT2, sodium-dependent glucose cotransporter-2.

nonsulfonylurea secretagogues is in reducing postmeal glucose levels. These agents have demonstrated a reduction in A_{1c} levels between 0.3% and 1% (0.003 and 0.01; 3–11 mmol/mol Hgb).[40] Because they have a rapid onset and short duration of action, they should be taken 15 to 30 minutes before a meal three times a day.

▶ *Biguanides*

Metformin is the only biguanide approved by the FDA and currently available in the United States. This agent is thought to lower BG by decreasing hepatic glucose production and increasing insulin sensitivity in both hepatic and peripheral muscle tissues; however, the exact mechanism of action remains unknown. Metformin reduces A_{1c} levels by 1.5% to 2% (0.015–0.02; 17–22 mmol/mol Hgb) and FPG levels by 60 to 80 mg/dL (3.3–4.4 mmol/L) when used as monotherapy.[40] Unlike sulfonylureas, metformin retains the ability to reduce FBG levels when they are over 300 mg/dL (16.7 mmol/L). Metformin does not affect insulin release from β-cells of the pancreas, so hypoglycemia is not a common side effect.[38]

Metformin significantly reduced all-cause mortality and risk of stroke in overweight patients with T2DM compared with intensive therapy with sulfonylurea or insulin in the UKPDS.[41] It also reduced diabetes-related death and myocardial infarction compared with a conventional therapy arm. Metformin is recommended for prevention of T2DM in patients with prediabetes, especially when the patient has a BMI greater than or equal to 35 kg/m^2, is less than 60 years old, or is a woman with a history of GDM.[34] Metformin is considered foundational therapy along with lifestyle modification for T2DM and often used in combination with other antihyperglycemics for synergistic effects.[28]

Per US labeling, metformin is contraindicated in patients with estimated glomerular filtration rates (eGFR) less than 30 mL/min/1.73 m^2.[38] It is not recommended for new start in patients whose eGFR is 30 to 45 mL/min/1.73 m^2. In those whose eGFR falls to less than 45 mL/min/1.73 m^2, a consideration of benefits and risks should be undertaken and the dose reduced to no more than 500 mg twice daily and renal monitoring every 3 months. No adjustment is required for patients with an eGFR greater than 45 mL/min/1.73 m^2, though more frequent monitoring (every 3 to 6 months versus annually) is recommended for patients with eGFR greater than 45 but less than 60 mL/min/1.73 m^2. Additionally, therapy with metformin should be withheld in patients undergoing radiographic procedures in which nephrotoxic dye is used if their eGFR is between 30 and 60 mL/min/1.73 m^2. Therapy should be withheld the day of the radiographic procedure, and renal function should be assessed 48 hours after the procedure. If renal function is normal, therapy may be resumed. Metformin should also be held 24 hours before surgery and restarted after oral intake is resumed and renal function is evaluated as normal.

Primary side effects associated with metformin include decreased appetite, nausea, and diarrhea. Side effects can be minimized through use of extended-release products and slow titration of the dose and often subside within 2 weeks.[42] Interference with vitamin B_{12} absorption has also been reported and periodic B_{12} testing is recommended especially in those patients with macrocytic anemia or peripheral neuropathy.[28] Metformin is thought to inhibit mitochondrial oxidation of lactic acid, thereby increasing the chance of lactic acidosis, a condition which rarely occurs. Patients at risk for lactic acidosis include those with renal impairment and those who are of advanced age.[38] Metformin should be withheld promptly in cases of hypoxemia, sepsis, or dehydration. Patients should avoid consumption of excessive amounts of alcohol while taking metformin, and use of the drug should be avoided in patients with liver disease.

▶ *Thiazolidinediones (TZDs)*

TZDs are known to increase insulin sensitivity by stimulating peroxisome proliferator-activated receptor gamma (PPAR-γ) which increases insulin sensitivity and decreases plasma fatty acids. As monotherapy, TZDs reduce FPG levels by around 60 to 70 mg/dL (3.3–3.9 mmol/L), and the effect on A_{1c} is an up to 1.5% (0.015; 17 mmol/mol Hgb) reduction.[40] Onset of action for TZDs is delayed for several weeks and may require 12 weeks or more before maximum effects are observed.

TZDs may produce fluid retention and edema and are, thus, contraindicated in New York Heart Association Class III and IV heart failure. Fluid retention appears to be dose related and increases when combined with insulin therapy. While rare, TZDs can worsen macular edema. Weight gain of 4 kg (8.8 lb) is common with TZDs and results from both fluid retention and fat accumulation.[40]

Increased rates of upper and lower limb fractures are known to occur with TZD therapy. Premenopausal anovulatory women may begin to ovulate on TZD therapy, and therefore, counseling regarding this should be provided to all women capable of becoming pregnant. An increased risk for bladder cancer has been noted with pioglitazone therapy, especially among men and smokers.

Safety of TZD therapy in patients with cardiovascular disease seems to differ between specific drugs. A meta-analysis reported a significantly greater risk of myocardial infarction with rosiglitazone compared with other oral agents.[43] A subsequent study found rosiglitazone use associated with a nonsignificant increase in myocardial infarction risk and nonsignificant reduction in stroke, but a trend toward increased cardiovascular risk in patients with a history of ischemic heart disease.[44] A meta-analysis of pioglitazone in patients with established cardiovascular disease demonstrated significant reduction in major adverse cardiovascular events (MACE), myocardial infarction, and stroke but did not reduce risk of all-cause mortality.[45]

▶ *α-Glucosidase Inhibitors*

Acarbose and miglitol are α-glucosidase inhibitors that compete with enzymes of the small intestines that break down complex carbohydrates. These drugs delay absorption of carbohydrates and reduce postprandial BG concentrations as much as 40 to 50 mg/dL (2.2–2.8 mmol/L); however, A_{1c} reductions range only from 0.3% to 1% (0.003–0.01; 3–11 mmol/mol Hgb).[40] High incidences of GI side effects have limited their use.[38]

▶ *Dipeptidyl Peptidase-4 Inhibitors*

DPP-4 inhibitors (or gliptins; sitagliptin, saxagliptin, linagliptin, and alogliptin) are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM. They lower BG concentrations by inhibiting DPP-4, the enzyme that degrades endogenous GLP-1, thereby increasing the amount of endogenous GLP-1. The BG-lowering effect of gliptins is primarily on postprandial levels. Typical A_{1c} reductions are 0.7% to 1% (0.007–0.01; 8–11 mmol/mol Hgb).[40] Common adverse effects include headache and nasopharyngitis. Hypoglycemia is not a common adverse effect with these agents because insulin secretion results from GLP-1 activation caused by meal-related glucose detection and not from direct pancreatic β-cell stimulation. Acute pancreatitis, including hemorrhagic and necrotizing pancreatitis, has been reported in patients taking glipitins.[38] These agents should not be given to patients with a history of pancreatitis. Cardiovascular outcomes trials (CVOTs) comparing DPP-4 inhibitors to placebo have not demonstrated cardiovascular benefits, and an increase in hospitalization for heart failure was shown with saxagliptin.[23]

▶ Sodium-Dependent Glucose Cotransporter-2 Inhibitors

SGLT2 inhibitors (canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin) are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM and may be used as monotherapy or add-on.[38] Several agents in this class have expanded FDA approvals to include cardiovascular benefits, though specific approval varies per agent. Inhibition of SGLT2 in the proximal tubules reduces reabsorption of filtered glucose and lowers the renal threshold for glucose which together cause increased urinary excretion of glucose and decreased plasma glucose concentrations. Typical A_{1c} reductions are 0.5% to 1% (0.005–0.01; 5–11 mmol/mol Hgb).[40]

Empagliflozin, added to standard of care in patients with established ASCVD, was shown to reduce the composite of cardiovascular death, all-cause mortality, and death from cardiovascular causes.[46] Canagliflozin was evaluated in two trials which enrolled patients with T2DM at high cardiovascular risk.[47] Canagliflozin reduced the risk of primary outcome of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke. An increased risk for lower-limb amputation was detected, primarily involving the toe or metatarsal in patients with a history of previous amputation or peripheral vascular disease. Dapagliflozin did not show a difference in the risk of cardiovascular death, nonfatal myocardial infarction, and stroke in patients with ASCVD or ASCVD risk factors but did lower risk of cardiovascular death or hospitalization for heart failure.[48] All three medications have shown a significant reduction in hospitalizations for heart failure, leading to development of ongoing clinical trials in patients with heart failure with and without diabetes.[23] Additionally, CVOTs for empagliflozin,[49] canagliflozin,[47] and dapagliflozin[48] evaluated the effects of these agents on renal outcomes. All were found to have a positive effect on renal outcomes in patients with T2DM at high cardiovascular risk.[47-49]

Possible adverse reactions with SGLT2 inhibitors include an increased incidence of urinary tract infections (UTIs) and genital mycotic infections due to increased glucose excretion.[38] Osmotic diuresis occurs which may result in symptomatic hypotension. Renal function should be monitored at baseline to guide initial dosing and periodically during treatment to assess suitability of continuation. Volume status including BP, hematocrit, serum potassium, serum magnesium, serum phosphate, and low-density lipoprotein (LDL) cholesterol are also recommended monitoring parameters for this drug class. Cases of euglycemic ketoacidosis have been reported with SGLT2 inhibitors. Before initiation, patients should have risk for ketoacidosis assessed (including insulin deficiency, dose decreases of insulin, caloric restriction, surgery, and infection). SGLT2 inhibitors should be held at least 3 days prior to surgery then restarted once the patient is stable to minimize risk of DKA. Should ketoacidosis occur, the SGLT2 inhibitor should be held or discontinued. Increased risk for bone fracture has been associated with SLGT2 inhibitor use as well as newly diagnosed bladder cancer with dapagliflozin. Although rare, patients may develop necrotizing fasciitis of the perineum (Fournier gangrene).

▶ Glucagon-Like Peptide 1 Receptor Agonists

Exenatide, liraglutide, dulaglutide, semaglutide, and lixisenatide are indicated for treatment of T2DM to improve glycemic control. These agents are part of the group of drugs known as incretins (Table 44–10).[38,39,50,51]

GLP-1 RAs lower BG levels by (a) producing glucose-dependent insulin secretion; (b) reducing postmeal glucagon secretion, which decreases postmeal glucose output; (c) increasing satiety which decreases food intake; and (d) regulating gastric emptying, which allows nutrients to be absorbed into the circulation more smoothly. Typical A_{1c} reductions vary between GLP-1 RAs and are also affected by baseline glucose control.[39,50,51] Exenatide immediate release and lixisenatide daily are less effective at lowering A_{1c} compared to other GLP-1 RAs: −0.5% to 1% reduction in A_{1c} (0.005–0.01; 5–11 mmol/mol Hgb) versus 1% to 1.9% (0.01–0.019; 11–20 mmol/mol Hgb) with liraglutide and weekly formulations of exenatide, dulaglutide, and semaglutide (injectable), as well as daily oral semaglutide. Exenatide immediate release has less impact on fasting blood sugar levels compared with longer acting GLP-1 RAs owing to its shorter duration of action.[40]

GLP-1 RAs typically produce moderate weight loss of around 2 to 4 kg (4.4–8.8 lb) depending on the drug chosen.[40,50,51] Exenatide and lixisenatide are eliminated renally. Exenatide is not recommended in patients with creatinine clearance (CrCl) of less than 30 mL/min (0.50 mL/s), and lixisenatide is not recommended in patients with CrCl less than 15 mL/min (0.25 mL/s).[38] No specific dose adjustments are recommended for liraglutide, semaglutide, or dulaglutide in renal impairment. The main side effects of GLP-1 RA therapy include nausea, vomiting, and diarrhea. These GI adverse effects tend to lessen over time.[38,50,51] GLP-1 RAs have been associated with cases of acute pancreatitis and should not be started in patients with a history of pancreatitis. Any patient with symptoms of acute pancreatitis, including abdominal pain, nausea, and vomiting, should have GLP-1 RA therapy discontinued until pancreatitis can be ruled out. All GLP-1 RAs except for lixisenatide contain a black-box warning about thyroid C-cell tumors.[38] These agents are contraindicated in patients with a personal or family history of medullary thyroid cancer and in those with a history of multiple endocrine tumors. Antibody formation can occur with GLP-1 RAs leading to treatment failure or increased allergic reaction side effects.

CVOTs with GLP-1 RAs have demonstrated mixed results.[23,51,52] The majority of trials compared active drug to placebo with a primary outcome of three-point MACE (first nonfatal myocardial infarction, nonfatal stroke, or cardiovascular death) over 1.3 to 5.5 years.[23,52] The number of patients with preexisting cardiovascular disease also varied across trials, with as few as 31% in the dulaglutide trial to 100% in the lixisenatide trial.[52] Although all GLP-1 RA CVOTs demonstrated noninferiority compared to placebo, liraglutide, dulaglutide, and injectable semaglutide significantly reduced risk of cardiovascular events.[23,52] Additionally, both liraglutide and semaglutide have been shown to reduce risk for new or worsening nephropathy.[52] Given these potential cardiovascular and renal outcome benefits coupled with their ability to produce weight loss and help control weight gain from insulin therapy, the GLP-1 RAs have had considerable increased utilization in recent years both as monotherapy and add-on. As such, a market for combination insulin and GLP-1 RA products has developed. There are now two basal insulin/GLP-1 RA combination products available.[38] One contains insulin glargine in combination with lixisenatide and the other contains insulin degludec in combination with liraglutide.

▶ Central-Acting Dopamine Agonist

A quick release formulation of the central-acting dopamine agonist, bromocriptine, is approved for treatment of T2DM but should be considered a last line option due to the modest impact on BG levels and A_{1c}.[22] The mechanism of action for how bromocriptine regulates glycemic control is unknown, but data indicate that bromocriptine administered in the morning improves

Table 44–10

Noninsulin Injectable Agents for Treatment of Diabetes[38,39,50,51]

Generic Name (Brand)	Type of Diabetes	Dosage Strengths[a]	Starting Dosage	Dosage Interval	Titration Interval	Maximum Dose	Time to Effect (minutes)	Comments and Cautions
Pramlintide[b] (Symlin)	T1DM	1.5 mL for 15, 30, 45, 60 mcg doses	15 mcg	Three times a day with meals	3–7 days	60 mcg	20	Take just before major meals; reduce insulin by 50% Maintenance dose 30–60 mcg
	T2DM	2.7 mL for 60, 120 mcg doses	60 mcg	Three times a day with meals	3–7 days	120 mcg	20	Side effects: Hypoglycemia, nausea, vomiting Available in SymlinPen 60 and 120
Exenatide[b] (Byetta, Bydureon, Bydureon BCISE)	T2DM	Immediate-release: 5 mcg, 10 mcg	Immediate-release: 5 mcg	Immediate-release: twice daily	Immediate-release: 1 month	Immediate-release: 10 mcg twice daily	Immediate-release: 15–30	Inject immediate-release formulation 15–20 minutes before two meals of the day with 6 hours separating the meals; prefilled disposable pen; may delay absorption of oral drugs; separate doses by 1 hour Side effects: Nausea, vomiting, diarrhea, increased hypoglycemia with sulfonylureas
		Extended-release: 2 mg	Extended-release: 2 mg	Extended-release: once weekly	Extended-release: N/A	Extended-release: 2 mg	N/A	Extended-release formulation can be administered regardless of meals
Lixisenatide[b] (Adlyxin)	T2DM	10 mcg and 20 mcg pen-injector starter kit; 20 mcg pen-injector	10 mcg	Once daily	14 days	20 mcg	N/A	If missed dose, administer within 1 hour of next meal
Liraglutide[b] (Victoza)	T2DM	18 mg/3 mL pen	0.6 mg	Once daily	1 week	1.8 mg	N/A	Can be dosed at any time of day regardless of meals; may delay absorption of oral drugs; separate doses by 1 hour Side effects: Nausea, vomiting, increased hypoglycemia with sulfonylureas
Dulaglutide[b] (Trulicity)	T2DM	0.75 mg single-dose pen; 1.5-mg single-dose pen; 3.0-mg single-dose pen; 4.5-mg single-dose pen	0.75 mg	Once weekly	4–8 weeks	4.5 mg	N/A	If missed dose occurs within 3 days of regularly scheduled dose, dose should be administered at that time. If missed dose occurs more than 3 days past scheduled dose, wait until next regularly scheduled dose to administer next dose Side effects: nausea, diarrhea, vomiting, abdominal pain, decreased appetite, dyspepsia, fatigue
Semaglutide[b] (Ozempic)	T2DM	2 mg/1.5 mL pen-injector for 0.25 or 0.5 mg/dose pen; 4 mg/3 mL pen-injector for 1 mg/dose pen	0.25 mg	Once weekly	4 weeks	1 mg	N/A	If missed dose occurs within 5 days, administer the dose as soon as possible. If > 5 days, do not administer until the next scheduled weekly dose. Side effects: nausea, vomiting, diarrhea, abdominal pain, risk of hypoglycemia, tachycardia

[a] Pramlintide supplied as 0.6 mg/mL in 5 mL vials. Exenatide immediate-release supplied as 250 mcg/mL, 1.2 mL for the 5-mcg prefilled pen, and 2.4 mL for the 10-mcg/dose prefilled pen. Exenatide extended-release supplied as prefilled pen-injector. Lixisenatide supplied in 10 and 20 mcg pen-injector starter kit and 20-mcg pen-injector for maintenance use. Liraglutide supplied in 6 mg/3 mL prefilled pen, which can be dialed to desired dose of 0.6, 1.2, or 1.8 mg. Dulaglutide supplied in 0.75-, 1.5-, 3.0-, and 4.5-mg single-dose pen. Semgalutide supplied in 2 mg/1.5 mL prefilled pen which can be dialed to desired dose of 0.25 or 5 mg in one pen or in 4 mg/3 mL prefilled pen for 1 mg dose.

[b] Generic not available in the United States.

N/A, not applicable; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

insulin sensitivity, likely a result of its effect on dopamine oscillations.[40] Main side effects include rhinitis, dizziness, asthenia, headache, sinusitis, constipation, and nausea. Contraindications include syncopal migraine and women who are nursing.[38]

▶ *Bile Acid Sequestrants*

Colesevelam is the only bile acid sequestrant currently approved as adjunctive therapy to improve glycemic control in conjunction with diet, exercise, and insulin or oral agents for treatment of T2DM, though rarely used. Drug–drug interactions are possible because of absorption and can be particularly important in patients who are taking levothyroxine, glyburide, oral contraceptives, phenytoin, warfarin, and digoxin. These medications should not be taken together, and should be separated by at least 4 hours before dosing colesevelam. Malabsorption of fat-soluble vitamins (A, D, E, and K) is also a concern.

▶ *Insulin*

Insulin is the one agent that can be used in all types of DM, has no specific maximum dose, and can be titrated to suit each individual patient's needs. **KEY CONCEPT** Insulin is the primary treatment to lower BG levels for patients with T1DM, and injected amylin can be added to decrease fluctuations in BG levels. An insulin treatment algorithm for T2DM is found in Figure 44–3.[28]

Insulin can be divided into two main classes, basal and bolus (prandial), based on length of action to mimic endogenous insulin physiology. Most formulations are available as U-100, indicating a concentration of 100 U/mL, though more concentrated insulin formulations have become available in recent years including 200 U/mL (insulin degludec and insulin lispro) and 300 U/mL (insulin glargine), which join the older 500 U/mL regular insulin traditionally available.[38,39] Insulin is typically refrigerated, though most products are stable for 28 days at room temperature.[38] Available insulins are listed in Table 44–11.[38,39,53]

The most common route of insulin administration is subcutaneous injection using a syringe or pen device. Patients should be educated to rotate injection sites to minimize lipohypertrophy, a buildup of fat that decreases or prevents proper insulin absorption. Additionally, patients should understand that absorption rate may vary among injection sites (abdomen, thigh, arm, and buttocks) because of differences in blood flow, with absorption occurring fastest in the abdomen and slowest in the buttocks.

Both insulin syringes and pens are available with shorter needles (4–6 mm) that do not require the patient to pinch up their skin before injecting. With the no pinch technique, the needle is injected straight in at a 90-degree angle until flush with the skin. These products require a 10-second count to allow time for insulin to be injected.

Bolus (Prandial) Insulins

Regular Regular insulin is unmodified crystalline insulin commonly referred to as natural or human insulin. It is a clear solution with a relatively short onset and duration of action and designed to cover insulin response to meals. On subcutaneous injection, regular insulin forms small aggregates called hexamers that undergo conversion to dimers followed by monomers before systemic absorption can occur. Patients should be counseled to inject regular insulin subcutaneously 30 minutes before consuming a meal. Regular insulin, insulin lispro (100 U/mL), insulin aspart, and insulin glulisine can be administered intravenously (IV).

Rapid-Acting Three rapid-acting injectable insulins have been approved in the United States: aspart, glulisine, and lispro (available as 100 and 200 U/mL). Substitution of one or two amino acids in regular insulin results in the unique pharmacokinetic properties characteristic of these agents. Onset of action of injectable rapid-acting insulins (typically dosed 15 minutes before or immediately prior to meals) varies from 15 to 30 minutes, with peak effects occurring 1 to 2 hours after administration. A unique formulation of niacinamide added to insulin lispro allows for a slightly faster onset of action for this specific product. An inhaled rapid-acting insulin is also available, with peak effect expected to occur around 12 to 15 minutes following a dose and duration of action of approximately 2.5 to 3 hours.

Basal Insulins

Intermediate-Duration NPH insulin is prepared by a process in which protamine is conjugated with regular insulin, rendering a product with delayed onset but extended duration of action. It is designed to cover insulin requirements in between meals and/or overnight. With the advent of the long-acting insulins, NPH insulin use has declined because of (a) an inability to accurately predict when peak effects occur, and (b) a duration of action of less than 24 hours. Additionally, protamine is a foreign protein that may increase the possibility of an allergic reaction.

NPH insulin can be mixed with regular insulin and used immediately or stored for future use. NPH insulin can be mixed with either aspart or lispro insulins, but it must be injected immediately after mixing. Whenever mixing insulin products with NPH insulin, the shorter acting insulin should be drawn into the syringe first.

When utilized in the 500 U/mL (U-500) concentration, regular insulin takes on a different pharmacokinetic/pharmacodynamic profile than when utilized in the 100 U/mL concentration.[38,53] While its onset of action remains about 30 minutes post injection, its duration of action extends to be more similar to that of NPH. Insulin regular U-500 is now available in a pen device to improve patient safety.[53] The pen device dials in 5-unit increments and takes care of dosing conversion for the patient, meaning the dose displayed in the pen window is the actual number of units being delivered. Capable of delivering a single dose of up to 300 U at one time, a single pen holds 1500 U total.

Long-Duration Glargine, detemir, and degludec are designed as once-daily-dosing basal insulins that provide a relatively constant insulin concentration over 24 hours.[38,39] Insulin glargine differs from regular insulin by three amino acids, resulting in a low solubility at physiologic pH. The clear solution is supplied at a pH of 4, which precipitates on subcutaneous administration. Detemir binds to albumin in the plasma, which gives it sustained action. Neither glargine nor detemir completely mimic physiological insulin since, when delivered at high doses, a peak occurs and, when delivered at low doses, the dose may not cover 24 hours.

Insulin glargine at a higher concentration of 300 U/mL (U-300) forms a depot with a smaller surface area which creates a more prolonged release than the 100 U/mL (U-100) formulation and a flatter pharmacokinetic/pharmacodynamic response curve. U-300 has been found to result in fewer episodes of hypoglycemia including nocturnal hypoglycemia and decreased weight gain compared with U-100 glargine. Duration of action for U-300 glargine is approximately 36 hours, about 12 hours longer than the U-100 product. Insulin glargine U-300 is available in a pen device which delivers up to 80 U in a single injection or 160 U, depending on the specific product.[38] The pen window displays actual units delivered, meaning no dosing conversion is required. Insulin should not be transferred from the pen to a syringe as incorrect dosing and subsequent adverse effects can occur.

Table 44–11

Insulin Agents for Treatment of Type 1 and Type 2 Diabetes Mellitus[38,39,53]

Generic Name (Insulin)	Brand/Rx Status	Strength	Onset	Peak (hours)	Duration (hours)	Administration Options
Ultra–rapid-acting Insulin						
Aspart with niacinamide	Fiasp/Rx	U-100	15–20 minutes	1.5–2	5–7	CSII, IV, SC; 10-mL vial; 3-mL cartridge and FlexTouch disposable pen
Recombinant human insulin regular	Afrezza/Rx	Not applicable	12–15 minutes	1	1.5–3	Inh; Technosphere insulin particles for oral inhalation; 4, 8, and 12 U as cartridges
Rapid-acting Insulin						
Lispro	Humalog/Rx	U-100, U-200	15–30 minutes	0.5–1.5	3–4	CSII, IV, SC; 3-mL and 10-mL vial, 3-mL cartridge, and KwikPen disposable pen
	Admelog/Rx	U-100				CSII, IV, SC; 3-mL and 10-mL vial; 3-mL SoloStar disposable pen
Lispro-aabc	Lyumjev/Rx	U-100, U-200	15–30 minutes	0.5-1.5	4-7	IV, SC; 10-mL vial, 3-mL cartridge and KwikPen disposable pen
Aspart	Novolog/Rx	U-100	15–30 minutes	0.5-1.5	3–5	CSII, IV, SC; 10-mL vial, 3-mL cartridge, and FlexPen disposable pen
Glulisine	Apidra/Rx	U-100	15–30 minutes	1–2	3–4	CSII, IV, SC; 10-mL vial, 3-mL SoloStar disposable pen
Short-acting Insulin						
Regular	Humulin R/OTC	U-100, U-500	30–60 minutes	2–4	5–8	CSII, IV, SC; U-100 10-mL vial; U-500 20-mL vial and 3-mL KwikPen disposable pen
	Novolin R/OTC	U-100				CSII, IV, SC; 10-mL vial, 3-mL cartridge, 3-mL *Innolet*
Intermediate-acting Insulin						
Neutral protamine Hagedorn	Humulin N/OTC	U-100	2–4 hours	4–10	10–24	SC; 10-mL vial, 3-mL cartridge
	Novolin N/OTC	U-100				SC; 10-mL vial, 3-mL cartridge, 3-mL *InnoLet*
Long-acting Insulin						
Glargine	Lantus/Rx	U-100	2–4 hours	Flat	20–24	SC; 10-mL vial, 3-mL SoloSTAR disposable pen
	Toujeo/Rx	U-300	6 hours	Flat	36	SC;1.5-mL SoloStar disposable pen
	Toujeo Max/Rx	U-300				SC; 3-mL SoloStar disposable pen
	Basaglar/Rx	U-100	2–4 hours	Flat	20–24	SC; 3-mL KwikPen disposable pen
	Semglee/Rx	U-100	1–3 hours	Flat	≥ 24	SC; 10-mLvial, 3-mL disposable pen
Detemir	Levemir/Rx	U-100	1.5–4 hours	6-14	16-20	SC; 10-mL vial, 3-mL FlexTouch disposable pen
Degludec	Tresiba/Rx	U-100, U-200	1 hour	Flat	42	SC; 3-mL disposable FlexTouch pen
Combination Insulin Products						
Neutral protamine Hagedorn and regular	Humulin 70/30/OTC	U-100	30–60 minutes	1.5–16	10–16	SC: 10-mL vial, 3-mL KwikPen disposable pen
	Novolin 70/30/OTC	U-100	30–60 minutes	2–12	10–16	SC; 10-mL vial, 3-mL FlexPen disposable pen
Neutral protamine lispro and lispro	Humalog Mix 75/25/Rx	U-100	15–30 minutes	1–6.5	15–18	SC; 10-mL vial, 3-mL KwikPen disposable pen
	Humalog Mix 50/50/Rx	U-100				SC; 10-mL vial, 3-mL KwikPen disposable pen
Neutral protamine aspart and aspart	Novolog Mix 70/30/Rx	U-100	15–30 minutes	1–4	Up to 24	SC; 10-mL vial, 3-mL cartridge, 3-mL FlexPen disposable pen
Combination Insulin GLP-1 Agonist Products						
Degludec and liraglutide	Xultophy/Rx	U-100 degludec/ 3.6 mg/mL liraglutide	N/A	N/A	N/A	SC; 3-mL pen-injector
Glargine and lixisenatide	Soliqua/Rx	U-100 glargine/ 33 mcg/mL liraglutide	N/A	N/A	N/A	SC; 3-mL pen-injector

CSII, continuous subcutaneous insulin infusion; GLP-1, glucagon like peptide; Inh, inhalation; IV, intravenous; N/A, not applicable; OTC, over-the-counter; Rx, prescription required; SC, subcutaneous.

Further search for a more physiologically perfect basal insulin led to development of degludec.[54] A modified B chain analogue which forms multihexamers when injected, insulin degludec provides a flatter pharmacokinetic/pharmacodynamic profile than detemir or glargine. Zinc molecules, present in the hexamers, slowly diffuse allowing insulin monomers to be absorbed. This ultraslow insulin release allows degludec to have a half-life of 25 hours and duration of action exceeding 42 hours. Though still recommended for daily dosing at the same time each day, degludec's long duration of action means patients taking it can miss or delay a dose as long as they keep an 8-hour interval between any two doses.

Combination Products A number of combination insulin products are available commercially.[38,39] These combination products allow some patients to manage their insulin therapy with only two injections per day, avoiding the difficulty and possible errors that can occur when manually mixing insulins. NPH is available in a combination of 70/30 (70% NPH and 30% regular insulin). Three short-acting insulin analog mixtures are also available. Humalog mix 75/25 contains 75% neutral protamine lispro suspension and 25% insulin lispro. Novolog mix 70/30 contains 70% insulin aspart protamine suspension and 30% insulin aspart. Humalog mix 50/50 contains 50% neutral protamine lispro and 50% lispro. The lispro and aspart insulin protamine suspensions were developed specifically for these mixture products and are not commercially available separately.

General Insulin Treatment Strategy

Over time, patients with T2DM may require initiation of insulin therapy to better control BG.[22,28] Basal insulin should be initiated first, generally at 10 U once daily or with a starting dose of 0.1 to 0.2 U/kg/day (see Figure 44–3). Doses should be individualized and titrated to control blood glucose. Prandial insulin may be considered when FBG is at or near goal, yet the A_{1c} remains elevated. GLP-1 RA therapy should be considered prior to prandial insulin if the patient is not already on this therapy. Adjustment of insulin doses will then depend on fasting and postprandial BG levels.

Insulin Pump Therapy Insulin pump therapy consists of a programmable infusion device that allows for basal infusion of insulin 24 hours daily (see Figure 44–1), as well as bolus administration before meals and snacks.[40] Optimal insulin dosing allows for 50% of the total daily dose of insulin to be delivered as a basal dose, with the remaining 50% divided into prandial doses. Regular or rapid-acting insulin is delivered from a reservoir either by infusion set tubing or through a small canula, though rapid-acting insulin is more commonly used. Most pump infusion sets are inserted in the abdomen, arm, or other infusion site by a small needle. Most patients prefer insertion in abdominal tissue because this site provides optimal insulin absorption. However, they must rotate sites to avoid development of scar tissue. Infusion sets should be changed every 2 to 3 days to reduce the possibility of infection.

Patients use a carbohydrate-to-insulin ratio to determine how many units of insulin are required. More specifically, an individual's ratio is calculated to determine how many units of the specific insulin being used in the pump "covers" for a certain amount of carbohydrates to be ingested at a particular meal. Generally, the carbohydrate-to-insulin ratio can be calculated by dividing 550 by the total daily dose of insulin. Once this ratio is determined, patients can eat more or fewer carbohydrates at a given meal and adjust the bolus dose accordingly.

In addition to mealtime boluses, correction doses (also known as the correction factor) based on premeal glucose readings are also used. The amount of additional insulin for the correction is based on dividing 1650 by the total daily dose of insulin. The resulting value will represent the reduction in glucose (mg/dL [multiplying the resulting value by 0.0555 will give the corresponding result in mmol/L]) produced by one unit of insulin. The correction dose would be given in addition to the bolus dose needed based on the patient's carbohydrate-to-insulin ratio and amount of carbohydrates present in the meal he or she is about to consume. These calculations are just estimates, as there are no set guidelines for determining these doses. A patient's correction factor and carbohydrate-to-insulin ratio may change over time and can be readjusted based on glycemic values.

Insulin pump therapy may be used to lower BG levels in any type of DM; however, patients must be on multiple daily insulin injections, and therefore, patients with T1DM are always candidates and those with T2DM are sometimes candidates to use these devices. Use of an insulin pump may improve BG levels, reduce wide fluctuations in BG levels, and allow individuals to have more flexibility in timing and content of meals and exercise schedules, resulting in improved quality of life.

▸ *Noninsulin Injectable Agents*

Amylin Pramlintide acetate is a synthetic analog of human amylin, which is a naturally occurring neuroendocrine peptide cosecreted with insulin by the β-cells of the pancreas in response to food.[38,39] Amylin secretion is very low or completely deficient in patients with T1DM and lower than normal in patients with T2DM who require insulin. Pramlintide slows gastric emptying without altering absorption of nutrients, suppresses glucagon secretion, and leads to reduction in food intake by increasing satiety. By slowing gastric emptying, the normal initial postmeal spike in BG is reduced.

Pramlintide is given by subcutaneous injection before meals to lower postprandial BG elevations in patients with types 1 or 2 DM. This generally results in an additional A_{1c} reduction of 0.4% to 0.5% (0.004–0.005; 4–5 mmol/mol Hgb).[38] Hypoglycemia, nausea, and vomiting are the most common side effects encountered with pramlintide therapy, although pramlintide itself does not produce hypoglycemia. To decrease risk of hypoglycemia, doses of short-acting, rapid-acting, or premixed insulins should be reduced by 30% to 50% before pramlintide is initiated. Primarily, the kidneys metabolize pramlintide, but dosage adjustments in liver or kidney impairment are not required.

Pramlintide has the potential to delay absorption of orally administered medications. When rapid absorption is needed for the efficacy of an agent, pramlintide should be administered 1 hour after or 3 hours before the drug. Pramlintide should not be used in patients receiving medications that alter GI motility.

Treatment of Concomitant Conditions

The ADA standards of medical care address many of the common comorbid conditions, as well as complications that result from progression of DM.

▸ *Cardiovascular Health*

Cardiovascular disease is the major cause of morbidity and mortality for patients with DM. Interventions targeting smoking cessation, BP control, lipid management, antiplatelet therapy, and lifestyle changes (including diet and exercise) can reduce risk of cardiovascular events and should be considered important as glycemic control in management of a patient with DM. All patients with a history of cardiovascular disease should be prescribed aspirin 75 to 162 mg/day as a secondary prevention strategy.[23] Clopidogrel is an option for patients with atherosclerosis who are allergic to aspirin. The ADA currently recommends antiplatelet therapy be considered for patients with DM and no history of heart disease if patient is 50 years of age or older and has at least one additional cardiovascular risk factor including family history of premature ASCVD, hypertension, dyslipidemia, smoking, or albuminuria.[23]

Results of a number of trials, including the Action to Control Cardiovascular Risk in Diabetes (ACCORD),[55] Action in Diabetes and Vascular Disease (ADVANCE),[56] and Veterans Affairs Diabetes Trial (VADT)[57] taken together with long-term follow-up information from the UKPDS[58] and DCCT[59,60] trials, have been used to formulate conclusions regarding the effect of glucose lowering on cardiovascular health. Those conclusions are (1) short-term (3–5 years) intensive glycemic control does not improve the risk of macrovascular complications in patients with long-standing T2DM; and (2) a decrease in macrovascular risk from improved glycemic control may take more than a decade to be realized. Because of the results of these trials, the A_{1c} goal used for most patients with T2DM is less than 7% (0.07; 53 mmol/mol Hgb), whereas a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hgb) may be used for otherwise healthy individuals without cardiovascular disease who are thought to be early in the course of their DM and controlled with lifestyle or metformin only and who have a long life expectancy.[20,22] A more relaxed target of less than 8% (0.08; 64 mmol/mol Hgb) may be employed for those who are older, have numerous medical conditions limiting life expectancy, are at increased risk for hypoglycemia, or have had T2DM for a long period of time.[20]

The FDA mandated in 2008 that CVOTs be completed for all new medications approved for treatment of T2DM.[23] As a result, drugs in the newest classes of glucose-lowering medications have been studied specifically for their outcomes on cardiovascular health, and findings of those clinical trials are now informing the newest ADA guidelines relative to selection of these agents for patients with certain comorbid conditions. Specific recommendations include: patients with T2DM and ASCVD or known kidney disease should be considered for therapy with a SGLT2 inhibitor or GLP-1 RA with demonstrated cardiovascular benefit (ie, empagliflozin, canagliflozin, liraglutide, injectable semaglutide, or dulaglutide) as part of their glucose-lowering drug therapy;[23] and patients with T2DM and low ejection fraction heart failure may be considered preferentially for a SGLT2 inhibitor with proven benefit in this population (ie, dapagliflozin or empagliflozin though class effect possible) to reduce risk of worsening heart failure and cardiovascular death.[23]

▶ *Dyslipidemia*

The ADA guidelines recommend obtaining a lipid profile at the time of diabetes diagnosis, at least every 5 years if under age 40, and when otherwise indicated (ie, at statin initiation, 4–12 weeks after statin initiation or dose change, and annually thereafter).[23] The ADA guidelines also outline specific dyslipidemia pharmacotherapy recommendations for those with DM including, but not limited to:[23]

1. Patients with diabetes and known ASCVD are recommended to receive high-intensity statin.
2. It may be reasonable to initiate statin therapy in patients with diabetes who are only 20 to 39 years old but have other ASCVD risk factors.
3. Patients with diabetes aged 40 to 75 years and without ASCVD are recommended to receive a moderate-intensity statin. A high-intensity statin might be considered for these patients if they are between 50 and 70 years of age and have multiple ASCVD risk factors.

Refer to Chapter 13, "Dyslipidemias," for additional information.

▶ *Hypertension*

KEY CONCEPT Uncontrolled BP plays a major role in development of macrovascular events and microvascular complications, including retinopathy, nephropathy, and erectile dysfunction, in patients with DM.[23] The ADA guidelines set BP goals based on risk, recommending a goal of less than 130/80 mm Hg for those with a 10-year ASCVD risk of greater than or equal to 15% and a goal of less than 140/90 mm Hg for those with 10-year ASCVD risk less than 15%.[23] Prompt initiation and appropriate titration of antihypertensive drug therapy is recommended in patients with BP greater than or equal to 140/90 mm Hg.[23] Various first-line antihypertensive agents can be utilized in patients with diabetes including thiazide-like diuretics, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), and calcium channel blockers.[23] However, when albuminuria is present, ACE inhibitors or ARBs are recommended because of their beneficial effects on renal function.[23]

Treatment of Acute Complications

▶ *Hypoglycemia*

Hypoglycemia, or low blood sugar, can be defined by the glucose alert value of less than or equal to 70 mg/dL (3.9 mmol/L).[27] Typical symptoms of hypoglycemia include shakiness, sweating, fatigue, hunger, headaches, and confusion. Causes of hypoglycemia include delayed or inadequate amounts of food intake,

Patient Encounter Part 2: Follow-Up Visit

The patient returns 1 week later with results from her fasting blood work. The provider also requests an FBG, A_{1c}, and vitals at today's visit. Results are listed below.

VS: BP 138/78 mm Hg, P 76 beats/min, RR 17 breaths/min, T 36.8°C (98.2°F)

A_{1c} (today): 7.9% (0.079; 63 mmol/mol Hgb)

FPG (today): 178 mg/dL (9.9 mmol/L)

Labs (2 days ago): Na 135 mEq/L (mmol/L); K 4.0 mEq/L (mmol/L); Cl 98 mEq/L (mmol/L); CO_2 24 mEq/L (mmol/L); blood urea nitrogen (BUN) 15 mg/dL (5.4 mmol/L); SCr 0.8 mg/dL (71 µmol/L); BG 186 mg/dL (10.3 mmol/L)
The patient is diagnosed with T2DM.

Identify the goals of treatment for this patient.

What nonpharmacologic alternatives are available for this patient for her diabetes?

What are the three general categories of pharmacologic alternatives used to lower blood glucose?

What is the most appropriate initial therapy for this patient in regard to her diabetes?

What additional interventions are recommended for this patient today?

especially carbohydrates, excessive doses of medications (eg, sulfonylureas, insulin), exercising when insulin doses are reaching peak effect, or inadequately adjusted drug therapy in patients with impaired renal or hepatic function. Patients experiencing symptoms of hypoglycemia should check their BG level, consume 15 g of carbohydrate, wait 15 minutes for symptom resolution, and retest.[61] Examples of 15 g of carbohydrate may include a small box of raisins, 4 oz (approximately 120 mL) of orange juice, 8 oz (approximately 240 mL) of skim milk, or three to four glucose tablets. In patients receiving an α-glucosidase inhibitor, hypoglycemia should be treated with glucose tablets or skim milk. For patients with hypoglycemia experiencing a loss of consciousness, a glucagon emergency kit should be administered by the intramuscular (IM) or subcutaneous route. It is important to contact emergency medical personnel in this situation. The patient should be rolled onto their side as many injected with glucagon vomit.

Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State (HHS)

DKA is a reversible but potentially life-threatening medical emergency that results from a deficiency in insulin. Without insulin, the body cannot use glucose and must obtain energy via lipolysis. This produces ketones and acidosis. Precipitating factors include infection and the omission or inadequate administration of insulin.[62] Signs and symptoms develop rapidly within 1 day or so and commonly include fruity or acetone breath, nausea, vomiting, dehydration, polydipsia, polyuria, and deep, rapid breathing.

Hallmark diagnostic criteria for DKA include hyperglycemia (greater than 250 mg/dL [13.9 mmol/L]), moderate ketonuria or ketonemia with bicarbonate less than or equal to 15 mEq/L [mmol/L], and acidosis (arterial pH less than or equal to 7.3).[62] Serum sodium is usually low due to extracellular movement of water. A corrected sodium (addition of 1.6 mEq/L [mmol/L] for every 100 mg/dL [5.6 mmol/L] of glucose above 100 mg/dL [5.6 mmol/L]) should be calculated to assess the true sodium and water deficit.[62] Serum potassium is typically elevated due to an extracellular shift brought on by insulin deficiency.[62]

DKA severity depends on magnitude of the decrease in arterial pH, serum bicarbonate levels, and mental state rather than magnitude of hyperglycemia. Treatment goals of DKA consist of reversing the underlying metabolic abnormalities, rehydrating the patient, and normalizing serum glucose. Fluid replacement with normal saline at 1 to 1.5 L/hour for the first hour is recommended to rehydrate the patient and ensure the kidneys are perfused.[62]

Potassium and other electrolytes are supplemented as indicated by laboratory assessment. Use of sodium bicarbonate in DKA is controversial and generally only recommended when the pH is less than 6.9.[62] Regular insulin at 0.1 U/kg/hour by continuous IV infusion is the preferred treatment in DKA to regain metabolic control rapidly.[62] When plasma glucose values drop below 250 mg/dL (13.9 mmol/L), dextrose 5% should be added to IV fluids.[62] During the recovery period, it is recommended to continue administering insulin and allow patients to eat as soon as possible. Dietary carbohydrates combined with insulin assist in clearance of ketones. See Table 44–12 for DKA management.[62]

HHS is a life-threatening condition similar to DKA that also arises from inadequate insulin, but HHS occurs primarily in older patients with T2DM. DKA and HHS also differ in that HHS lacks the ketonemia and acidosis associated with DKA. Key diagnostic criteria for HHS are a plasma glucose value of greater than 600 mg/dL (33.3 mmol/L), arterial pH greater than 7.3, serum bicarbonate greater than 15 mEq/L (mmol/L), and minimal ketonuria and ketonemia.[62] Similar to DKA, treatment of HHS consists of aggressive rehydration, correction of electrolyte imbalances, and continuous insulin infusion to normalize serum glucose. BG levels should be reduced gradually to minimize risk of cerebral edema.

Table 44–12

Management of Diabetic Ketoacidosis[62]

1. Confirm diagnosis (increased plasma glucose, positive serum ketones, metabolic acidosis).
2. Admit to hospital; intensive care setting may be necessary for frequent monitoring or if pH < 7 or unconscious.
3. Assess serum electrolytes (K^+, Na^+, Mg^{2+}, Cl^-, bicarbonate, phosphate), acid–base status—pH, HCO_3^-, PCO_2, β-hydroxybutyrate, and renal function (creatinine, urine output).
4. Replace fluids: 0.9% saline 1 L/hour over first 1–3 hours; subsequently, 0.45% saline at 4–14 mL/kg/hour; change to 5% dextrose with 0.45% saline when plasma glucose reaches 250 mg/dL (13.9 mmol/L).
5. Administer regular insulin: IV (0.15 U/kg bolus followed by 0.1 unit/kg/hour infusion); check glucose hourly and double insulin infusion until glucose level falls at steady hourly rate of 50–70 mg/dL (2.8–3.9 mmol/L). Alternatively, could use SC or IM routes, although dosing regimen different. If initial serum potassium is < 3.3 mEq/L (mmol/L), do not administer insulin until the potassium is corrected to > 3.3 mEq/L (mmol/L).
6. Assess patient: What precipitated the episode (eg, nonadherence, infection, trauma, infarction, cocaine)? Initiate appropriate workup for precipitating event (cultures, chest X-ray, ECG).
7. Measure chemistry (especially K^+, bicarbonate, phosphate, and anion gap) every 2–4 hours until stable.
8. Replace K^+: If K^+ is < 3.3 mEq/L (mmol/L), hold insulin and give 40 mEq (mmol) of K^+ per liter of IV fluid. If K^+ is > 5 mEq/L (mmol/L), do not give K^+ but check level every 2 hours. When K^+ > 3.3 mEq/L (mmol/L) but < 5 mEq/L (mmol/L), ECG normal, urine flow and normal creatinine documented, administer 20–30 mEq/L (mmol/L) of IV fluid to maintain K^+ at 4–5 mEq/L (mmol/L).
9. Continue the previous step until patient is stable, glucose goal is 150–250 mg/dL (8.3–13.9 mmol/L), and acidosis is resolved. Insulin infusion may be decreased to 0.05–0.1 U/kg/hour.
10. Administer intermediate- or long-acting insulin as soon as patient is eating. Allow for overlap in insulin infusion and SC insulin injection.

Cl, chloride; ECG, electrocardiogram; HCO_3, serum bicarbonate; IM, intramuscular; IV, intravenous; K, potassium; Mg, magnesium; Na, sodium; PCO_2, partial pressure of carbon dioxide in the arterial blood; SC, subcutaneous.

Treatment of Long-Term Complications

Retinopathy

Diabetic retinopathy occurs when the microvasculature that supplies blood to the retina becomes damaged. This damage permits leakage of blood components through the vessel walls. The ADA recommends that patients with T2DM receive a dilated eye examination at the time of diagnosis by an ophthalmologist or optometrist.[24] Examinations should begin within 5 years of diagnosis of T1DM.[24] Once one or more normal examinations occur, dilated eye examination is recommended to be repeated at least every 2 years.[24] In patients with any level of documented retinopathy, an annual dilated eye examination is recommended.[24] Glucose and BP control are the best strategies for decreasing risk and slowing progression of retinopathy.

▶ *Neuropathy*

KEY CONCEPT Peripheral neuropathy is a possible complication of DM. The most common types of peripheral neuropathy include chronic sensorimotor distal peripheral neuropathy, which can cause pain, tingling, and numbness in the feet and hands, and autonomic neuropathy, which can lead to hypotension, gastroparesis, sexual dysfunction, and autonomic failure in response to hypoglycemia. The ADA recommends use of pregabalin, duloxetine, or gabapentin as first-line pharmacologic treatment for neuropathic pain.[24] Optimization of glucose control is key to prevention and slowing progression of neuropathy.

▶ *Microalbuminuria and Nephropathy*

DM is a leading contributor to end-stage renal disease. Early evidence of nephropathy is presence of albumin in the urine. Therefore, as the disease progresses, larger amounts of protein spill into the urine. The ADA recommends urine protein tests annually in T2DM patients.[24] For patients with T1DM, annual urine protein testing should begin 5 years after diagnosis of diabetes.[24] The most common form of screening for protein in the urine is a random collection for measurement of the urine albumin-to-creatinine ratio. The desirable value is less than 30 mcg of albumin per milligram of creatinine (3.4 mg/mmol creatinine).[24] There is high variability between measurements of urinary albumin excretion. As such, the ADA recommends that two out of three albumin-to-creatinine ratios, collected over a 3- to 6-month period, be abnormal before considering the patient to have high (traditionally referred to as microalbuminuria and defined as between 30 and less than 299 mcg of albumin per milligram of creatinine [3.4–33.8 mg/mmol creatinine]) or very high (defined as greater than or equal to 300 mcg of albumin per milligram of creatinine [34 mg/mmol creatinine]) albuminuria.[24]

Glycemic and BP control are primary measures for prevention of progression of nephropathy. Patients with T2DM and kidney disease related to DM, whose estimated glomerular filtration rate remains greater than or equal to 30 mL/min/1.73 m^2, and whose urinary albumin-to-creatinine ratio is greater than 30 mcg of albumin per milligram of creatinine (3.4 mg/mmol creatinine), should be considered for therapy with a SGLT2 inhibitor to reduce risk for kidney disease progression, cardiac events, or both.[24] Patients with CKD at increased risk for cardiac events may be considered for therapy with a GLP-1 RA to reduce risk of subsequent cardiac events, progression of albuminuria, or both.[24] Either an ACE inhibitor or ARB is recommended for nonpregnant patients with diabetes and hypertension who have modest or high urinary albumin-to-creatinine ratio and/or an eGFR rate less than 60 mL/min/1.73 m^2.[24] Treatment of advanced nephropathy includes dialysis and kidney transplantation and patients with an eGFR less than 30 mL/min/1.73 m^2 should be referred to a nephrologist.[24]

▶ *Foot Ulcers*

KEY CONCEPT Lower extremity amputations are one of the most feared and disabling sequelae of long-term uncontrolled DM. A foot ulcer is an open sore that develops and penetrates to the subcutaneous tissues. Complications of the feet develop primarily as a result of peripheral arterial disease (PAD), neuropathies, and foot deformations.

Patient Encounter Part 3: Follow-Up

The patient returns in 3 months for a follow-up visit. She brings her BG readings from the past week for review in addition to more fasting blood work. BG readings are in units of mg/dL (or mmol/L). Her most recent medication list is below. There are no changes to her health record from previous visits.

Allergies: Amoxicillin

Meds: Hydrochlorothiazide 25 mg daily; ibuprofen 400 mg PRN headache; metformin 1000 mg by mouth twice daily

VS: BP 150/92 mm Hg, P 82 beats/min, RR 16 breaths/min, T 36.5°C (97.7°F)

Labs: Total cholesterol 235 mg/dL (6.08 mmol/L); HDL cholesterol 39 mg/dL (1.01 mmol/L); LDL cholesterol 158 mg/dL (4.09 mmol/L); triglycerides 191 mg/dL (2.16 mmol/L); aspartate aminotransferase (AST) 24 U/L (0.40 μkat/L); alanine aminotransferase (ALT) 35 U/L (0.58 μkat/L); A_{1c} 7.5% (0.075; 58 mmol/mol Hgb)

Day	Fasting	2-hour Postprandial
Monday	129 (7.2)	178 (9.9)
Tuesday	122 (6.8)	195 (10.8)
Wednesday	118 (6.5)	182 (10.1)
Thursday	101 (5.6)	164 (9.1)
Friday	112 (6.2)	221 (12.3)
Saturday	132 (7.3)	284 (15.8)
Sunday	136 (7.5)	262 (14.5)

Are this patient's blood glucose levels within target? What pattern seems to be established?

Which classes of antidiabetic drugs act in a manner that would specifically correct the undesirable glucose pattern?

What if the patient had a history of ASCVD or heart failure? Which antidiabetic drugs would be preferred and why?

Based on the information available from this and previous encounters, develop a care plan for this patient including (a) identification and assessment of all drug-related needs and/or problems, (b) a detailed therapeutic plan to address each need and problem, and (c) monitoring parameters to assess safety and efficacy.

PAD causes ischemia to the lower limbs depriving the tissues of oxygen and nutrients and impairing the immune system from functioning adequately. Symptoms of PAD include intermittent claudication, cold feet, pain at rest, and loss of hair on the feet and toes. Smoking cessation is the most important treatment for PAD. Exercising by walking to the point of pain and then resting until pain subsides and resuming can be a vital therapy to maintain or improve the symptoms of PAD. Pharmacologic intervention with antiplatelet therapy (aspirin 160–325 mg/day or clopidogrel 75 mg/day) is indicated in PAD.[63] For those remaining symptomatic, cilostazol 100 mg twice daily may be useful to improve blood flow and reduce symptoms of PAD.[63]

Neuropathies play a large part in development of foot ulcers. To prevent complications, the ADA recommends daily visual examination of the feet and a comprehensive foot evaluation

Table 44–13

Macrovascular and Microvascular Complications Signs and Symptoms

	Complication	Signs and Symptoms
Macrovascular	Coronary heart disease	Stable or unstable angina pectoris, myocardial infarction, or dysrhythmias; however, many patients have unrecognizable symptoms.
	PAD	Exertional leg pain that can progress to pain at rest and ischemic ulcers. Most cases are asymptomatic.
	Cerebrovascular disease/Stroke	Sudden onset of a focal neurologic deficit such as facial droop, hemiparesis, or isolated weakness of an arm or leg. Dizziness, slurred speech, gait difficulties, and visual loss may also occur.
Microvascular	Retinopathy	Minimal until advanced disease ensues with loss or blurring of vision.
	Nephropathy	Hypertension, which often coincides with the development of microalbuminuria (persistent proteinuria).
	Neuropathy	Numbness, tingling, burning, muscle pain/cramps/weakness that often gets worse at night.
	Foot care (neuropathy and/or PAD)	Calluses and corns, tinea pedis, hammertoes, bunions, cracking of skin of the feet and heels.

PAD, peripheral arterial disease.

each year.[24] Sensory testing with a 10-gauge monofilament can detect neuropathy. Ulcer treatment consists of glycemic control, preventing infection, debriding dead tissues, applying dressings, treating edema, and limiting ambulation. Individuals with diabetes should wear properly fitted, cushioned footwear and padded socks. Table 44–13 provides a list of microvascular and macrovascular complications as well as their signs and symptoms.

Special Situations

▶ *Hospitalized Care*

Current recommendations call for critically ill patients to be started on IV insulin therapy at a threshold of 180 mg/dL (10.0 mmol/L).[27] A goal range of 140 to 180 mg/dL (7.8–10.0 mmol/L) is recommended for the majority of patients.[27] More stringent goals may be considered for selected critically ill postsurgical patients, but only if hypoglycemia can be avoided.[27] Scheduled subcutaneous insulin regimens with basal, bolus, and correction components are recommended for patients who are not critically ill.[27] Patients who required insulin during hospitalization but had previously not used insulin will need education/training to successfully transition home.

Patient Encounter Part 4: Insulin Therapy

The patient returns to the office for her quarterly checkup. It has been 8 years since she was first diagnosed with diabetes—she is now 50 years old. Her updated information is below. Her past medical and family histories are unchanged with the exception that her father passed away after a stroke 2 years ago. She states that she has been adherent to medications and lifestyle changes with the exception of physical activity. She has developed osteoarthritis in her knees and has more difficulty walking.

SH: Prior history of smoking one-half pack per day for 10 years, but quit 18 years ago; denies alcohol or illicit drug use

Allergies: Amoxicillin

Meds: Losartan-hydrochlorothiazide 100-25 mg by mouth once daily; atorvastatin 40 mg by mouth once daily; metformin 1000 mg by mouth twice daily; semaglutide 1 mg SC weekly; empagliflozin 25 mg daily; ibuprofen 400 mg PRN headache; multivitamin by mouth once daily

Meal History: Has been consuming approximately 30 to 45 g of carbohydrates per meal three times a day; saturated fat is limited to 12 g/day, and sodium is 2000 mg/day

Physical Activity: Was walking 4 or 5 days per week for 30 minutes at moderate intensity but has not done so recently due to arthritis

VS: BP 126/78 mm Hg, P 78 beats/min, RR 18 breaths/min, T 36.9°C (98.4°F), Ht 5′3″ (160 cm), Wt 162 lb (74 kg)

Labs: Na 139 mEq/L (mmol/L); K 4.8 mEq/L (mmol/L); Cl 103 mEq/L (mmol/L); CO_2 24 mEq/L (mmol/L); BUN 20 mg/dL (7.1 mmol/L); SCr 1.2 mg/dL (106 μmol/L); FPG 202 mg/dL (11.2 mmol/L); A1c 9.2% (0.092; 77 mmol/mol Hgb); AST 28 U/L (0.47 μkat/L); ALT 31 U/L (0.52 μkat/L)

Fasting lipid profile:

- Total cholesterol: 202 mg/dL (5.22 mmol/L)
- LDL cholesterol: 108 mg/dL (2.79 mmol/L)
- HDL cholesterol: 43 mg/dL (1.11 mmol/L)
- Triglycerides: 205 mg/dL (2.32 mmol/L)

What additional pharmacologic options are available for this patient to lower her blood glucose to goal?

Which insulin and starting dose would be most appropriate for this patient?

When should prandial insulin be considered?

What additional medications, screenings, labs, and/or referrals are recommended for the patient at this point?

What is an important lifestyle modification this patient still needs to make?

▶ *Sick Days*

Patients should monitor their BG levels more frequently during sick days because it is common for illness to increase

Patient Care Process

Collect Information:

- Review medical history.
- Perform medication history of prescription, over-the-counter, and herbal product use.
- Collect laboratory data including chemistry panel, A_{1c}, lipid panel, and albumin-to-creatinine ratio.
- Measure BP.
- Examine patient for development or progression of DM complications.
- Record SMBG, including FPG and postprandial levels.
- Interview patient to gather information related to quality-of-life measures such as physical, psychological, and social functioning and well-being.

Assess the Information:

- SMBG for glycemic control, including FPG and postprandial levels (see Table 44–6).
  - Are BG values too high or low?
  - Are there specific times of day or specific days not within glucose goals?
  - Is hypoglycemia occurring?
- Review laboratory data for attainment of goals (see Table 44–6). What goals are not being met?
- Are there any medication problems, including presence of adverse drug reactions, drug allergies, and drug interactions?
  - Is the patient taking medications that may affect glucose control?
- If patient is already receiving treatment for DM, has he/she been adherent to recommended lifestyle modifications and drug therapies? Is the patient having difficulty affording therapies?
- Assess patient for quality-of-life measures such as physical, psychological, and social functioning and well-being.

Develop a Care Plan:

- Recommend appropriate therapy and develop a plan to assess effectiveness (see Tables 44–7, 44–10, and 44–11, and Figures 44–2 and 44–3).

Implement the Care Plan:

- Stress adherence to prescribed lifestyle and medication regimen.
  - Ensure patient has prescription coverage and/or is able to afford prescribed regimen and self-care.
- Provide education on diabetes, lifestyle modifications, appropriate monitoring, and drug therapy:
  - Causes of DM complications and how to prevent them.
  - How diet and exercise can affect diabetes.
  - How to perform SMBG and what to do with the results.
  - When to take medications and what to expect, including adverse effects.
  - What warning sign(s) should be reported to the provider.
- What tests or referrals to other health-care team members are needed?

Follow-up: Monitor and Evaluate:

- Set follow-up for SMBG and tolerability/presence of adverse effects based on therapy chosen.
- Follow-up A_{1c} every 3 months until patient reaches goal, then every 6 months. See Table 44–6 for other monitoring parameters and frequency.
- Monitor for macrovascular and microvascular signs and symptoms (Table 44–13).

BG values.[64] Patients should check their glucose and urine for ketones every 4 hours when sick and when their BG levels are greater than 240 mg/dL (13.3 mmol/L).[65] Patients should continue to take their medications while sick.[66] T1DM patients may require additional insulin coverage, and some with T2DM who are currently on oral medication regimens may require insulin during an acute illness. Patients should be advised to maintain normal caloric and carbohydrate intake while ill as well as to drink plenty of noncaloric beverages to avoid dehydration.[64] When having difficulty eating a normal diet, patients may be advised to use nondiet beverages, sports drinks, broths, crackers, soups, and nondiet gelatins to provide normal caloric and carbohydrate intake and avoid hypoglycemia. With proper management, patients can decrease their chance of illness-induced hospitalization, particularly DKA and HHS.

OUTCOME EVALUATION

- **KEY CONCEPT** The success of therapy for DM is measured by the ability of the patient to manage disease appropriately between health-care provider visits.
- Appropriate therapy necessitates adequate patient education about the disease, development of a meal plan to which patients can comply, and integration of a regular exercise program.
- Patient care plans should include a number of daily evaluations to be performed by the patient, such as examining feet for any sores, cuts, or abrasions; checking skin for dryness to prevent cracking and chafing; and monitoring BG values as directed. Weekly appraisals of weight and BP are also advised.
- Until A_{1c} levels are at goal, quarterly visits with the patient's primary health-care provider are recommended. Table 44–6 summarizes specific ADA goals for therapy. The practitioner should review SMBG data and a current A_{1c} level for progress and address any therapeutic or educational issues.
- At a minimum, yearly laboratory evaluation of serum lipids, urinary albumin-to-creatinine ratio, and SCr should be performed.
- Appropriate monitoring and treatment for DM complications should occur (Table 44–13).

Abbreviations Introduced in This Chapter

A_{1c}	Hemoglobin A_{1c}
AACE	American Association of Clinical Endocrinologists
ACCORD	Action to Control Cardiovascular Risk in Diabetes
ACE	Angiotensin-converting enzyme
ADA	American Diabetes Association
ADVANCE	Action in Diabetes and Vascular Disease
ALT	Alanine aminotransferase
ARB	Angiotensin II receptor blocker
ASCVD	Atherosclerotic cardiovascular disease
AST	Aspartate aminotransferase
ATP	Adenosine triphosphate
BG	Blood glucose
BMI	Body mass index
BP	Blood pressure
BUN	Blood urea nitrogen
CKD	Chronic kidney disease
Cl	Chloride
CrCl	Creatinine clearance
CSII	Continuous subcutaneous insulin infusion
CVOTs	Cardiovascular outcomes trials
DCCT	Diabetes Control and Complications Trial
DKA	Diabetic ketoacidosis
DM	Diabetes mellitus
DPP-4	Dipeptidyl peptidase-4
ECG	Electrocardiogram
eGFR	Estimated glomerular filtration rate
ER	Extended release
FBG	Fasting blood glucose
FDA	Food and Drug Administration
FPG	Fasting plasma glucose
GDM	Gestational diabetes mellitus
GI	Gastrointestinal
GIP	Glucose-dependent insulinotropic peptide
GLP-1	Glucagon-like peptide-1
GLP-1 RA	Glucagon-like peptide-1 receptor agonist
HCO_3	Serum bicarbonate
HDL	High-density lipoprotein
HFrEF	Heart failure with reduced ejection fraction
Hgb	Hemoglobin
HHS	Hyperosmolar hyperglycemic state
IFG	Impaired fasting glucose
IGT	Impaired glucose tolerance
IM	Intramuscular
ISF	Interstitial fluid
IV	Intravenous
K	Potassium
LADA	Latent autoimmune diabetes in adults
LDL	Low-density lipoprotein
MACE	Major adverse cardiovascular events
Mg	Magnesium
MNT	Medical nutrition therapy
MODY	Maturity onset diabetes in the young
Na	Sodium
NGSP	National Glycohemoglobin Standardization Program
NPH	Neutral protamine Hagedorn
OGTT	Oral glucose tolerance test
OTC	Over-the-counter
PAD	Peripheral arterial disease
PCO_2	partial pressure of carbon dioxide
PPAR-γ	Peroxisome proliferator-activated receptor gamma
PPG	Postprandial glucose
SC	Subcutaneous
SCr	Serum creatinine
SGLT2	Sodium-dependent glucose cotransporter-2
SMBG	Self-monitoring of blood glucose
T1DM	Type 1 diabetes mellitus
T2DM	Type 2 diabetes mellitus
TLC	Therapeutic lifestyle change
TZD	Thiazolidinedione
UKPDS	United Kingdom Prospective Diabetes Study
ULN	Upper limit of normal
UTI	Urinary tract infection
VADT	Veterans Affairs Diabetes Trial
WHO	World Health Organization

Thyroid Disorders

Michael D. Katz

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss the prevalence of common thyroid disorders, including mild and overt hypothyroidism and hyperthyroidism.
2. Explain the major components of the hypothalamic–pituitary–thyroid axis and interaction among these components.
3. Discuss the relationship between serum thyroid-stimulating hormone (TSH) levels and primary thyroid disease, and advantages for the use of TSH levels over other tests such as serum T_4 (thyroxine) and T_3 (triiodothyronine) levels.
4. Identify typical signs and symptoms of hypothyroidism and consequences of suboptimal treatment.
5. Describe clinical use of levothyroxine (LT_4) in the treatment of hypothyroidism.
6. Discuss issues regarding LT_4 product bioequivalence and reasons for maintaining patients on the same product.
7. Describe the management of hypothyroidism and hyperthyroidism in special populations, including pregnant women.
8. Identify typical signs and symptoms of Graves disease and consequences of inadequate treatment.
9. Discuss the pharmacotherapy of Graves disease, including advantages and disadvantages of antithyroid drugs versus radioactive iodine, adverse effects, and patient monitoring.
10. Describe potential effects of selected drugs including amiodarone, lithium, interferon-α, tyrosine kinase inhibitors (TKIs), and immune checkpoint inhibitors on thyroid function.

INTRODUCTION

Thyroid disorders are common, with more than 2 billion people or 38% of the world's population having iodine deficiency, resulting in 74 million people with goiter. Although overt iodine deficiency is not a significant problem in developed countries, a number of common thyroid conditions exist. The most common are hypothyroidism and hyperthyroidism, which often require long-term pharmacotherapy. Undetected or improperly treated thyroid disease can result in long-term adverse sequelae, including increased mortality. It is important that clinicians are aware of the prevalence of thyroid disorders, methods of identifying thyroid disorders, and appropriate therapy. This chapter focuses on the most common pharmacologically treated thyroid disorders.

EPIDEMIOLOGY

In iodine sufficient countries such as the United States, United Kingdom, and other Western European countries, overall prevalence of hypothyroidism ranges from 1% to 2%. More specifically, in the United States, overall prevalence of overt hypothyroidism ranges from 0.3% to 3.7% in various studies, depending on how hypothyroidism is defined and patient population studied. Prevalence increases with age, rising to 7% in people between 85 and 89 years.[1] Compared with the total population, people aged 50 to 79 years have an almost twofold higher prevalence, and those aged 80 years and older have a fivefold higher prevalence. Prevalence of hypothyroidism is similar in White and Hispanic patients but lower in those of African or Afro-Caribbean descent. Pregnant women have a higher prevalence of hypothyroidism than nonpregnant women across all races and ethnicities.

Prevalence of overt hyperthyroidism ranges from 0.2% to 1.3% in iodine-sufficient parts of the world. In the United States, overt hyperthyroidism was detected in 0.5% of the general population, while 0.7% had subclinical hyperthyroidism. The Colorado Thyroid Health Survey assessed thyroid function in 25,862 subjects attending a health fair.[2] Overall prevalence of an abnormal thyroid-stimulating hormone (TSH; thyrotropin) level was 11.7% of the study population, with 9.4% hypothyroid (9% subclinical) and 2.2% hyperthyroid (2.1% subclinical). Of the 916 subjects taking thyroid medication, 60% were euthyroid (had normal thyroid function or hormone activity), with an equal distribution between subclinical hypothyroidism and hyperthyroidism. These findings imply that many patients who are receiving thyroid medications are not being managed successfully.

PATHOPHYSIOLOGY

The thyroid gland is the largest endocrine gland in the body, residing in the neck anterior to the trachea between the cricoid cartilage and suprasternal notch. The thyroid gland produces two biologically active hormones, thyroxine (T_4) and triiodothyronine (T_3).

Thyroid hormones are essential for proper fetal growth and development, particularly of the central nervous system (CNS). After delivery, the primary role of thyroid hormone is in regulation of energy metabolism. Thyroid hormones can affect the function of virtually every organ in the body. The parafollicular C cells of the thyroid gland produce calcitonin.

T_4 and T_3 are produced by the organification of iodine in the thyroid gland. Iodine is actively transported into the thyroid follicular cells. This inorganic iodine is oxidized by thyroid peroxidase and covalently bound to tyrosine residues of thyroglobulin. These iodinated tyrosine residues, monoiodotyrosine and diiodotyrosine, couple to form T_4 and T_3. About 80% of thyroid hormone is synthesized as T_4 and stored in the thyroid bound to thyroglobulin. Thyroid hormones are released from the gland when needed, primarily under the influence of TSH, which is also known as thyrotropin, from the anterior pituitary. T_4 and T_3 are transported in the blood by three proteins, 70% bound to thyroid-binding globulin (TBG), 15% to transthyretin (thyroid-binding prealbumin), and 15% to albumin. T_4 is 99.97% protein bound and T_3 is 99.7% protein bound, with only the unbound or free fractions physiologically active. The high degree of protein binding results in a long half-life of these hormones: approximately 7 to 10 days for T_4 and 24 hours for T_3.

Most of the physiologic activity of thyroid hormones is from the actions of T_3. T_4 can be thought of primarily as a prohormone. About 80% of needed T_3 is derived from conversion of T_4 to T_3 in peripheral tissue under the influence of tissue deiodinases. These deiodinases allow end organs to produce the amount of T_3 needed to control local metabolic functions. These enzymes also catabolize T_3 and T_4 to biologically inactive metabolites.

KEY CONCEPT Production and release of thyroid hormones are regulated by the hypothalamic–pituitary–thyroid axis (Figure 45–1). Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of TSH when there are physiologically inadequate levels of thyroid hormones. TSH promotes production and release of thyroid hormones. As circulating thyroid hormone levels rise to needed levels, negative feedback results in the decreased release of TSH and TRH. Release of TRH is also inhibited by somatostatin and its analogs, and the release of TSH can also be inhibited by dopamine, dopamine agonists, and high levels of glucocorticoids.

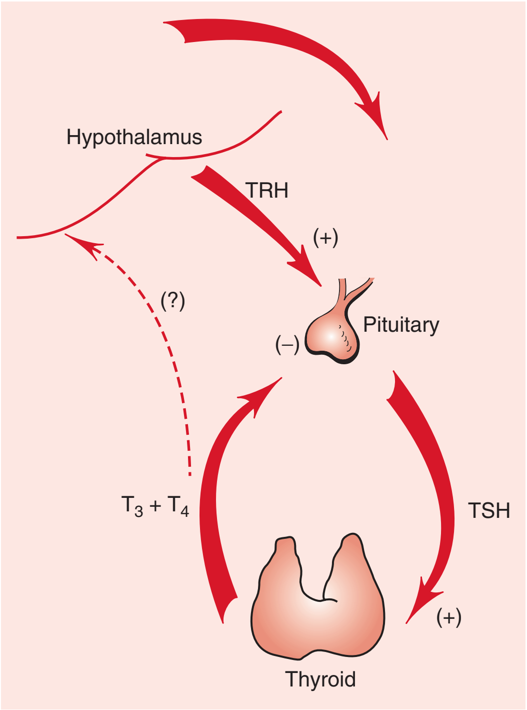

FIGURE 45–1. Hypothalamic–pituitary–thyroid axis. Thyrotropin-releasing hormone (TRH) is synthesized in the neurons within the paraventricular nucleus of the hypothalamus. TRH is released into the hypothalamic–pituitary portal circulation and carried to the pituitary, where it activates the pituitary to synthesize and release thyrotropin (TSH, or thyroid stimulating hormone). TSH activates the thyroid to stimulate the synthesis and secretion of thyroxine (T_4) and triiodothyronine (T_3). T_4 and T_3 inhibit TSH secretion, closing the feedback loop. Negative feedback from T_4 and T_3 to hypothalamic TRH is less certain, hence the question mark.

SPECTRUM OF THYROID DISEASE

There are two general modes of presentation for thyroid disorders: changes in size or shape of the gland and changes in secretion of hormone from the gland. In some cases, structural changes can result in changes in hormone secretion. Thyroid nodules and goiters in euthyroid patients are common problems. Patients with a goiter who are biochemically euthyroid do not often require specific pharmacotherapy, unless the goiter is caused by iodine deficiency. In developing countries, iodized salt is the primary therapy in treating goiter. Thyroid nodules, seen in 4% to 7% of adults, may be malignant, benign, and/or may autonomously secrete thyroid hormones. A discussion of thyroid nodules is beyond the scope of this chapter; however, thyroid cancer is discussed briefly in the context of levothyroxine (LT_4) suppressive therapy. Refer to other resources for a more extensive review of thyroid cancer management.

Changes in hormone secretion, often due to an underlying inflammatory disorder (thyroiditis), can result in hormone deficiency or excess. Although patients with overt hypothyroidism and hyperthyroidism may have dramatic signs and symptoms, most patients have subtle signs and symptoms that progress slowly over time. Availability of sensitive and specific biomarkers for the diagnosis of thyroid hormone disorders has facilitated screening and early case-finding and diagnosis, including in those with mild or subclinical thyroid disorders. Screening of newborns for congenital hypothyroidism has dramatically reduced incidence of permanent thyroid-related cognitive and developmental impairment and neonatal hypothyroidism in the United States. However, congenital hypothyroidism due to iodine deficiency remains a significant worldwide public health problem.

PATIENT ASSESSMENT AND MONITORING

Assessment of patients for thyroid disorders entails a history and physical examination. In many patients with mild or subclinical thyroid disease, there may be an absence of specific signs and symptoms, and physical examination findings may be normal. Various diagnostic tests can be used, including levels of serum thyroid hormone(s), TSH, thyroid antibody levels, and imaging techniques (Table 45–1). Laboratory assessment of patients with suspected thyroid disorders must be based on the continuum of disease from subclinical to mild to overt (Figure 45–2).

TSH Levels

KEY CONCEPT In most patients with thyroid hormone disorders, measurement of serum TSH level is adequate for initial screening and diagnosis of hypothyroidism and hyperthyroidism. Serum free thyroxine (FT_4) and triiodothyronine (FT_3) levels may be helpful

Table 45–1

Selected Thyroid Tests for Adults

Test	Reference Range	Comments
TSH	0.5–4.5 mIU/L (μIU/mL)	Gold standard; may be lowered by dopamine, dopamine agonists, glucocorticoids, octreotide, recovery from severe nonthyroidal illness
FT_4	0.7–1.9 ng/dL (9.0–24.5 pmol/L)	May be normal in mild thyroid disease
Anti-TPOAb, Anti-TGAb	Variable[a]	Present in autoimmune hypothyroidism; predicts more rapid progression from subclinical to overt hypothyroidism
TSI (TSHR-SAb)	< 1.3 (< 130%)	Confirms Graves disease

[a] Anti-TPOAb reference ranges are highly variable from one laboratory to another depending on the method used. Results greater than the upper cutoff are considered abnormal and are consistent with increased risk for autoimmune thyroid disease.

Anti-TGAb, antithyroglobulin antibody; Anti-TPOAb, antithyroid peroxidase antibody; FT_4, free T_4 (thyroxine); TSH, thyroid-stimulating hormone; TSHR-SAb, TSH receptor-stimulating antibodies; TSI, thyroid-stimulating immunoglobulin.

in distinguishing mild (subclinical) thyroid disease from overt disease. TSH for most patients being treated for thyroid disorders should be the mean normal value of 1.5 milli international units/L (mIU/L) or 1.5 micro international units/mL (μIU/mL) (target range, 0.5–4.5 mIU/L or μIU/mL; clinical laboratories use either unit of measurement, usually expressed as mIU/L or μIU/mL), although patients must be individually titrated based on resolution of signs and symptoms as well as biochemical tests. Target TSH may be different in the elderly and in patients being treated with LT_4 for thyroid cancer.

TSH is a highly sensitive biomarker of the thyroid axis. A twofold change in FT_4 levels will result in a 100-fold change in TSH levels. This biologic magnification by TSH allows it to be used in early diagnosis as well as in closely titrating therapy in hypothyroidism and hyperthyroidism. In patients with primary hypothyroidism or hyperthyroidism resulting from gland dysfunction, there is an inverse relationship between TSH level and thyroid function. High TSH signifies hypothyroidism (or iatrogenic underreplacement) and low TSH signifies hyperthyroidism (or iatrogenic overreplacement).

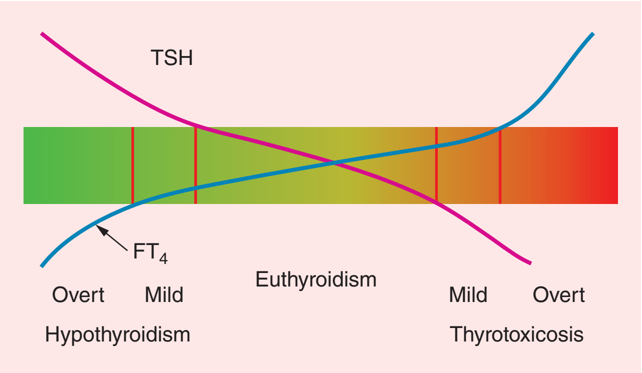

FIGURE 45–2. The continuum of thyroid disorders. (FT_4, free T_4 [thyroxine]; TSH, thyroid-stimulating hormone).

There is controversy regarding the normal or laboratory reference ranges for TSH.[3] The National Health and Nutrition Examination Survey (NHANES) showed the mean TSH level in a normal population was 1.46 mIU/L (μIU/mL), but the values were not normally distributed. Although most laboratories quote the upper limit of normal for TSH between 4 and 5 mIU/L (μIU/mL), 95% of subjects had a TSH level between 0.5 and 2.5 mIU/L (μIU/mL). The population of subjects whose TSH level was 2.5 to 4.5 mIU/L (μIU/mL) may have had mild hypothyroidism, or the nonnormal distribution may reflect different normal ranges in a heterogeneous (age, sex, and race) population. The mean normal TSH appears to be higher in the elderly with no clinical evidence of hypothyroidism,[3] and normal TSH ranges are sex and ethnicity specific.[1] Target TSH for most patients being treated for thyroid disorders is not the same as the reference range. Ideally, TSH should be the aforementioned mean normal value of 1.5 mIU/L (μIU/mL; target range, 0.5–4.5 mIU/L [μIU/mL]).[3] The upper limit of the target range may be higher in the elderly. Therapy may be titrated within the target TSH range to maximally improve patient signs and symptoms without causing adverse effects of overtreatment or undertreatment.

Serum T_4 and T_3 Levels

Serum T_4 and T_3 levels are used commonly to assess thyroid function. Older screening tests of thyroid function measure total serum T_4 or T_3 levels. Because of the high degree of protein binding of these hormones, the free fraction can be altered by changes in the levels of binding proteins or degree of protein binding. Since a number of factors can alter protein binding, these older assays are very insensitive and should no longer be used. FT_4 and FT_3 assays are readily available and more sensitive in identifying thyroid dysfunction than older total assays.[3] However, patients with mild hypothyroidism or hyperthyroidism have normal FT_4 levels despite abnormal TSH levels.

Other Diagnostic Tests

Global tests of thyroid gland function can be performed to assess the rate of hormone synthesis. Radioactive iodine uptake (RAIU) is elevated in those with hyperthyroidism and can aid in identifying thyrotoxicosis due to nonthyroid gland sources. Radionuclide thyroid scans are used in the evaluation of thyroid nodules. Because many thyroid disorders are autoimmune, measurement of various serum antithyroid antibodies can be performed. Antithyroid peroxidase antibodies (anti-TPOAb) and antithyroglobulin antibodies (anti-TGAb) are present in many patients with hypothyroidism. Most patients with Graves disease have TSH receptor-stimulating antibodies (TSHR-SAb) as well as elevated anti-TPOAb and antimicrosomal antibodies.

HYPOTHYROIDISM

Hypothyroidism is the most common clinical disorder of thyroid function and results from inadequate secretion of thyroid hormones from the thyroid gland. The vast majority of hypothyroid patients have primary gland failure, but occasional patients have pituitary or hypothalamic failure, resulting in secondary hypothyroidism. Most studies define primary hypothyroidism based on a serum TSH level above the upper limit of the laboratory reference range. In adults, 1.4% of women and 0.1% of men are biochemically hypothyroid. However, incidence is highly age dependent. In the Colorado Thyroid Health Study, by age 64 years, 12% of women and 5% of men were hypothyroid, and in the over 74 years age group, incidence in men approached that of women.[2] Most epidemiologic studies of hypothyroidism in the elderly show a prevalence of 6% to 12%.[3] There is a strong correlation between presence of anti-TPOAb or anti-TGAb and the risk of developing hypothyroidism. In patients with subclinical hypothyroidism, the clinician should be aware conditions other than hypothyroidism can cause mild elevations in TSH such as significant obesity (body mass index [BMI] > 40). Elderly patients may have an increase in TSH with aging that may not reflect a pathologic problem.[4,5] Many patients with a mild increase in TSH will revert to having normal TSH over the next 1 to 2 years, while 2% to 6% per year will progress to overt hypothyroidism, with risk of progression higher in women, those with higher TSH levels, those with higher levels of anti-TPOAbs, and those with low-normal FT_4 levels.[5] Other risk factors for development of hypothyroidism include the postpartum state, family history of autoimmune thyroid disorders, a previous history of head and neck or thyroid surgery, head and neck irradiation, other autoimmune endocrine disorders such as type 1 diabetes and Addison disease, other nonendocrine autoimmune diseases such as celiac disease and pernicious anemia, history of treatment for hyperthyroidism, treatment with certain medications including amiodarone or lithium, and an iodine-deficient diet.[3,6]

Screening

Because prevalence of hypothyroidism is high in certain populations, screening may be useful. Screening for hypothyroidism in women older than age 35 years may be cost-effective, though some organizations recommend screening of adults after age 50 or 60 years.[7] Others advocate a case-finding approach, defined as performing a TSH determination in patients based on risk factors or the presence of signs and symptoms.[3] However, there are no studies that demonstrate a positive impact of screening for thyroid disease on morbidity and mortality.[8]

Causes

The most common causes of hypothyroidism are listed in Table 45–2.[3-6,9-12] Up to 90% of patients with autoimmune thyroiditis (Hashimoto disease) have circulating anti-TPOAbs. The autoimmune inflammatory response results in a lymphocytic infiltration of the thyroid gland and its eventual destruction.

Table 45–2

Common Causes of Hypothyroidism[3-6,9-12]

Primary Hypothyroidism
Chronic autoimmune thyroiditis (Hashimoto disease)
Iatrogenic (irradiation, surgery)
Drugs (amiodarone, radiocontrast media, lithium, interferon-α, tyrosine kinase inhibitors, immune checkpoint inhibitors)
Transient thyroiditis (including viral and postpartum)
Iodine deficiency and excess
Thyroid gland infiltration (infectious, malignant, autoimmune, inflammatory)

Secondary Hypothyroidism
Pituitary disease
Hypothalamic disease

Iatrogenic hypothyroidism can occur after thyroid irradiation or surgery and excessive doses of antithyroid drugs. Several drugs can cause hypothyroidism including iodine-containing drugs (such as amiodarone and iodinated radiocontrast media), lithium, interferon-α, multikinase and tyrosine kinase inhibitors (TKIs, such as imatinib, sunitinib, and sorafenib), immune checkpoint inhibitors (ICPIs, such as ipilimumab, nivolumab, atezolizumab, avelumab, and durvalumab), *p*-aminosalicylic acid, ethionamide, sulfonylureas, tetracyclines, thalidomide, valproic acid and other antiepileptic drugs, and aminoglutethimide.[3,9,12,13] Iodine deficiency is a common worldwide cause of hypothyroidism, including congenital hypothyroidism in newborns. Patients with hypothalamic or pituitary disease often have other signs of pituitary disease, such as hypogonadism, and their TSH levels are low.

Signs and Symptoms

Hypothyroidism can affect virtually any tissue or organ in the body. The most common symptoms, such as fatigue, lethargy, sleepiness, cold intolerance, and dry skin, are nonspecific and can be seen with many other disorders. The classic overt signs, such as myxedema and delayed deep tendon reflexes, are seen uncommonly now because more patients are screened or seek medical attention earlier. Patients with mild (also known as subclinical) hypothyroidism or elderly patients may have subtle symptoms or may progress so slowly they are not noticed easily by the patient or family. The lack of overt or specific signs and symptoms emphasizes the importance of using serum TSH level to identify patients with hypothyroidism.

Clinical Presentation and Diagnosis of Hypothyroidism[3-6,9-11]

Symptoms

Fatigue
Lethargy
Sleepiness
Mental impairment
Depression
Weight gain
Menstrual disturbances
Paresthesia
Cold intolerance
Change in voice
Dry skin
Decreased perspiration
Decreased appetite
Constipation
Arthralgia, myalgia
Infertility

Signs

Slow movements
Goiter
Slow speech
Hoarseness
Bradycardia
Anemia
Dry skin
Weight gain (slight to moderate)
Nonpitting edema (myxedema)
Hyporeflexia
Delayed relaxation of reflexes

Screening/Diagnosis

- TSH level of 4.5 to 10 mIU/L (μIU/mL) may constitute mild or subclinical hypothyroidism.
- TSH level greater than 10 mIU/L (μIU/mL) signifies overt hypothyroidism.
- FT_4 level will be normal (0.7–1.9 ng/dL or 9.0–24.5 pmol/L) in mild or subclinical hypothyroidism and low (< 0.7 ng/dL or 9.0 pmol/L) in patients with obvious signs and/or symptoms.

Mild (Subclinical) Hypothyroidism

Mild or subclinical hypothyroidism is present when a patient has a TSH above the upper limit of the laboratory reference range but usually below 10 mIU/L (μIU/mL), normal FT_4, and no overt hypothyroid signs and symptoms.[4,5,9-11] Many of these patients have autoimmune thyroiditis and anti-TPOAbs, and some will progress to overt hypothyroidism. Although patients may not express typical symptoms of hypothyroidism, many patients do have mild, nonspecific symptoms (eg, fatigue, cold intolerance, and constipation). Studies have shown subclinical hypothyroidism to be a risk factor for cardiovascular mortality and to be associated with decreased myocardial contractility, decreased exercise tolerance, elevated low-density lipoprotein (LDL) cholesterol, and neuropsychiatric symptoms.[4-6,10,11,14-16]

Sequelae of Hypothyroidism

Hypothyroidism is a chronic disease that may result in significant long-term sequelae. Hypercholesterolemia is associated with hypothyroidism, increasing long-term risk of cardiovascular disease and cardiovascular mortality. Between 4% and 14% of patients with hypercholesterolemia are found to be hypothyroid. The Colorado Thyroid Health Study showed a direct correlation between degree of TSH elevation and rise in serum cholesterol.[2] Hypothyroidism also may result in increased systemic vascular resistance, decreased cardiac output, and increased diastolic blood pressure. Hypothyroidism can cause significant neuropsychiatric problems, including a dementia-like state in the elderly that is reversible with LT_4 therapy. Maternal hypothyroidism can have dire consequences for developing fetuses. Fetuses are almost completely dependent on maternal thyroid hormones during the first trimester, a time crucial for development of the CNS. Inadequately treated maternal hypothyroidism results in increased risk of miscarriage and developmental impairment in the child.[3]

Myxedema coma is seen in advanced hypothyroidism. These patients develop CNS depression, respiratory depression, cardiovascular instability, and fluid and electrolyte disturbances. Myxedema coma often is triggered by an underlying acute medical condition such as infection, stroke, trauma, or administration of CNS depressant drugs.

Treatment

▶ *Desired Outcomes*

KEY CONCEPT There are three major goals in the treatment of hypothyroidism: replace the missing hormones, relieve signs and symptoms, and achieve a stable biochemical euthyroid state. Although these goals should not be difficult to achieve, 20% to 40% of treated patients are not receiving optimal pharmacotherapy.

▶ *Thyroid Hormone Products*

A number of thyroid hormone products are marketed in the United States (Table 45–3). These products include synthetic LT_4 and T_3, combinations of synthetic LT_4 and T_3, and animal-derived products. KEY CONCEPT Despite the availability of a wide array of thyroid hormone products, synthetic LT_4 is the treatment of choice for almost all patients with hypothyroidism.[3,6,10,14,17-19] LT_4 mimics the normal physiology of the thyroid gland, which secretes mostly T_4 as a prohormone. Peripheral tissues convert T_4 to T_3 as needed based on metabolic demands. If T_3 is used to treat hypothyroidism, the peripheral tissues lose their ability to control local metabolic rates. LT_4 also has distinct pharmacokinetic advantages over T_3. With a 7- to 10-day half-life, LT_4 provides a very smooth dose-response curve with little peak and trough effect. In a small number of patients who have impairment of conversion of T_4 to T_3, addition of T_3 may be warranted. T_3, with a 24-hour half-life, provides a significant peak and trough effect, and many patients have symptoms of thyrotoxicosis after each dose is administered. The use of compounded T_3 or other thyroid hormone products not approved by the Food and Drug Administration (FDA) or dietary supplements marketed for "thyroid health" should be strongly discouraged.[17] For patients who have difficulty adhering to a once-daily regimen, a once-weekly LT_4 regimen is safe and effective.[3,17]

Table 45–3

Thyroid Preparations

Drug (Brand Name)	Content	Relative Dose	Comments
Levothyroxine, (Synthroid, Levoxyl, Unithroid), other brands, and generics	Synthetic LT_4; 25-, 50-, 75-, 88-, 100-, 112-, 125-, 137-, 150-, 175-, 200-, and 300-mcg tablets; 13-, 25-, 50-, 75-, 100-, 125-, 150-mcg softgel capsules; 100-, 200-, and 500-mcg vial for injection	60 mcg	Gold standard for treating hypothyroidism; products not therapeutically equivalent; full replacement dose, 1–1.6 mcg/kg/day; when switching from animal product, lower calculated daily dose by 25–50 mcg; IV form rarely needed
Liothyronine (Cytomel)	Synthetic T_3; 5-, 25-, and 50-mcg tablets	15 mcg	Rarely needed in treatment of hypothyroidism; rapid absorption and pharmacologic effect; increased toxicity versus LT_4; no outcome benefit to combining with LT_4
Thyroid (desiccated) USP (Armour, others)	Desiccated pork thyroid glands; contains T_3 and T_4; 15-, 16.25-, 30-, 32.5-, 48.75-, 60-, 65-, 90-, 97.5-, 120-, 130-, 162.5-, 180-, 195-, 240-, 260-, 300-, and 325-mg tablets	65 mg	Nonphysiologic T_4:T_3 ratio; T_3 content may cause toxicity; no advantage over LT_4 monotherapy; no role in modern therapy
Liotrix (Thyrolar)	Synthetic T_4, T_3 in fixed 4:1 ratio; ¼-, ½-, 1-, 2-, 3-strength tablets	12.5/50 mcg T_3:T_4 (1 strength)	Nonphysiologic T_4:T_3 ratio; T_3 content may cause toxicity; no role in modern therapy; *withdrawn in United States by manufacturer in 2018*

IV, intravenous; LT_4, levothyroxine; T_3, triiodothyronine; T_4, thyroxine.

Animal-derived products such as desiccated thyroid are obtained from pig or cow thyroid and have various degrees of purity. These products contain both LT_4 and T_3, but the ratio of T_3 is much higher (T_4:T_3 = 4:1) than what would be found in the human thyroid gland (T_4:T_3 = 14:1). Although some patients want to use desiccated thyroid extract because it is "natural," the products are in no way natural for humans. With strong evidence supporting the safety and efficacy of LT_4 in the treatment of hypothyroidism, there is no rationale for use of these animal-derived products, and no evidence that desiccated thyroid extract has any benefits over synthetic LT_4.[18,19] Patients who are treated with these agents should be strongly encouraged to switch to synthetic LT_4. Additionally, patients should be encouraged to not purchase thyroid hormone- or iodine-containing products from health food stores or Internet sites.

Several studies have been published that evaluate the use of LT_4 and T_3 combinations in ratios that mimic human physiology. A large number of clinical trials and meta-analyses of studies comparing LT_4 and T_3 combinations with LT_4 monotherapy show no outcome benefit with combination therapy.[17,20] Except in rare circumstances (eg, patients with impaired T_4-to-T_3 conversion as evidenced by adequate LT_4 dose, continued symptoms, and low FT_3 level), there is no evidence to support the use of LT_4 and T_3 combinations over LT_4 monotherapy.

▶ *Bioequivalence and LT_4 Product Selection*

LT_4 products have a long history of bioavailability problems.[3,17-19] Over the years, LT_4 bioavailability has increased, so maintenance doses today are significantly lower than those seen before the early 1980s. Currently, average bioavailability of LT_4 tablet products is about 70% to 80%. Because of long-standing concerns about LT_4 bioequivalence and because LT_4 products had never undergone formal approval by the FDA under the 1938 Food, Drug, and Cosmetics Act, the FDA mandated that all manufacturers of LT_4 products submit an abbreviated new drug application (ANDA) to keep their products on the US market after 2001.[15,17-19] Products approved under this process would have to comply with FDA manufacturing and bioequivalence standards. This action has resulted in many changes in the US LT_4 market, as well as renewed interest in LT_4 bioequivalence. Since 2001, a variety of brand and generic products have been approved by the FDA. Some marketed products carry AB ratings (bioequivalence) to certain other products, using a complex AB1, AB2, AB3, and AB4 system.[21,22]

For many years, there have been concerns regarding the FDA bioequivalence methodology for LT_4 products. FDA bioequivalence standards allow a −20% to +25% variance in single-dose pharmacokinetic parameters between the test and reference products. Many people believe this degree of allowed variance is not appropriate for a narrow-therapeutic-index (NTI) drug such as LT_4. Furthermore, there are unique challenges to performing bioequivalence studies with an endogenous hormone such as LT_4. Because these single-dose pharmacokinetic studies are done in healthy volunteers, the pharmacokinetic data are a combination of endogenous and exogenous LT_4. About 70% of the area under the curve (AUC) in these studies consists of the subjects' endogenous T_4. A study showed the standard FDA bioequivalence methodology would rate 600-, 450-, and 400-mcg LT_4 doses as bioequivalent, and that mathematically removing the subjects' endogenous T_4 level (baseline correction) improves sensitivity of the analysis.[22] Based on these data, since 2003, the FDA has required that LT_4 bioequivalence data undergo baseline correction. Although this method has improved the ability to identify large differences in LT_4 bioequivalence, small but clinically significant differences will not be identified. In 2008, the FDA adopted stricter criteria for LT_4 tablet shelf-life potency (95%–105% of stated potency versus standard 90%–110%), which may reduce the intrapatient variability seen during long-term LT_4 therapy.

More important than bioequivalence is the therapeutic equivalence of LT_4 products. Will patients have the same outcomes if bioequivalent products are used? Studies show that switching among various LT_4 products in stable hypothyroid patients results in abnormal TSH levels in about half the patients, providing strong evidence that products deemed bioequivalent by the US FDA may not be therapeutically equivalent.[19,22]

Evidence does exist that small differences in LT_4 dose can result in large changes in TSH. In one study, when daily dose was reduced by 25 mcg, 78% had an elevated TSH level.[23] When daily dose was increased by 25 mcg, 55% had a low TSH level. Clearly, differences in LT_4 dose or bioavailability within the FDA-allowed variance for bioequivalent products can cause significant changes in TSH.

KEY CONCEPT There is no evidence that one LT_4 product is better than another. However, given the evidence that these products do have differences in bioavailability, patients should be maintained on the same LT_4 product. Given the generic substitution regulations of most states, this is best accomplished by prescribing a brand-name product or otherwise ensuring the product remains constant and not allowing substitution.[17-19] Although practitioners are pressured by insurance companies and employers to substitute LT_4 products as a cost-saving measure, such switching is not in the best interest of the patient and should not be allowed. If patients are switched to a different product, the prescriber should be notified, and a TSH determination should be done in 6 to 8 weeks to allow dose retitration. Changes in LT_4 dose significantly increase the cost of care.[24]

▶ *Therapeutic Use of LT_4*

LT_4 replacement is indicated for patients with overt hypothyroidism.[3,5,8-11,14,16-19] However, the need for treatment is controversial in patients with mild or subclinical disease. There are no prospective clinical trials showing an outcome benefit with treating these patients. A systematic review of 21 trials in nonpregnant adults with subclinical hypothyroidism showed that the use of thyroid hormone therapy was not associated with improvements in general quality of life or thyroid-related symptoms.[25] In patients without symptoms, who are children or have an underlying heart disease, high cardiovascular risk, diabetes, elevated serum cholesterol, goiter, positive anti-TPOAb, progressive rise in TSH, depression or bipolar disorder, and/or are infertile or pregnant, LT_4 replacement may be considered.[3,10,11,14,17] Patients with mild or subclinical hypothyroidism do not need to be started on the full LT_4 replacement dose because they still have some endogenous hormone production.[26] Start these patients on 12.5 to 50 mcg/day and titrate every 6 to 8 weeks to target TSH level. Over time, it is likely the LT_4 dose will need to be increased slowly as the patient's thyroid gland loses residual function.

In patients younger than age 65 years with overt hypothyroidism and moderate-to-severe signs and symptoms, the average LT_4 replacement dose is 1.6 to 1.8 mcg/kg/day (use ideal body weight in obese patients[17,18]). Patients with mild, overt signs and symptoms may be started on a lower than full replacement dose. There is wide interpatient variability in the optimal replacement dose, so individual dose titration is necessary.

The full replacement dose in patients older than age 75 years is lower, about 1 mcg/kg/day.[3,17] In the elderly, starting dose should be 12.5 to 25 mcg/day, and dose should then be titrated to the target TSH value. In patients with ischemic heart disease, start with 12.5 to 25 mcg/day and slowly titrate. If the patient develops angina or other forms of myocardial ischemia, lower the dose and titrate more slowly. At the start of therapy, and with each change in dose, recheck the TSH in 6- to 8-week intervals. If the TSH is not in the target range (0.5–2.5 mIU/L [μIU/mL]), change the dose by 10% to 20% and then recheck TSH 6 to 8 weeks later. As the dose is titrated, assess the patient's symptoms. Many patients will improve quickly, and younger patients will feel best if TSH is titrated to low-normal to middle-normal levels (0.5–1.5 mIU/L [μIU/mL]).

▶ *Risks of Overtreatment and Undertreatment*

Patients receiving LT_4 therapy who are not maintained in an euthyroid state are at risk for long-term adverse sequelae.[18] In general, overtreatment and a suppressed TSH are more common than undertreatment with an elevated TSH. Patients with long-term overtreatment are at higher risk for atrial fibrillation and other cardiovascular morbidities; anxiety, depression, or mental status changes; and osteoporosis. Elderly patients being treated with LT_4 may have a dose-related risk of fractures even if TSH is not suppressed below normal values. Although studies have not defined a specific TSH target range for the elderly, these patients should receive close monitoring and dose adjustments to prevent over- and undertreatment. Patients who are undertreated are at higher risk for hypercholesterolemia and other cardiovascular problems, depression and/or other mental status changes, and obstetric complications.

Patient Encounter 1, Part 1

A 36-year-old female comes to the clinic complaining of fatigue and feeling a little "slow" for the past 3 months. She thought it was because she is working too hard and her kids are stressing her out, but the symptoms have not improved despite her taking some vitamins with iron and an energy drink. She noticed a 2-kg (4.4 lb) weight gain over the past few months. Her friend gave her a ginseng product to give her energy, but she is not sure it helps. Her current medications include the vitamin and herbal product mentioned above, hormonal contraceptive, calcium and vitamin D, occasional acetaminophen for headache, and MiraLAX for occasional constipation.

PE:

Wt 67 kg (147 lb); Ht 5 ft 5 in. (165 cm); BMI 24.6 kg/m^2

VS: BP 124/76 mm Hg, P 68, RR 12 breaths/min

Skin, HEENT, thyroid, pulmonary, and cardiovascular examinations are normal.

Labs

Serum Cholesterol: 205 mg/dL (5.30 mmol/L); LDL cholesterol 96 mg/dL (2.48 mmol/L)

TSH: 6.8 mIU/L (μIU/mL; reference range, 0.5–4.5 mIU/L [μIU/mL])

FT_4: 0.96 ng/dL (12.4 pmol/L; reference range, 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L)

Should the patient receive LT_4 therapy? Why or why not?

If you think treatment is indicated, what initial dose of LT_4 would you choose?

If you think treatment is not indicated, how would you monitor the patient?

What would you tell the patient regarding the significance of her symptoms, elevated TSH level, and risk versus benefits of LT_4 therapy?

▶ *Alterations in LT_4 Dose Requirements*

A number of factors can alter LT_4 dose requirements (Table 45–4), including time of administration and drug–drug and drug–food interactions.[3,8,17-19] LT_4 has the greatest and most consistent bioavailability when taken in the evening on an empty stomach.[17,22,27] The most common cause of increased dose requirement is coadministration of LT_4 with calcium or iron supplements (including prenatal vitamins) or concomitant use of proton pump inhibitors. In patients who have impaired absorption of standard LT_4 dosage forms, the use of a liquid or gelcap formulation may improve absorption.[28] Counsel patients that they should take the LT_4 dose at least 2 hours before or 6 hours after the calcium or iron dose. The most common reason for decreased dose requirement is aging.

▶ *Patient Monitoring*

Patients on stable LT_4 therapy do not need frequent monitoring. In most patients, measuring TSH every 6 to 12 months along with an assessment of clinical status is adequate (Table 45–5). If the patient's clinical status changes (eg, pregnancy), more frequent monitoring may be necessary. LT_4 prescriptions should be written as microgram doses to avoid potential errors when written as milligram doses.

Patient education is an important component of care. Treatment adherence rate (at least 80% of doses taken) in hypothyroid patients is 68%, slightly less than adherence rates seen in patients with hypertension.[29] Educate patients about the benefits of proper therapy, importance of adherence, consistency in time and method of administration, and importance of receiving a consistent LT_4 product. Some patients take excessive amounts of LT_4 in an effort to "feel better" or as a weight loss treatment. Explain to patients that excessive amounts of LT_4 will not improve symptoms more than therapeutic doses, can cause serious problems, and is not an effective nor safe treatment for obesity.

▶ *Special Populations and Conditions*

Hypothyroidism and Pregnancy Hypothyroidism during pregnancy has a variety of maternal and fetal adverse effects.[3,30,31] During pregnancy, β-human chorionic gonadotropin (β-hCG) acts as a TSH receptor agonist, increasing the amount of thyroid hormone available for fetal growth and development.

Maternal hypothyroidism results in an increased rate of miscarriage and decreased intellectual capacity of the child. Endocrinologists recommend a TSH measurement as soon as pregnancy is confirmed. Most hypothyroid women who become pregnant will quickly need an increased dose of LT_4, typically 20% to 30% or two tablets per week above the prepregnancy dose.[30] The increased dose should be maintained throughout the pregnancy, with monthly TSH monitoring to keep TSH in the middle- to low-normal range. After delivery, LT_4 dose usually can be reduced to prepregnancy levels, although patients with preexisting autoimmune thyroiditis may have increased postpartum

Table 45–4

Factors That Alter LT_4 Dose Requirements[3,17-19]

Increased Dose Requirement	Decreased Dose Requirement
Nonadherence	Aging
Decreased LT_4 Absorption	Post-menopause
Malabsorption syndromes	Delivery of pregnancy
Helicobacter pylori infection	Withdrawal of interacting substance
Drugs or Diet	Weight loss
Bile acid binders	
Caffeine

Table 45–5

Monitoring Levothyroxine (LT_4) Therapy

- Serum TSH
  - Every 6–12 months or if change in clinical status
  - 6–8 weeks after any dose or product change
  - As soon as possible in pregnancy; then monthly
- Same product prescribed and dispensed with every refill
- Watch for mg/mcg dosing errors
- Assess patient's understanding of disease, therapy, and need for adherence and tight control
- Assess for signs and symptoms of over- and undertreatment
- Identify potential interactions between LT_4 and foods and/or drugs
- In persons with diabetes, monitor for changes in glycemic control as thyroid function changes

TSH, thyroid-stimulating hormone.

dose requirements. Because prenatal vitamins contain significant amounts of calcium and iron, remind patients to take the LT_4 dose at least 2 hours before or 6 hours after the vitamin.

Children Congenital hypothyroidism is uncommon in the United States, and all newborns there undergo screening with a TSH level. As soon as the hypothyroid state is identified, the newborn should receive the full LT_4 replacement dose. The replacement dose of LT_4 in children is age dependent. In newborns, the usual dose is 10 to 15 mcg/kg/day. LT_4 tablets may be crushed and mixed with breast milk or formula, but it is best to administer LT_4 to infants and children on an empty stomach.[32] Serum TSH in the mid-to-lower half and FT_4 levels in the mid-to-upper half of the pediatric reference ranges are used for dose titration. By 6 months of age, the required dose is reduced to 6 to 8 mcg/kg/day; from ages 1 to 5 years, 5 to 6 mcg/kg/day; and from ages 6 to 12 years, 4 to 5 mcg/kg/day. After age 12 years, adult doses can be given. In children with subclinical hypothyroidism, treatment can be considered when serum TSH is over 10 mIU/L (μIU/mL).

Myxedema Coma Myxedema coma is a life-threatening condition owing to severe, long-standing hypothyroidism and has a mortality rate of 60% to 70%. These patients are given 200 to 400 mcg LT_4 intravenously (IV) initially, using caution in patients with underlying cardiac disease. Although administration of T_3 would provide a more rapid onset of action, there is no evidence T_3 improves outcomes in patients with myxedema coma.

Patient Encounter 1, Part 2

Twelve months later, the patient comes back to you for a routine follow-up stating that she has felt progressively worse since her last visit, especially over the past few months. Her best friend passed away from breast cancer 6 months ago, but she does not think she is depressed. She feels more fatigued and has gained 2 kg (4.4 lb) since her last visit. She has noticed that her skin is always dry, she has more frequent constipation, and her periods have become heavier. After her friend died, she elected to "go natural," and started taking more supplements purchased at a health food store. Her most recent TSH determination, obtained 2 days ago, was 14.2 mIU/L (μIU/mL; reference range, 0.5–4.5 mIU/L [μIU/mL]) and FT_4 0.61 ng/dL (7.9 pmol/L; reference range, 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L)

Why is LT_4 therapy indicated now?

What would you recommend regarding her LT_4 dose and monitoring?

What instructions would you give the patient regarding her LT_4 therapy?

Patient Care Process: Hypothyroidism

Collect Information:

- Perform a medication history or medication reconciliation for the use of all medications and supplements. Identify adverse drug events, allergies, and hypersensitivities.
- Review the medical history and physical assessment findings.
- Speak with the patient and other caregivers as appropriate to identify the issues that affect medication access and other aspects of care.

Assess the Information:

- Evaluate for signs and symptoms of hypothyroidism (see Clinical Presentation and Diagnosis of Hypothyroidism). As signs and symptoms of hypothyroidism are nonspecific, clinicians should have a high index of suspicion in higher risk patients including women and the elderly.
- Use serum TSH to identify patients with hypothyroidism (see Clinical Presentation and Diagnosis of Hypothyroidism), and check TSH in pregnant women as soon as pregnancy is determined.
- If the patient has been or is already receiving pharmacotherapy to treat thyroid disease, assess efficacy, safety, LT$_4$ product received (eg, any recent changes in product), and patient adherence. Are there any significant drug interactions?
- If patient is not at desired TSH level and not on therapy, determine if pharmacotherapy is indicated.

Develop a Care Plan:

- Provide synthetic LT$_4$ replacement to patients with overt hypothyroidism.
- Consider replacement therapy in patients with TSH level of greater than 4.5 but less than 10 mIU/L (μIU/mL) who have nonspecific or subtle symptoms (eg, mild fatigue, lethargy), an elevated cholesterol level, underlying heart disease, or positive anti-TPOAbs.
- Patients with mild hypothyroidism may be started at 12.5 to 25 mcg/day of LT$_4$.
- Patients with overt hypothyroidism who are older than 12 and younger than 65 years and do not have cardiac disease may receive the calculated full replacement LT$_4$ dose of 1.6 mcg/kg/day (based on ideal body weight if obese).
- Elderly patients or those with cardiac disease should be started at a lower LT$_4$ dose (eg, 12.5–25 mcg/day).
- Provide a brand-name LT$_4$ product, and do not allow product switches. If the product is switched, check TSH in 6 weeks and retitrate the dose.
- Provide LT$_4$ prescriptions as microgram, not milligram, doses to avoid errors.
- Make sure patients understand importance of adherence and risks of overuse and underuse of LT$_4$.
- In pregnant patients, expect to increase LT$_4$ dose early in the first trimester. Maintain TSH in low- to middle-normal range. After delivery, reduce LT$_4$ dose to prepregnancy level, if appropriate.

Implement the Care Plan:

- Educate the patient about any changes in therapy and how to manage and report adverse effects.
- Review proper medication administration with the patient, including issues related to food and concomitant medications.
- Discuss the importance of adherence and risks of over- and undertreatment.
- Determine if the patient has insurance coverage for prescription medications.

Follow-up: Monitor and Evaluate:

- Measure serum TSH 6 to 8 weeks after starting LT$_4$ or after any dose change. If TSH level is not in target range, alter dose by 10% to 20% increments. Target TSH for patients on LT$_4$ replacement therapy for hypothyroidism is 0.5 to 2.5 mIU/L (μIU/mL). Younger patients often feel best at a TSH level in the low- to middle-normal range (ie, 0.5–1.5 mIU/L [μIU/mL]).
- Check TSH every 6 to 12 months in stable patients receiving LT$_4$ replacement.
- Monitor for drug interactions, such as LT$_4$ absorption problems caused by calcium and iron.
- At each visit, assess for signs and symptoms of over- and undertreatment.
- In pregnant patients, check TSH monthly.

Historically, glucocorticoids, such as hydrocortisone 50 to 100 mg every 6 hours, are administered owing to concern about simultaneous adrenal insufficiency. Although there is no strong evidence for an outcome benefit, the use of glucocorticoids is reasonable because such treatment may be lifesaving, and risks of a short course of corticosteroids at this dose are low. As patients improve, LT$_4$ dose can be given orally in a typical full replacement dose. Reduce the full replacement dose by 75% if continued IV therapy is needed.[17]

HYPERTHYROIDISM AND THYROTOXICOSIS

Hyperthyroidism, a subset of thyrotoxicosis, is much less common than hypothyroidism. Refer to the Epidemiology section.

Causes of Thyrotoxicosis and Hyperthyroidism

Thyrotoxicosis is any syndrome resulting from excess thyroid hormone. Hyperthyroidism is related to excess thyroid hormone production and secretion by the thyroid gland. Common causes of thyrotoxicosis are shown in Table 45–6.[33-35] **KEY CONCEPT** Graves disease is the most common cause of hyperthyroidism. Hyperthyroidism in the elderly is more likely caused by toxic thyroid nodules or multinodular goiter than by Graves disease. Excessive intake of thyroid hormone may be caused by overtreatment with prescribed therapy or as self-treatment for obesity, as thyroid hormones can be obtained easily without a prescription from health food stores or Internet sources. Ingestion of high doses of biotin may cause falsely elevated FT$_4$ levels and a false-positive

Table 45–6

Causes of Thyrotoxicosis[33-35]

Primary Hyperthyroidism
Graves disease
Toxic multinodular goiter
Toxic adenoma
Thyroid cancer
Struma ovarii
Iodine excess (including radiocontrast, amiodarone)

Thyrotoxicosis Without Hyperthyroidism
Subacute thyroiditis
Silent (painless) thyroiditis
Postpartum thyroiditis
Excess thyroid hormone intake (thyrotoxicosis factitia)
Drug-induced (amiodarone, iodine, lithium, interferons, tyrosine kinase inhibitors, immune checkpoint inhibitors)

Secondary Hyperthyroidism
TSH-secreting pituitary tumors
Trophoblastic (hCG-secreting) tumors
Gestational thyrotoxicosis

hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

TSHR-SAb assay with subsequent misdiagnosis of Graves disease.[33,35]

Clinical Manifestations of Thyrotoxicosis

Many of the signs and symptoms seem to be related to autonomic hyperactivity. Clinical manifestations of hyperthyroidism may be subtle and slowly progressive. Screening of patients for thyroid disease may identify patients with subclinical or mild thyrotoxicosis. Patients may seek medical attention only after a long period of thyrotoxicosis or owing to an acute complication such as atrial fibrillation. Clinical manifestations of thyrotoxicosis in the elderly may be blunted or atypical. These patients may present only with atrial fibrillation, depression, or altered mental status or cognition.

Mild (Subclinical) Hyperthyroidism

Mild (subclinical) hyperthyroidism is defined as a low TSH level with a normal FT_4 level.[33-36] Although there may be few or no symptoms in these patients, there are several areas of concern. Some patients progress to overt thyrotoxicosis, especially when TSH is fully suppressed.[36] Patients with subclinical hyperthyroidism have been shown to experience long-term cardiovascular and bone sequelae.[33,36,37] Mild hyperthyroidism appears to increase cardiovascular morbidity and mortality.[36] Prolonged subclinical thyrotoxicosis speeds the loss of bone mineral density and increases fracture rates in postmenopausal women.[33,36,37] Associations have been reported between subclinical hyperthyroidism and cognitive impairment or dementia.[36] Treatment of patients with mild hyperthyroidism is controversial but should be considered in patients with TSH levels less than 0.1 mIU/L (μIU/mL), Graves disease, postmenopausal women, and patients with underlying cardiovascular disease.[33,36,38] Patients who do not have fully suppressed (below the lower limit of detection) TSH or other risk factors for hyperthyroid complications (eg, osteoporosis, atrial fibrillation, and heart failure) may undergo observation, with TSH testing every 6 months to identify progression of the hyperthyroid state.

Graves Disease

Graves disease is an autoimmune syndrome that includes hyperthyroidism, diffuse thyroid enlargement, exophthalmos (abnormal protrusion of the eyeball) and other eye findings, and skin findings.[33-35] Prevalence of Graves disease in the United States is approximately 0.4% in women and 0.1% in men. Peak age of incidence is 20 to 49 years, with a second peak after 80 years of age. Hyperthyroidism results from the production of TSHR-SAbs in at least 80% of patients with clinical Graves disease. These antibodies have TSH agonist activity, thereby stimulating hormone synthesis and release. These antibodies cross-react with orbital and fibroblastic tissue, resulting in ophthalmopathy and dermopathy. Although the underlying cause of Graves disease is not known, heredity seems to play a role. Subclinical Graves disease may become acutely overt in the presence of iodine excess, infection, stress, parturition, smoking, and lithium and immune modulating therapy.

Clinical Presentation and Diagnosis of Hyperthyroidism[33-35]

Symptoms

- Nervousness
- Fatigue
- Weakness
- Increased perspiration
- Heat intolerance
- Tremor
- Hyperactivity, irritability
- Palpitations
- Appetite change (usually increased)
- Weight change (usually weight loss)
- Menstrual disturbances (often oligomenorrhea)
- Frequent bowel movements or diarrhea

Signs

- Hyperactivity
- Tachycardia
- Atrial fibrillation (especially in elderly adults)
- Hyperreflexia
- Warm, moist skin
- Ophthalmopathy, dermopathy (Graves disease)
- Goiter
- Muscle weakness

Screening/Diagnosis

- Low TSH level (< 0.5 mIU/L [μIU/mL]) signifies thyrotoxicosis.
- FT_4 is elevated in overt hyperthyroidism but may be normal in mild hyperthyroidism.
- Increased radioiodine uptake in the thyroid indicates increased hormone production by the thyroid gland.
- Almost all patients with Graves disease will have positive TSHR-SAbs and positive anti-TPOAbs.

Several features of Graves disease are distinct from other forms of thyrotoxicosis. Clinically apparent ophthalmopathic changes are seen in 20% to 40% of patients and include exophthalmos, proptosis, chemosis, conjunctival injection, and periorbital edema.[33,34,39] Eyelid retraction causes a typical staring or startled appearance (Figure 45–3). Patients may complain of vague eye discomfort and excess tearing. In severe cases, the eyelids are unable to close completely, resulting in corneal damage. In very severe cases, the optic nerve can be compressed, resulting in permanent vision loss. All patients with suspected or known Graves disease must be evaluated and monitored by an ophthalmologist. Treatment of the underlying hyperthyroid state often, but not always, improves the ophthalmopathy. Teprotumumab is a relatively new agent that blocks the insulin-like growth factor I receptor (IGF-IR) and has shown better outcomes in treating thyroid eye disease versus placebo.[40]

Dermopathy occurs in 5% to 10% of patients with Graves disease and usually is associated with severe ophthalmopathy. Skin findings include hyperpigmented, nonpitting induration of the skin, typically over the pretibial area (pretibial myxedema), dorsa of the feet, and shoulder areas. Clubbing of the digits (thyroid acropachy) is associated with long-standing thyrotoxicosis.

Treatment

▶ *Desired Outcomes*

Treatment of thyrotoxicosis caused by hyperthyroidism is similar regardless of the underlying cause.[33-35] **KEY CONCEPT** Goals of treating hyperthyroidism are to relieve signs and symptoms, reduce thyroid hormone production to normal levels and achieve biochemical euthyroidism, and prevent long-term adverse sequelae.

▶ *β-Blockers*

Because many manifestations of hyperthyroidism appear to be mediated by the β-adrenergic system, β-adrenergic blockers are used to rapidly relieve palpitations, tremor, anxiety, and heat intolerance. Because β-blockers do not reduce the synthesis of thyroid hormones, they are used only until more specific antithyroid therapy is effective. Because nonselective agents can impair the conversion of T_4 to T_3, propranolol and nadolol are preferred. An initial propranolol dose of 10 to 40 mg four times daily should be titrated to relieve signs (target resting heart rate less than 90 beats/min) and symptoms. β-Blockers should not be used in patients with decompensated heart failure or asthma. A more β-1 specific blocker (eg, metoprolol, atenolol) may be used when a relative contraindication to a β-blocker exists; however, when an absolute contraindication to β-blockers exists, clonidine, verapamil, or diltiazem may be used for heart rate control.

▶ *Methods to Reduce Thyroid Hormone Synthesis*

Excess production of thyroid hormone can be reduced in four ways: iodides, antithyroid drugs, radioactive iodine, and surgery.

Iodide Large doses of iodide inhibit the synthesis and release of thyroid hormones. Serum T_4 levels may be reduced within 24 hours, and the effects may last for 2 to 3 weeks. Iodides are most commonly used in Graves disease patients before surgery and to quickly reduce hormone release in patients with thyroid storm. Potassium iodide is administered either as a saturated solution (SSKI) that contains 38-mg iodide per drop or as Lugol solution, which contains 6.3-mg iodide per drop. In thyroid storm, the typical starting dose of SSKI is five drops every 6 to 8 hours. Iodide therapy should start 7 to 14 days before surgery. Iodide should

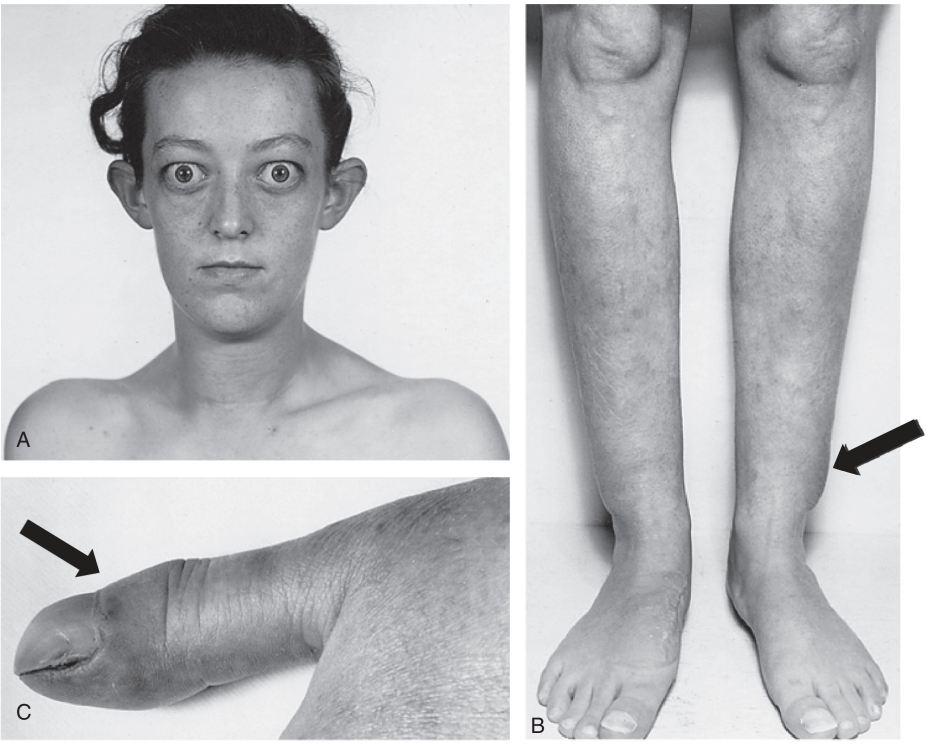

FIGURE 45–3. Features of Graves disease. (**A**) Facial appearance: exophthalmos, eyelid retraction, periorbital edema, and proptosis. (**B**) Thyroid dermopathy over lateral aspects of the shins (*arrow*). (**C**) Thyroid clubbing or acropachy (*arrow*). (From Jameson JL, Weetman AP. Disorders of the thyroid gland. In: Kasper DL, Braunwald E, Fauci AS, et al., eds. Harrison's Principles of Internal Medicine, 16th ed. New York, NY: McGraw-Hill; 2004:2114.)

not be given before radioactive iodine treatment because the iodide will inhibit concentration of the radioactivity in the thyroid. Iodides are also used to protect the thyroid from radioactive iodine fallout after a nuclear accident or attack. Administration of 30- to 100-mg iodide markedly reduces thyroid gland uptake of radioactive iodine. The most frequent toxic effects with iodide therapy are hypersensitivity reactions, "iodism" (characterized by palpitations, depression, weight loss, and pustular skin eruptions), and gynecomastia.

Antithyroid Drugs The thionamide agents propylthiouracil (PTU) and methimazole (MMI) are used in the United States to treat hyperthyroidism.[33,35,41] Carbimazole, an MMI prodrug, is used in some countries (10 mg carbimazole = 6 mg MMI). These drugs inhibit thyroid hormone synthesis by interfering with thyroid peroxidase–mediated iodination of tyrosine residues in thyroglobulin. PTU has the added effect of inhibiting conversion of T_4 to T_3. The thionamides also have immunosuppressant effects. In patients with Graves disease treated with thionamides, TSHR-SAb levels and other immune mediators decrease over time. Both drugs are well absorbed from the gastrointestinal (GI) tract. PTU has a half-life of one to 2.5 hours, whereas half-life of MMI is 6 to 9 hours.

Antithyroid drugs are used as primary therapy for Graves disease or as preparative therapy before surgery or radioactive iodine administration. The decision to use antithyroid drugs as primary therapy must be weighed against the risks and benefits of radioiodine or surgery. Patient preference must be considered.

In most patients, there is no clear efficacy advantage of one thionamide over the other, but in the United States, MMI use has increased dramatically since the mid-1990s in lieu of PTU.[42] Although PTU has the advantage of inhibiting T_4-to-T_3 conversion, MMI can be given as a single daily dose and may have a better overall safety profile, particularly less hepatotoxicity. MMI is preferred to normalize thyroid function before radioactive iodine therapy, although both thionamides increase the failure rate of radioactive iodine therapy.[43] Usual starting dose of MMI is 10 to 20 mg/day (range 5–40 mg based on initial FT_4 level), and usual starting dose of PTU is 50 to 150 mg three times daily. Thyroid hormone levels drop in 2 to 3 weeks, and after 6 weeks, 90% of patients with Graves disease will be euthyroid. Thyroid function testing should be performed every 4 to 6 weeks until stable. After the patient becomes euthyroid, antithyroid drug dose often can be decreased (5–10 mg/day MMI, 100–200 mg/day PTU) to maintain the euthyroid state. Excessive doses of antithyroid drugs will result in hypothyroidism.

Remission of Graves disease occurs in 40% to 60% of patients after 1 to 2 years of therapy. Antithyroid therapy may be stopped or tapered after 12 to 24 months. Relapse usually occurs in the first 3 to 6 months after stopping antithyroid therapy. Levels of TSHR-SAb after a course of treatment may have predictive value for risk of relapse in that antibody-positive patients almost always relapse. However, antibody-negative patients also may relapse after therapy is stopped. About 75% of women in remission who become pregnant will have a postpartum relapse. When therapy is discontinued, a therapeutic strategy should be in place in the event of relapse. Many patients will opt for radioactive iodine as a long-term solution.

Antithyroid drugs are associated with an overall low rate of adverse effects, although serious adverse effects can occur. Current recommendation for choice of antithyroid medication is to use MMI in most patients, while PTU should only be used in patients who cannot tolerate MMI or during first trimester of pregnancy. Skin rash, arthralgias, and GI upset are seen in 5% of patients, with cutaneous reactions somewhat more common with MMI.[35] Although these drugs can be continued in the presence of a minor skin rash, development of arthralgia warrants discontinuation. Hepatotoxicity is an uncommon but potentially serious or fatal adverse effect, occurring in 0.1% to 0.2% of patients, with severe hepatotoxicity more common with PTU.[33-35] Transient rises in aminotransferase enzyme levels are seen in up to 30% of patients treated with PTU. Antineutrophil cytoplasmic antibody (ANCA) vasculitis is another potentially serious but uncommon reaction that is more common with PTU, and patients may develop a drug-induced lupus syndrome.

KEY CONCEPT Agranulocytosis is one of the most serious adverse effects of antithyroid drug therapy. Agranulocytosis must be distinguished from a transient decrease in white blood cell count seen in up to 12% of adults and 25% of children with Graves disease. Agranulocytosis occurs in 0.3% of patients, and incidence may be the same with PTU and MMI therapy. Lower doses of MMI may be associated with a lower incidence.[33] Agranulocytosis, thought to be autoimmune, almost always occurs within the first 3 to 6 months of therapy and occurs suddenly and unpredictably. Patients will present with fever, malaise, and sore throat, and absolute neutrophil count will be less than 1000/mm^3 (1×10^9/L). Patients may develop sepsis and die rapidly. If agranulocytosis occurs, discontinue the antithyroid drug immediately, administer broad-spectrum antibiotics if the patient is febrile, and consider administration of filgrastim. The white blood cell count should recover in 1 or 2 weeks. Patients who develop agranulocytosis should not be switched to another thionamide drug. Monitoring for agranulocytosis is controversial owing to its sudden and unpredictable nature. Most do not recommend routine monitoring of the complete blood count (CBC), although early detection could improve patient outcomes. Patients initiating thionamide therapy must be informed about the signs and symptoms of agranulocytosis and other serious side effects. Patients should be counseled to report signs and symptoms suggestive of infection, such as fever and sore throat lasting more than 2 or 3 days, bruising, pruritic rash, jaundice, dark urine, arthralgias, abdominal pain, nausea, or fatigue.

Radioactive Iodine Radioactive iodine, typically ^{131}I, produces thyroid ablation without surgery. ^{131}I is well absorbed after oral administration. Iodine is concentrated in the thyroid gland and has a half-life of 8 days. Over a period of weeks, thyroid cells that have taken up ^{131}I begin to develop abnormalities and necrosis. Eventually, thyroid cells are destroyed, and hormone production is reduced. After a single dose, 40% to 70% of patients will be euthyroid in 6 to 8 weeks, and 80% will be cured. In most patients, hypothyroidism will develop, and long-term LT_4 replacement will be necessary. Because ^{131}I has a slow onset of action and may cause added release of thyroid hormone, most patients are treated initially with β-blockers and antithyroid drugs to prevent ^{131}I-induced thyroid storm. MMI is the preferred agent before administration of ^{131}I. MMI is discontinued 3 to 5 days before administration of ^{131}I and restarted 3 to 7 days later. MMI is then slowly tapered over the next 4 to 6 weeks as thyroid function normalizes. β-Blockers can be continued during ^{131}I therapy. Dose of ^{131}I is based on the estimated weight of the patient's thyroid gland (typical dose, 10–15 mCi [370–555 MBq]). Radioactive iodine therapy is contraindicated during pregnancy and breastfeeding. Radioactive iodine therapy may acutely worsen Graves ophthalmopathy. Patients with prominent eye disease may be started on prednisone 40 mg/day, with dose tapered over 2 to 3 months. Radioactive iodine also may cause a painful thyroiditis, which may necessitate anti-inflammatory therapy.

Patient Encounter 2, Part 1

A 19-year-old female comes to the clinic stating, "I'm having trouble sleeping. I might be getting a little manic." She first noticed these symptoms a few weeks ago, which have not improved despite the use of over-the-counter sleep aids. She also feels more anxious for no reason, though she says cannabidiol (CBD) helps. She may have lost a little weight, but she is not sure. Sometimes she can feel her heart beating in her chest when she exercises but denies chest pain, syncope, or palpitations at rest. Her medications include lamotrigine and quetiapine for bipolar disorder, a multivitamin product, occasional acetaminophen for headaches, and a hormonal contraceptive. She thinks her mother had some kind of thyroid problem when she was pregnant with her.

PE:

General appearance: Patient appears slightly anxious and responds appropriately to all questions.

Weight 56 kg (123 lb); was 57.5 kg (126.5 lb) at her last visit

VS: Pulse 92 beats/min, BP 108/73 mm Hg, RR 12 breaths/min, T 37°C (98.6°F)

Skin: Warm, moist, and soft

HEENT: Slightly and symmetrically enlarged thyroid, which is nontender and without appreciable nodules; mild exophthalmos

CV: Apical HR: 92/min, RRR

Exts: No tremor

Diagnostic studies

ECG: Slight sinus tachycardia

Labs: Electrolytes, CBC normal. TSH 0.15 mIU/L (µIU/mL; reference range 0.5–4.5 mIU/L [µIU/mL]); FT_4 2.2 ng/dL (28.3 pmol/L; reference range 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L); + TSHR-SAbs. Pregnancy test is negative.

Should this patient be treated for hyperthyroidism?

What therapeutic options exist for this patient's Graves disease?

What pharmacotherapy would you recommend? What if she were pregnant?

How would you initiate and titrate therapy?

What would you tell the patient regarding the cause of her signs and symptoms, significance of her abnormal thyroid function tests, and therapeutic options?

Patient Encounter 2, Part 2

Two years later, the patent is admitted to the hospital for altered mental status and to rule out acute psychosis and sepsis. For the past year, she had been working in Thailand as an English teacher. Due to the COVID-19 situation, she was unable to obtain her medications from home and was only taking a local herbal product. Her coworkers in Thailand noticed she was becoming increasingly fatigued, lethargic, and possibly delusional, saying that the Central Intelligence Agency and Thai police were watching her. Her family arranged for medical evacuation to the United States for further assessment and treatment.

PE:

Wt: 52 kg (114.4 lb)

General appearance: Patient appears sweaty and agitated.

VS: Pulse 146 beats/min, BP 92/66 mm Hg, RR 22 breaths/min, T 40°C (104°F), O_2 saturation 97% (0.97) on room air

Skin: Warm, sweaty, and soft

HEENT: Diffusely enlarged, nontender thyroid without any appreciable nodules; + exophthalmos

CV: Apical HR: 145 beats/min, RRR

Pulm: Clear to auscultation

Exts: + tremor; Reflexes: biceps, triceps, patellar, and Achilles: 3+/4

GI: Hyperactive bowel sounds

Mental status examination: Patient is only oriented to year and familiar persons. Cannot recall date, time, or location.

Diagnostic studies

COVID-19 PCR: neg

ECG: Sinus tachycardia with occasional premature atrial contractions

Labs: Electrolytes, CBC normal. TSH less than 0.1 mIU/L (µIU/mL; reference range 0.5–4.5 mIU/L [µIU/mL]); FT_4 9.4 ng/dL (121 pmol/L; reference range 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L); + TSHR-SAbs. Pregnancy test is negative.

Diagnoses:

1) Thyroid storm.

2) **Sepsis:** rule out communicable diseases endemic to Thailand such as malaria and dengue fever.

What are the signs and symptoms of thyroid storm?

How should this patient be treated?

No long-term carcinogenic effect of ^{131}I has been demonstrated in clinical trials.[33]

Surgery Subtotal thyroidectomy is indicated in patients with very large goiters and thyroid malignancies and those who do not respond or cannot tolerate other therapies. Patients must be euthyroid before surgery, and they are often administered iodide preoperatively to reduce gland vascularity. Overall surgical complication rate is 2.7%. Postoperative hypothyroidism occurs in 10% of patients who undergo subtotal thyroidectomy. After thyroidectomy, serum calcium and intact parathyroid hormone levels should be monitored for early identification of postoperative hypoparathyroidism. Postoperative administration of 1250 to 2500 mg/day of calcium and 0.5 mcg/day of calcitriol may be given and then tapered over 1 to 2 weeks if the patient does not develop hypoparathyroidism.[33]

▶ *Special Conditions and Populations*

Graves Disease and Pregnancy Pregnancy may worsen or precipitate thyrotoxicosis in women with underlying Graves disease owing to the TSH agonist effect of β-hCG.[30] Untreated maternal thyrotoxicosis may result in increased rates of miscarriage, premature delivery, eclampsia, and low-birth-weight infants. Fetal and neonatal hyperthyroidism may occur as a result of transplacental passage of TSHR-SAbs. Because radioactive iodine is contraindicated and surgery is best avoided during pregnancy, most patients are treated with antithyroid drugs. PTU is considered the treatment of choice, particularly in the first trimester. While MMI is thought to have greater teratogenic potential versus PTU, the relative safety of these medications in pregnancy is not clear.[44] Patients receiving prepregnancy MMI are switched to PTU as soon as the pregnancy is confirmed. The lowest possible dose of PTU to maintain maternal euthyroidism should be used. Given the potential maternal adverse effects of PTU (eg, hepatotoxicity), patients should be switched from PTU to MMI for the second and third trimesters.[30,35] Antithyroid therapy in excessive doses may suppress fetal thyroid function. Although PTU and MMI are found in breast milk, nursing mothers should be switched to MMI after delivery because of the risk of hepatotoxicity from PTU in the mother and infant.

Pediatric Hyperthyroidism β-Blockers are administered to children who are symptomatic or have a heart rate greater than 100 beats/min.[33] MMI is the preferred antithyroid drug therapy in children at a dose of 0.2 to 0.5 mg/kg/day (divided doses preferred by some clinicians).[33] Once a euthyroid state is achieved, MMI dose can be reduced by 50% or more to maintain euthyroidism. As in adults, antithyroid drugs are administered to children with Graves disease for 1 to 2 years. If remission does not occur in that time, long-term antithyroid drug therapy, radioactive iodine, or surgical therapy is offered. Long-term studies with ^{131}I use in children show no increased risk of thyroid cancer or leukemia.[32]

Thyroid Storm Thyroid storm is a life-threatening condition caused by severe thyrotoxicosis.[30,45] Signs and symptoms include high fever, tachycardia, tachypnea, dehydration, delirium, coma, and GI disturbances. Thyroid storm is precipitated in a previously

Patient Care Process: Hyperthyroidism

Collect Information:

- Perform a medication history or medication reconciliation for the use of all medications and supplements. Identify adverse drug events, allergies, and hypersensitivities.
- Review the medical history and physical assessment findings.
- Speak with the patient and other caregivers as appropriate to identify issues affecting medication access and other aspects of care.

Assess the Information:

- Identify the potential underlying cause via a constellation of symptoms and signs (eg, nervousness, palpitations, smooth symmetrical goiter; and the presence of eye and/or skin findings in a person with Graves disease).
- Substantiate assessment via a TSH and FT_4 and TSHR-SAbs, if appropriate. A low or undetectable TSH level identifies thyrotoxicosis.

Develop a Care Plan:

- Treat severe or troublesome autonomic signs and symptoms with a nonselective β-blocker such as propranolol 10 to 40 mg four times daily. Titrate β-blocker dose based on signs and symptoms.
- Consider reducing excess thyroid hormone production with an antithyroid drug and/or radioactive iodine. If radioactive iodine is given, make sure that antithyroid drugs are stopped 4 to 6 days before treatment.
- MMI is the antithyroid drug of choice in most patients.
- Refer patients with Graves disease to an ophthalmologist for assessment and monitoring.
- Treat pregnant hyperthyroid women with PTU in first trimester.
- Address any patient concerns regarding therapy.

Implement the Care Plan:

- Educate the patient about any changes in therapy and how to identify, manage, and report adverse effects.
- Review proper medication administration with the patient, including issues related to food and concomitant medications.
- Discuss the importance of adherence and risks of over- and undertreatment.
- Determine if the patient has insurance coverage for prescription medications.
- If patient has been or is currently receiving pharmacotherapy to treat hyperthyroidism, assess efficacy, safety, and patient adherence. Note if there are there any significant drug interactions.
- If patient is not at desired TSH level, determine if pharmacotherapy or a change in pharmacotherapy is indicated.

Follow-up: Monitor and Evaluate:

- Monitor patients on antithyroid drugs for signs and symptoms of adverse effects.
- After baseline CBC with differential and liver profile, repeat CBC when patient has a febrile illness and repeat liver panel if signs or symptoms of hepatotoxicity occur (some recommend routine monitoring during the first 6 months of therapy).
- Assess for any skin rash or development of arthralgias.
- Antithyroid drugs have a delayed effect. After 2 to 4 weeks of therapy, adjust dose if the TSH is not in target range (0.5–2.5 mIU/L [μIU/mL]). When the patient is euthyroid, consider reducing dose of antithyroid drug to avoid hypothyroidism.
- Complete a periodic assessment of TSHR-SAbs.
- Consider stopping antithyroid therapy in patients with Graves disease after 12 to 18 months to see if remission has occurred.
- Several months after radioactive iodine, expect the patient will require permanent LT_4 replacement and evaluate for such.

hyperthyroid patient by infection, trauma, surgery, radioactive iodine treatment, and sudden withdrawal from antithyroid drugs. Patients are treated with a short-acting β-blocker such as IV esmolol, IV or oral iodide, and large doses of PTU (500–1000 mg load; then 250 mg every 4 hours) or MMI (60–80 mg/day). Supportive care with acetaminophen to suppress fever, fluid and electrolyte management, and antiarrhythmic agents are important components of therapy. IV hydrocortisone 300 mg initially and then 100 mg every 8 hours is used often because of the potential presence of adrenal insufficiency.

NONTHYROIDAL ILLNESS (EUTHYROID SICK SYNDROME)

Several changes in the hypothalamic–pituitary–thyroid axis occur during acute illness, termed *nonthyroidal illness* or *euthyroid sick syndrome*.[17,46] Type and degree of abnormalities depend on the severity of illness. Mild-to-moderate medical illness, surgery, or starvation causes a decrease in serum T_3 levels owing to decreased peripheral conversion of T_4 to T_3. Reduced T_3 levels do not correlate with ultimate mortality and are thought to be an adaptive response to stress. Patients with more severe illness, especially those in the intensive care unit, frequently have reduced total T_4 levels, although FT_4 levels often are normal. In critically ill patients, there is a correlation between degree of serum T_4 reduction and mortality. In most acutely ill patients who are euthyroid, TSH level is normal. However, administration of dopamine, octreotide, or high doses of glucocorticoids can reduce TSH levels. During recovery from acute illness, TSH level may become modestly elevated to renormalize serum T_4 levels. During this time, thyroid function tests may be misinterpreted to indicate hypothyroidism. Despite the sometimes very low T_4 levels, there is no evidence that LT_4 administration has any survival benefit.[3,17,47] Patients with possible thyroid abnormalities during acute illness should be evaluated by an endocrinologist.

THYROID CANCER AND LT_4 SUPPRESSION

KEY CONCEPT Growth and dissemination of thyroid carcinoma are stimulated by TSH. As such, LT_4 is an integral component of thyroid carcinoma management as it suppresses TSH secretion. Early in therapy, patients may receive the lowest LT_4 dose sufficient to fully suppress TSH to undetectable levels. Controlled trials show that suppressive LT_4 therapy reduces tumor growth and improves survival.[48] These patients are purposefully "overtreated" with LT_4, sometimes to a fully suppressed TSH level, and rendered subclinically or mildly hyperthyroid. Postmenopausal women and other individuals at high risk for osteoporosis should receive aggressive osteoporosis therapy to prevent LT_4-induced bone loss. Other thyrotoxic complications, such as atrial fibrillation, should be monitored and managed appropriately.

DRUG-INDUCED THYROID ABNORMALITIES

Drugs can affect thyroid function in several ways.[3,12] The effects of drugs on thyroid hormone protein binding, LT_4 absorption, and metabolism have been discussed previously. Several commonly used medications can alter thyroid hormone secretion.

Amiodarone

Amiodarone is a commonly prescribed antiarrhythmic drug that contains two iodide atoms, constituting 38% of its mass.[49] Each 200 mg dose of amiodarone provides 75 mg of iodide. Amiodarone deiodination releases about 6 mg of free iodine daily, 20 to 40 times more than the average daily intake of iodine in the United States. Amiodarone blocks conversion of T_4 to T_3, inhibits entry of T_3 into cells, and decreases T_3 receptor binding. Amiodarone causes rapid reduction in serum T_3 levels, increases free and total T_4 levels, and increases TSH level. After 3 months of therapy, TSH levels usually return to normal, although serum T_3 and T_4 level changes may remain. Most of these patients are euthyroid because FT_3 levels are in the low-normal range.

Amiodarone can frequently cause thyroid abnormalities in previously euthyroid patients. In patients treated with amiodarone for persistent atrial fibrillation, 25% developed subclinical hypothyroidism and 5% developed overt hypothyroidism.[50] Hyperthyroidism occurred in 5%. Thyroid abnormalities, when they occurred, were seen within 6 months of initiation of amiodarone therapy in almost all patients. Amiodarone-induced hypothyroidism is more common in iodine-sufficient areas of the world. Patients with underlying autoimmune thyroiditis are much more likely to develop amiodarone-induced hypothyroidism. Amiodarone-induced hypothyroidism occurs most commonly within the first year of therapy. If amiodarone cannot be discontinued, LT_4 therapy will be effective in most patients. If amiodarone can be stopped, thyroid function will return to normal in 2 to 4 months.

Amiodarone is more likely to cause thyrotoxicosis in iodine-deficient areas. Type 1 amiodarone-induced thyrotoxicosis is caused by iodine excess and typically occurs in patients with preexisting multinodular goiter or subclinical Graves disease. Type 2 amiodarone-induced thyrotoxicosis is a destructive thyroiditis that occurs in patients with no underlying thyroid disease. Amiodarone-induced thyrotoxicosis is more common in men. Because amiodarone has β-blocking activity, palpitations and tachycardia may be absent. In type 1 thyrotoxicosis, amiodarone should be discontinued. If amiodarone therapy cannot be stopped, larger doses of antithyroid drugs may be needed to control thyrotoxicosis. In type 2 thyroiditis, stopping amiodarone may not be necessary because spontaneous resolution may occur. Prednisone 40 to 60 mg/day will quickly improve thyrotoxic symptoms. Prednisone may be tapered after 1 to 2 months of therapy.

KEY CONCEPT Patients receiving amiodarone must receive monitoring for thyroid abnormalities. Baseline measurements of serum TSH, FT_4, FT_3, anti-TPOAbs, and TSHR-SAbs should be performed. TSH, FT_4, and FT_3 should be checked 3 months after initiation of amiodarone and then TSH at least every 3 to 6 months.

Lithium

Lithium is associated with hypothyroidism in up to 34% of patients, and hypothyroidism may occur after years of therapy.[12,51] Lithium appears to inhibit thyroid hormone synthesis and secretion. Patients with underlying autoimmune thyroiditis are more likely to develop lithium-induced hypothyroidism. Patients may require LT_4 replacement even if lithium is discontinued.

Interferon-α

Interferon-α causes hypothyroidism in up to 39% of patients being treated for hepatitis C infection.[3,12] Patients may develop transient thyroiditis with hyperthyroidism before becoming hypothyroid, which may be transient as well. Asian patients and patients with preexisting anti-TPOAbs are more likely to develop interferon-induced hypothyroidism. The mechanism of interferon-induced hypothyroidism is not known. If LT_4 replacement is initiated, it should be stopped after 6 months to reevaluate need for replacement therapy.

Tyrosine Kinase and Immune Checkpoint Inhibitors

TKIs are targeted antineoplastic agents used in several types of malignancies, including thyroid cancer.[13] Several TKIs have significant effects on thyroid function, both in previously hypothyroid patients on LT_4 replacement and in previously euthyroid patients. Imatinib has been shown to cause a fourfold increase in TSH levels in patients being treated for thyroid cancer. Sunitinib and sorafenib have been associated with primary hypothyroidism in 20% to 40% of treated patients. Some sorafenib patients developed mild hyperthyroidism before becoming hypothyroid. Patients receiving TKI therapy should have baseline and periodic thyroid function monitoring.

A variety of immune checkpoint inhibitors are used as targeted anticancer therapy. These agents have different specific mechanisms of action and include ipilimumab, nivolumab, atezolizumab, avelumab, and durvalumab. These agents can cause both hypothyroidism and hyperthyroidism. Incidence of thyroid dysfunction varies among the specific agents and combinations but ranges from 3% to 6% for hypothyroidism and 1% to 4.5% for hyperthyroidism with nivolumab to over 10% for both conditions with combination nivolumab and ipilimumab therapy.[13]

OUTCOME EVALUATION

- Desired outcomes include relieving signs and symptoms and achieving a euthyroid state.
- Success of therapy for thyroid disorders must be based not only on short-term improvement of the patient's clinical status and abnormal laboratory values but also on achievement of a long-term, stable euthyroid state. Maintaining TSH level in the normal range improves symptoms and reduces risk of long-term complications.
- Because pharmacotherapy is often lifelong, especially in patients with hypothyroidism, patients must undergo periodic monitoring to avoid long-term complications. In hypothyroid patients, such monitoring may involve simply asking the patient about signs and symptoms and a yearly measurement of TSH level.
- Any change in the patient's clinical status, such as a new pregnancy or a major change in body weight, necessitates a reevaluation of therapy. Patients at high risk for complications, such as pregnant women, the elderly, and patients with underlying cardiac disease, must be monitored more closely.
- Patients should be educated and periodically reminded about the importance of adherence and long-term tight control, need for periodic clinical and laboratory monitoring, and importance of staying on one LT_4 product.
- In hyperthyroid patients, the method of achieving desired outcomes may change over time with the use of antithyroid drugs versus radioactive iodine.
- Patients who receive antithyroid drugs must be monitored for adverse drug events such as hepatotoxicity and agranulocytosis.
- Patients who receive radioactive iodine must be monitored for development of hypothyroidism.
- In patients with thyroid cancer, desired outcomes with LT_4 therapy are often different from those in hypothyroid patients. LT_4 doses sufficient to suppress tumor growth may result in a suppressed TSH and mild hyperthyroidism. These patients must be monitored closely for complications of the mild hyperthyroid state, such as bone mineral loss and development of atrial fibrillation.

Abbreviations Introduced in This Chapter

ANCA	Antineutrophil cytoplasmic antibody
ANDA	Abbreviated New Drug Application
Anti-TGAb	Antithyroglobulin antibody
Anti-TPOAb	Antithyroid peroxidase antibody
AUC	Area under the (time-concentration) curve
β-hCG	β-Human chorionic gonadotropin
BMI	Body mass index
CBC	Complete blood count
CBD	Cannabidiol
CNS	Central nervous system
FDA	Food and Drug Administration
FT_3	Free T_3
FT_4	Free T_4
GI	Gastrointestinal
hCG	Human chorionic gonadotropin
ICPI	Immune checkpoint inhibitor
IGF-IR	Insulin-like growth factor I receptor
IV	Intravenous
LDL	Low-density lipoprotein
LT_4	Levothyroxine
MMI	Methimazole
NHANES	National Health and Nutrition Examination Survey
NTI	Narrow therapeutic index
PTU	Propylthiouracil
RAIU	Radioactive iodine uptake
SSKI	Saturated solution of potassium iodide
T_3	Triiodothyronine
T_4	Thyroxine
TBG	Thyroid- or Thyroxine-binding globulin
TKI	Tyrosine kinase inhibitor
TRH	Thyrotropin-releasing hormone
TSH	Thyroid-stimulating hormone (thyrotropin)
TSHR-SAb	Thyroid-stimulating hormone receptor-stimulating antibodies
TSI	Thyroid-stimulating immunoglobulin

46 Adrenal Gland Disorders

Christina M. Polomoff, Devra K. Dang,
and Judy T. Chen

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the regulation and physiologic roles of hormones produced by the adrenal glands.
2. Recognize the clinical presentation of adrenal insufficiency.
3. Describe the pharmacologic management of acute and chronic adrenal insufficiency.
4. Recommend therapy monitoring parameters for adrenal insufficiency.
5. Recognize the clinical presentation of Cushing syndrome and the physiologic consequences of cortisol excess.
6. Describe the pharmacologic and nonpharmacologic management of Cushing syndrome.
7. Recommend strategies to prevent the development of hypercortisolism and hypocortisolism.
8. Recommend therapy monitoring parameters for Cushing syndrome.

INTRODUCTION

The adrenal glands are important in the synthesis and regulation of key human hormones. They play a crucial role in water and electrolyte homeostasis, as well as regulation of blood pressure, carbohydrate and fat metabolism, physiologic response to stress, and sexual development and differentiation. This chapter focuses on pharmacologic and nonpharmacologic management of the two most common conditions associated with adrenal gland dysfunction: glucocorticoid insufficiency (eg, Addison disease) and glucocorticoid excess (Cushing syndrome). Other adrenal disorders such as congenital adrenal hyperplasia, pheochromocytoma, hypoaldosteronism, and hyperaldosteronism are beyond the scope of this chapter.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY OF THE ADRENAL GLAND

The adrenal gland is located on the upper segment of the kidney. It consists of an outer cortex and an inner medulla. The adrenal medulla secretes the catecholamines, epinephrine (also called adrenaline) and norepinephrine (also called noradrenaline), which are involved in the regulation of the sympathetic nervous system. The adrenal cortex consists of three histologically distinct zones: the outer zona glomerulosa, the zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for the production of different hormones (Figure 46–1).

The zona glomerulosa is responsible for the production of the mineralocorticoids, aldosterone, 18-hydroxy-corticosterone, corticosterone, and deoxycorticosterone. Aldosterone promotes renal sodium retention and potassium excretion. Its synthesis and release are regulated by renin in response to decreased vascular volume and renal perfusion. Adrenal aldosterone production is regulated by the renin–angiotensin–aldosterone system.

The zona fasciculata is the middle layer and produces the glucocorticoid hormone, cortisol. Cortisol is responsible for maintaining homeostasis of carbohydrate, protein, and fat metabolism. Its secretion follows a circadian rhythm, generally beginning to rise at approximately 3 to 4 AM and peaking around 6 to 8 AM. Thereafter, cortisol levels decrease throughout the day, approach 50% of the peak value by 4 PM, and reach their nadir around midnight. The normal rate of cortisol production is approximately 8 to 25 mg/day. Cortisol plays a key role in the body's response to stress. Its production increases markedly during physiologic stress, such as during acute illness, surgery, or trauma. In addition, certain conditions such as alcoholism, depression, anxiety disorder, obsessive-compulsive disorder, poorly controlled diabetes, morbid obesity, starvation, anorexia nervosa, and chronic renal failure are associated with increased cortisol levels. High total cortisol levels are also observed in the presence of increased cortisol-binding globulin (the carrier protein for 80% of circulating cortisol molecules), which is seen in pregnancy or other high-estrogen states (eg, exogenous estrogen administration). Cortisol is converted in the liver to an inactive metabolite known as cortisone.[1]

The zona reticularis produces the androgens, androstenedione, dehydroepiandrosterone (DHEA), and the sulfated form of DHEA (DHEA-S). Only a small amount of testosterone and estrogen is produced in the adrenal glands. Androstenedione and DHEA are converted in the periphery, largely to testosterone and estrogen.

Adrenal hormone production is controlled by the hypothalamus and pituitary. Corticotropin-releasing hormone (CRH) is secreted by the hypothalamus and stimulates secretion of adrenocorticotropic hormone (ACTH; also known as corticotropin) from the anterior pituitary. ACTH in turn stimulates the adrenal cortex to produce cortisol. When sufficient or excessive cortisol levels are reached, negative feedback is exerted on the secretion of CRH and ACTH, thereby decreasing the overall cortisol production. The control of adrenal androgen synthesis also follows a similar negative feedback mechanism. Figure 47–1 in Chapter 47,

New York City, NY: McGraw-Hill, 2018.)

"Pituitary Gland Disorders," depicts hormonal regulation with the hypothalamic–pituitary–adrenal (HPA) axis.

ADRENAL INSUFFICIENCY

Epidemiology and Etiology

Adrenal insufficiency generally refers to the inability of the adrenal glands to produce adequate amounts of cortisol for normal physiologic functioning or in times of stress. The condition is usually classified as primary, secondary, or tertiary, depending on the etiology (Table 46–1).[1-5] The estimated prevalence of primary adrenal insufficiency and secondary adrenal insufficiency are approximately 60 to 143 and 150 to 280 cases per 1 million persons, respectively. Whereas primary adrenal insufficiency is usually diagnosed in the third to fifth decade of life, secondary adrenal insufficiency is commonly detected during the sixth decade.[1,6] Adrenal insufficiency is more prevalent in women than in men, with a ratio of 2.6:1.[1] Chronic adrenal insufficiency is rare.

Pathophysiology

Primary adrenal insufficiency, also known as Addison disease, occurs when the adrenal glands are unable to produce cortisol. It occurs from the destruction of the adrenal cortex, usually

Table 46–1

Etiologies of Adrenal Insufficiency[1-5]

Primary Adrenal Insufficiency (Addison Disease)

- Autoimmune—accounts for 70%–90% of all cases of primary adrenal insufficiency
- Infectious or granulomatous diseases
  - Cytomegalovirus
  - Fungal (histoplasmosis, coccidioidomycosis, cryptococcosis, *Blastomyces dermatitidis* infection)
  - HIV (human immunodeficiency virus), AIDS (acquired immunodeficiency syndrome)
    - Mycobacterial, cytomegaloviral, *Pneumocystis jiroveci*, and *Toxoplasma gondii* infection
  - Sarcoidosis
  - Tuberculosis
- Bilateral adrenal hemorrhage or infarction—usually due to anticoagulant therapy, coagulopathy, thromboembolic disease, or meningococcal infection. Causes acute adrenal insufficiency
- **Adrenalectomy**
- Adrenoleukodystrophy (in men)
- Adrenomyeloneuropathy
- Infiltrative disorders: amyloidosis, hemochromatosis
- Genetic causes
  - Congenital adrenal hyperplasia
  - Familial glucocorticoid deficiency and hypoplasia
- Metastatic malignancy

Secondary Adrenal Insufficiency

- Cushing syndrome
- **Panhypopituitarism**
- Pituitary tumor
- Transsphenoidal pituitary microsurgery
- Pituitary irradiation
- Traumatic brain injury

Tertiary Adrenal Insufficiency

- Hypothalamic dysfunction

Drug-Induced (Most Common Cause of Secondary and Tertiary Adrenal Insufficiency)

- Chronic glucocorticoid administration at supraphysiologic doses
- Steroidogenesis inhibitors
- Megestrol acetate—has glucocorticoid-like activity
- Mifepristone (RU 486)—antagonizes glucocorticoid receptors
- Tyrosine kinase inhibitors
- Inducers of cytochrome P450 enzymes that increase cortisol metabolism (2B1, 2B2, 3A4)

from an autoimmune process. In general, the clinical manifestations are observed when destruction of the cortex exceeds 90%.[4] **KEY CONCEPT** Signs and symptoms of adrenal insufficiency reflect the disturbance of normal physiologic carbohydrate, fat, and protein homeostasis caused by inadequate cortisol production and inadequate cortisol action. Primary adrenal insufficiency usually develops gradually. Patients may remain asymptomatic in the early stages with signs and symptoms present only during times of physiologic stress. Persistent signs and symptoms of hypocortisolism typically occur with disease progression. Additionally, primary adrenal insufficiency may be accompanied by a reduction in aldosterone and androgen production.

Secondary adrenal insufficiency occurs as a result of pituitary gland dysfunction, whereby decreased production and secretion of ACTH leads to a decrease in cortisol synthesis. Tertiary adrenal insufficiency is a disorder of the hypothalamus that results in decreased production and release of CRH, which in turn decreases pituitary ACTH production and release. In contrast to

Clinical Presentation and Diagnosis of Chronic Adrenal Insufficiency[1,3,4,6]

General

- Symptoms develop gradually, especially in the early stages, may be vague, and mimic other medical conditions.
- Patients with autoimmune adrenal insufficiency may have other autoimmune disorders such as type 1 diabetes mellitus or autoimmune thyroiditis.

Symptoms (Percent Prevalence)

- Weakness and fatigue (99%).
- Anorexia, nausea, and diarrhea (56%–90%); may range from mild to severe with vomiting and abdominal pain.
- Hypoglycemia may occur.
- Amenorrhea may occur.
- Salt craving occurs in approximately 22% with Addison disease due to aldosterone deficiency.

Signs

- Weight loss (97%).
- Hypotension (< 110/70 mm Hg) and orthostasis (87%).
- Dehydration, hypovolemia, and hyperkalemia (in primary adrenal insufficiency only) due to aldosterone deficiency.
- Hyponatremia and hypochloridemia levels due to aldosterone deficiency. Hyponatremia can also be present in secondary insufficiency due to cortisol deficiency and increased antidiuretic hormone secretion leading to subsequent water retention.
- Increased serum blood urea nitrogen (BUN) and creatinine due to dehydration.
- Hyperpigmentation of skin and mucous membranes (92%). Usually observed around creases, pressure areas, areolas, genitalia, and new scars. Dark freckles and patches of vitiligo may be present. Hyperpigmentation, due to increased ACTH levels, occurs in most patients with primary but not secondary or tertiary insufficiency.
- Personality changes (irritability and restlessness) due to cortisol deficiency.
- Loss of axillary and pubic hair in women due to decreased androgen production.
- Blood count abnormalities (normocytic, normochromic anemia, relative lymphocytosis, neutrophilia, eosinophilia) due to cortisol and androgen deficiency.

Laboratory Tests (Table 46–2[1,3,4,7])

- Decreased basal and stress-induced cortisol levels.
- Decreased aldosterone level (in primary insufficiency only).
- Lack of increase in cortisol and aldosterone level after ACTH stimulation.

Other Diagnostic Tests

- Computed tomography (CT) scan or magnetic resonance imaging (MRI) of the adrenal glands, pituitary, and/or hypothalamus can aid in determining etiology.
- The presence of antiadrenal antibodies is suggestive of an autoimmune etiology.

Table 46–2

Tests for Diagnosing Adrenal Insufficiency[1,3,4,7]

Test	Procedure	Rationale	Finding in Adrenal Insufficiency	Comments
Screening and Diagnostic Tests for Adrenal Insufficiency				
Unstimulated serum cortisol measurement	Measure serum cortisol at 6–8 AM	Serum cortisol level peaks in the early morning	Serum cortisol < 3 mcg/dL (83 nmol/L)	• Evaluate result in the context of those from other test(s) • Can be performed in conjunction with the rapid ACTH stimulation test (measure baseline serum cortisol before administering 250 mcg of cosyntropin)
Rapid ACTH stimulation test (also called **cosyntropin** stimulation test)	Measure serum cortisol 30–60 minutes after administering cosyntropin 250 mcg IM or IV	Increased cortisol secretion in normal individuals in response to ACTH stimulation but not in adrenal insufficiency	Serum cortisol concentration < 18–20 mcg/dL (497–552 nmol/L)	• Used as gold standard test for diagnosing primary adrenal insufficiency • False-negative results may occur if ACTH deficiency is of recent onset (< 1 month) • If measured serum cortisol concentration is low, measure plasma ACTH, aldosterone, and renin concentrations to differentiate between primary and secondary or tertiary adrenal insufficiency (see below) • A normal response does not exclude mild secondary adrenal insufficiency or recent onset ACTH deficiency. Additional testing (eg, insulin tolerance or metyrapone test) may be required
Insulin tolerance test (insulin-induced hypoglycemia test)	Administer insulin IV to induce hypoglycemia then measure serum cortisol during symptomatic hypoglycemia (confirm that blood glucose is < 40 mg/dL [2.2 mmol/L])	Evaluates ability of entire HPA axis to respond to stress (hypoglycemia)	Serum cortisol concentration < 18 mcg/dL (497 nmol/L) is indicative of secondary adrenal insufficiency	• If the result of the rapid ACTH stimulation test is normal, either this or the overnight metyrapone test is still needed to evaluate for secondary adrenal insufficiency. The insulin tolerance test is considered the gold standard • Contraindicated in patients with a seizure history, aged > 60 years, or cardiovascular or cerebrovascular disease • Requires close medical supervision • Contraindicated in adrenal crisis and primary adrenal insufficiency
Overnight metyrapone test	Administer metyrapone at midnight then measure serum cortisol at 8 AM the next day	Metyrapone inhibits cortisol synthesis. Its administration leads to rise in levels of ACTH and the precursor of cortisol, 11-deoxycortisol. Patients with adrenal insufficiency do not exhibit this	Normal response is a decrease in serum cortisol to < 5 mcg/dL (138 nmol/L) and an increase in 11-deoxycortisol to > 7 mcg/dL (202 nmol/L). Response not seen in secondary adrenal insufficiency	• Distinguishes between normal individuals and patients with secondary adrenal insufficiency • Contraindicated in adrenal crisis and primary adrenal insufficiency
Tests for Differential Diagnosis of Primary, Secondary, and Tertiary Adrenal Insufficiency				
Plasma ACTH concentration	Measure plasma ACTH	In primary adrenal insufficiency, hypocortisolism leads to elevated plasma ACTH concentration via positive HPA axis feedback	• Primary adrenal insufficiency: elevated plasma ACTH • Secondary or tertiary adrenal insufficiency: plasma ACTH low or inappropriately normal	• Evaluate result of test in combination with those from the plasma aldosterone and plasma renin tests

(Continued)

Table 46–2

Tests for Diagnosing Adrenal Insufficiency[1,3,4,7] (*Continued*)

Test	Procedure	Rationale	Finding in Adrenal Insufficiency	Comments
Plasma aldosterone concentration	Measure plasma aldosterone from the same blood samples as those used in ACTH stimulation test	Patients with primary adrenal insufficiency may experience a reduction in aldosterone production	• Primary adrenal insufficiency: low plasma aldosterone • Secondary or tertiary adrenal insufficiency: aldosterone concentration is usually normal (≥ 5 ng/dL [139 pmol/L])	• Evaluate result of test in combination with those from plasma ACTH and plasma renin tests
Plasma renin concentration or activity	Measure plasma renin concentration or activity	Mineralocorticoid deficiency occurs in primary adrenal insufficiency but is usually not present in secondary or tertiary adrenal insufficiency	• Primary adrenal insufficiency: elevated plasma renin • Secondary or tertiary adrenal insufficiency: plasma renin concentration or activity is usually normal	• Evaluate result of test in combination with those from plasma ACTH and plasma aldosterone concentration tests

ACTH, adrenocorticotropic hormone or corticotropin; HPA, hypothalamic–pituitary–adrenal; IM, intramuscularly; IV, intravenously.

Addison disease, aldosterone production is unaffected in the secondary and tertiary forms of the disease. Chronic adrenal insufficiency often has a good prognosis if diagnosed early and treated appropriately.

Acute adrenal insufficiency (ie, adrenal crisis) results from the body's inability to sufficiently increase endogenous cortisol during periods of excessive physiologic stress. Adrenal crisis can occur when patients with chronic adrenal insufficiency do not receive adequate glucocorticoid replacement during stressful conditions such as those experienced during surgery, infection, fever, acute illness, invasive medical procedures, or trauma. Acute adrenal insufficiency can also result from bilateral adrenal infarction due to hemorrhage, embolus, sepsis, or adrenal vein thrombosis. Patients who are critically ill may also experience impaired HPA axis function, with an overall prevalence rate of 10% to 20%, and as high as 60% in those experiencing septic shock. These patients are also at risk for the life-threatening consequences of an adrenal crisis. To better recognize this condition, the term *critical illness–related corticosteroid insufficiency* was coined by the American College of Critical Care Medicine Task Force in 2008.[8] Additionally, abrupt discontinuation or rapid tapering of glucocorticoids, given chronically in supraphysiologic doses, may lead to adrenal crisis. This condition results from prolonged suppression of the HPA axis and subsequent adrenal gland atrophy and hypocortisolemia. Other drugs associated with adrenal insufficiency include those that inhibit production (eg, ketoconazole) or increase metabolism (eg, the cytochrome P450 [CYP] 3A4 inducer rifampin) of cortisol.[4]

Clinical Presentation and Diagnosis of Acute Adrenal Insufficiency (Adrenal Crisis)[1,4,6]

General

- Onset of symptoms is acute and precipitated by excessive physiologic stress or abrupt discontinuation of supraphysiologic doses of chronic glucocorticoid.

Symptoms

- Severe weakness and fatigue.
- Abdominal or flank pain.

Signs

- Severe dehydration leading to hypotension and shock (circulatory collapse). Hypovolemia may not be responsive to intravenous (IV) hydration and may require use of vasopressors.
- Tachycardia.
- Nausea, vomiting.
- Fever.
- Confusion.
- Hypoglycemia.
- Laboratory abnormalities are similar to those observed in chronic adrenal insufficiency.

Laboratory Tests

- The unstimulated serum cortisol and rapid ACTH stimulation tests are useful in diagnosis (Table 46–2). The insulin tolerance test is contraindicated due to preexisting hypoglycemia. The metyrapone test is also contraindicated since metyrapone inhibits cortisol production.

Note: Due to the life-threatening nature of this condition, empiric treatment should be started before laboratory confirmation in patients who present with the clinical picture of acute adrenal crisis.

Regardless of the etiology, patients experiencing an adrenal crisis require immediate glucocorticoid treatment since manifestations such as circulatory collapse can lead to life-threatening sequelae.

Treatment

▶ *Chronic Adrenal Insufficiency*

The general goals of treatment are to manage symptoms and prevent development of adrenal crisis. KEY CONCEPT Lifelong glucocorticoid replacement therapy may be necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy is usually required for those with Addison disease. Glucocorticoids with sufficient mineralocorticoid activity are generally required. However, the addition of a potent mineralocorticoid such as fludrocortisone, along with adequate salt intake, is sometimes needed to prevent sodium loss, hyperkalemia, and intravascular volume depletion. Mineralocorticoid supplementation typically is not indicated for the treatment of secondary or tertiary adrenal insufficiency because aldosterone production is often unaffected. Moreover, patients with secondary or tertiary adrenal insufficiency may only require replacement therapy until the HPA axis recovers. Hydrocortisone is often prescribed because it most closely resembles endogenous cortisol with its relatively high mineralocorticoid activity and short half-life and allows the design of regimens that simulate the normal circadian cycle.[3] Other glucocorticoids, however, can be used. Table 46–3 lists the pharmacologic characteristics of commonly used glucocorticoids.[9] Because the primary source of DHEA and androgens is the adrenal cortex, women with adrenal insufficiency may experience decreased libido and energy. Therefore, DHEA supplementation has been advocated as an option for female patients experiencing these effects from adrenal insufficiency. However, a meta-analysis that included 23 randomized controlled trials found that DHEA supplementation was not associated with significant improvement in libido or sexual function.[10] The use of DHEA remains controversial and requires further study. Management strategies for chronic adrenal insufficiency are outlined below:[1-3,6,11,12]

- For the treatment of primary adrenal insufficiency (Addison disease) in adults, hydrocortisone (15–25 mg) or cortisone acetate (20–35 mg) in two or three divided oral doses per day is recommended, with the highest dose given in the morning at awakening to mimic the early morning rise in endogenous cortisol. In a two-dose regimen, the second dose is taken in the early afternoon (2 hours after lunch); and in a three-dose regimen, the second dose is taken at lunch and the third dose is taken no closer than 4 to 6 hours before bedtime. This will avoid insomnia and allow for the lowest concentration in the blood at around midnight. In patients with concerns about adherence, oral prednisolone 3 to 5 mg/day, administered once or twice daily, may be given. Dexamethasone, a long-acting glucocorticoid is not recommended due to the risk of Cushingoid side effects from difficulty in dose titration. Doses of the glucocorticoid replacement therapy may need to be increased or decreased in patients taking CYP 3A4 inducers or inhibitors, respectively. Glucocorticoid therapy at physiologic replacement doses should not lead to the development of Cushing syndrome; however, careful monitoring should still be performed, and the smallest effective dose is used. Patients should be educated regarding the need for increased glucocorticoid dosage during excessive physiologic stress. In addition, administer oral fludrocortisone at a starting daily dose of approximately 0.05 to 0.1 mg in the morning and monitor for resolution of postural hypotension, dizziness, salt craving, dehydration, hyponatremia, and hyperkalemia; increase the dose if needed. Conversely, consider decreasing the dose if adverse reactions from mineralocorticoid administration such as hypertension, hypokalemia, fluid retention, and other significant adverse events occur. In patients receiving hydrocortisone, it should be noted that this drug also possesses mineralocorticoid activity; and patients should be educated to avoid licorice

Table 46–3

Pharmacologic Characteristics of Major Corticosteroids[9]

Corticosteroid	Glucocorticoid (Anti-Inflammatory) Potency	Mineralocorticoid (Sodium-Retaining) Potency	Duration of Action[a]	Equivalent Dose (mg)[b]
Glucocorticoid				
Cortisol (hydrocortisone)	1	1	S	20
Cortisone	0.8	0.8	S	25
Prednisone	4	0.8	I	5
Prednisolone	4	0.8	I	5
Methylprednisolone	5	0.5	I	4
Triamcinolone	5	0	I	4
Betamethasone	25	0	L	0.75
Dexamethasone	25	0	L	0.75
Mineralocorticoid				
Fludrocortisone	10	125	I	c

[a] S, short (ie, 8–12 hour biological $t_{1/2}$); I, intermediate (ie, 12–36 hour biological $t_{1/2}$); L, long (ie, 36–72 hour biological $t_{1/2}$).

[b] These dose relationships apply only to oral or intravenous administration, as glucocorticoid potencies may differ greatly following intramuscular or intra-articular administration.

[c] This agent is used for its mineralocorticoid effects, not for glucocorticoid effects.

Adapted, with permission, from Shimmer BP, Funder JW. Adrenocorticotropic hormone, adrenal steroids, and the adrenal cortex. In: Brunton LL, Hilal-Dandan R, Knollmann BC, eds. Pharmacological Basis of Therapeutics, 13th ed. New York City, NY: McGraw-Hill; 2018: Table 46–3.

Patient Encounter 1, Part 1: Presentation and Medical History

A 38-year-old woman presents to the primary care clinic with complaints of weakness, dizziness, abdominal pain, and upset stomach that have gradually worsened over the last few months. In tracking her home blood pressure readings, she sees her systolic blood pressure has dropped to 95 to 100 mm Hg consistently. Her husband feels she has become more easily irritable.

PMH:

- Graves disease
- Asthma

FH: Father with hypertension and coronary artery disease

SH: Denies smoking and alcohol or illicit drug use

Current Meds:

- Methimazole 5 mg three times daily
- Fluticasone propionate HFA 88 mcg via oral inhalation twice daily
- Albuterol two oral inhalations (90 mcg/actuation) every 4 to 6 hours as needed for shortness of breath

PE:

VS: Sitting BP 100/71 mm Hg, P 68 beats/min, standing BP 94/60 mm Hg, RR 16 breaths/min, Wt 128 lb (58.1 kg) (8 lb [3.6 kg] loss in last 6 months), Ht 5′5″ (165 cm)

Skin: Hyperpigmentation increases in palms

CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops

Labs (fasting): Serum electrolytes: sodium 137 mEq/L (mmol/L), potassium 4.8 mEq/L (mmol/L), chloride 97 mEq/L (mmol/L), bicarb 29 mEq/L (mmol/L), BUN 24 mg/dL (8.6 mmol/L), serum creatinine 1.1 mg/dL (97 μmol/L), glucose 65 mg/dL (3.6 mmol/L)

Which signs or symptoms of adrenal insufficiency does the patient exhibit?

Does her presentation offer any clues as to etiology or classification of adrenal insufficiency?

Which tests would be most useful for determining etiology and confirming diagnosis of adrenal insufficiency?

and grapefruit juice as they can enhance hydrocortisone's mineralocorticoid effect. Patients taking concurrent phenytoin may need a higher dose of fludrocortisone as it can induce fludrocortisone's metabolism. All patients with Addison disease should also maintain adequate sodium intake. Lastly, although controversial (as indicated above), consider giving DHEA 25 to 50 mg/day (as a single oral dose in the morning) for a 6-month trial to premenopausal female patients who do not experience an improvement in mood and well-being even with adequate glucocorticoid and mineralocorticoid replacement. In these patients, monitor serum DHEA-S (aim for the middle range of normal levels in healthy young people).

- Patients with secondary and tertiary adrenal insufficiency are treated with oral hydrocortisone or another glucocorticoid as described for primary adrenal insufficiency. However, patients with secondary and tertiary adrenal insufficiency may require a lower dose. Some patients (eg, patients with drug-induced adrenal insufficiency or adrenal insufficiency following treatment for Cushing syndrome) will only require glucocorticoid replacement temporarily, which can be discontinued after the recovery of the HPA axis. Fludrocortisone therapy is generally not needed.

► *Acute Adrenal Insufficiency*

KEY CONCEPT During an acute adrenal crisis, the immediate treatment goals are to correct volume depletion, manage hypoglycemia, and provide glucocorticoid replacement. The 2016 Endocrine Society's Clinical Practice Guideline on the Diagnosis and Treatment of Primary Adrenal Insufficiency recommends that adults receive a rapid infusion of 1-L isotonic saline within the first hour or 5% glucose in isotonic saline, followed by continuous IV isotonic saline guided by individual patient needs.[12] For hypoglycemia, dextrose 0.5 to 1 g/kg or 2 to 4 mL/kg of D25W (maximum single dose 25 g) should be infused slowly. Glucocorticoid replacement can be accomplished by hydrocortisone 100 mg IV followed by hydrocortisone 200 mg/day as a continuous infusion for 24 hours, reduced to 100 mg/day the following day.[12] After achieving hemodynamic stability, hydrocortisone can be tapered to a lower maintenance dose by the fourth or fifth day and fludrocortisone can be added if needed. The dose can be increased from 200 to 400 mg/day if there are complications.[1] For the treatment of patients with critical illness-related corticosteroid insufficiency, see the 2017 consensus statements from the Society of Critical Care Medicine and the European Society of Intensive Care Medicine.[13]

KEY CONCEPT Patients with known adrenal insufficiency should be educated about the need for additional glucocorticoid replacement and prompt medical attention during periods of physiologic stress. Although the dosage of glucocorticoid is generally individualized, a common recommendation is to double the maintenance dose of hydrocortisone if the patient experiences fever or undergoes invasive dental or diagnostic procedures.[3] Patients who experience vomiting or diarrhea may not adequately absorb oral glucocorticoids and may benefit from parenteral therapy until symptoms resolve. Prior to surgery, additional glucocorticoid replacement (higher dose and parenteral route) must be given to prevent adrenal crisis. The dose and protocol vary depending on the type of surgery (eg, larger doses for major surgery compared to minor surgery).

Patient Encounter 1, Part 2: Treatment

After appropriate laboratory and diagnostic tests are performed, the patient is diagnosed with Addison disease.

How should her chronic primary adrenal insufficiency be treated?

What monitoring parameters (therapeutic and toxic) should be implemented?

Patient Care Process: Adrenal Insufficiency

Collect Information:

- Perform a medication history of prescription and nonprescription medications.
- Identify allergies.
- Review the medical history and physical assessment findings.
- Identify lifestyle habits, health goals, and socioeconomic factors that affect care.

Assess the Information:

- Evaluate for typical clinical manifestations of chronic or acute adrenal insufficiency.
- Determine if the patient has any etiologies of adrenal insufficiency.
- Assess results from the rapid ACTH stimulation test for the presence of adrenal insufficiency (Table 46–2).
- Assess follow-up tests that differentiate between primary, secondary, and tertiary adrenal insufficiency (Table 46–2).

Develop a Care Plan:

- Determine whether patient will require mineralocorticoid replacement therapy in addition to glucocorticoid supplementation.
- Determine if the patient not previously diagnosed with adrenal insufficiency is presenting with acute adrenal crisis, in which case immediate treatment with injectable hydrocortisone and IV saline and dextrose solutions should be initiated prior to the confirmation of diagnosis.
- Determine and correct the underlying cause of the acute adrenal crisis (eg, infection).
- Devise a strategy for patients with chronic adrenal insufficiency that includes supplemental doses of glucocorticoid when varying degrees of physiologic stress are experienced (eg, minor infection, pending surgery).
- Monitor patient for signs of an acute adrenal crisis and develop a plan to treat this emergency condition.

Implement the Care Plan:

- Educate patient and caregivers on causes of adrenal insufficiency, how to recognize clinical manifestations, and the need to notify all healthcare providers of condition.
- Inform patients how to prevent an acute adrenal crisis: adhere to therapy, do not abruptly stop glucocorticoid treatment and increase glucocorticoid dose during different severity levels of physiologic stress, including childbirth.
- Discuss when to self-administer parenteral glucocorticoid and seek emergency care.
- Suggest wearing or carrying a medical alert (eg, bracelet, card).
- Review dietary and pharmacologic therapy, including duration of treatment and potential adverse consequences of glucocorticoid and mineralocorticoid replacement.

Follow-up: Monitor and Evaluate:

- Monitor for adequacy of treatment and adverse reactions from glucocorticoid and/or mineralocorticoid therapy.
- Determine duration of treatment for patients with secondary and tertiary adrenal insufficiency.

Outcome Evaluation

- Monitor weight, blood pressure, and serum electrolytes, along with symptom resolution and general well-being, in patients with adrenal insufficiency treated with glucocorticoid therapy; adjust dosages accordingly as needed.
- Monitor for adverse drug reactions related to glucocorticoid administration.
- Monitor for the progression of the underlying etiology of adrenal insufficiency in patients with secondary or tertiary adrenal insufficiency.

HYPERCORTISOLISM (CUSHING SYNDROME)

Epidemiology and Etiology

Cushing syndrome refers to the pathophysiologic changes associated with exposure to supraphysiologic cortisol concentrations (endogenous hypercortisolism) or pharmacologic doses of glucocorticoids (exogenous hypercortisolism). Cushing syndrome from endogenous causes is a rare condition, with an estimated incidence of two to five cases per 1 million persons per year.[14] Patients receiving chronic supraphysiologic doses of glucocorticoids, such as those with rheumatologic disorders, are at high risk of developing Cushing syndrome.

Pathophysiology

Cushing syndrome can be classified as ACTH dependent or ACTH independent (Table 46–4).[1,15-17] ACTH-dependent Cushing syndrome results from ACTH-secreting (or rarely CRH-secreting) adenomas. The term *Cushing disease* refers specifically to Cushing syndrome from an ACTH-secreting pituitary adenoma. ACTH-independent Cushing syndrome is due to either excessive cortisol secretion by the adrenal glands (independent of ACTH stimulation) or exogenous glucocorticoid administration. The plasma ACTH concentration is elevated in ACTH-dependent conditions but not in ACTH-independent conditions because elevated cortisol concentrations suppress pituitary ACTH secretion via negative feedback. ACTH and cortisol concentrations are elevated episodically in ACTH-dependent disease due to random hypersecretion of ACTH.[4] In general, patients with Cushing syndrome due to endogenous or exogenous glucocorticoid excess present with similar clinical manifestations. However, patients with ectopic ACTH syndrome may not exhibit the typical signs and symptoms of hypercortisolism due to the acute onset nature of the underlying disease process.[1,9]

Cushing disease and adrenal carcinomas cause adrenal androgen hypersecretion in high enough concentrations to result in signs of androgen excess such as acne, menstrual irregularities, and hirsutism and also cause virilization in women.[4]

Drug-induced Cushing syndrome from glucocorticoid administration occurs most commonly in patients receiving oral therapy, but other routes such as inhalation, dermal, nasal, and intra-articular have also been implicated.[15] Over-the-counter products, including dietary supplements, should also be evaluated since they may contain corticosteroids. Drug-induced Cushing syndrome has been reported with the use of herbal products adulterated with corticosteroids.[18,19] Risk of glucocorticoid-induced Cushing syndrome appears to increase with higher doses and/or longer treatment durations.[15]

Left untreated, patients with Cushing syndrome may experience severe complications of hypercortisolism, resulting in up to a nearly fourfold increase in mortality.[20] Mortality in patients with Cushing is mostly attributed to cardiovascular disease. Hypertension, hyperglycemia, and hyperlipidemia are common findings and can be associated with cardiac hypertrophy, atherosclerosis, and hypercoagulability. Osteopenia, osteoporosis, and increased fractures also have been reported.[20] Prevention and management of these conditions are discussed elsewhere in this chapter. Children may experience linear growth retardation from reduced growth

Clinical Presentation and Diagnosis of Cushing Syndrome[1,14,15,21]

General

- Onset of signs and symptoms ranges from gradual to rapid, depending on etiology.
- Differential diagnoses include diabetes mellitus and the metabolic syndrome because these conditions share several similar characteristics with Cushing syndrome (eg, obesity, hypertension, hyperlipidemia, hyperglycemia, and insulin resistance). In women, the presentations of hirsutism, menstrual abnormalities, and insulin resistance are similar to those of polycystic ovary syndrome. Cushing syndrome can be differentiated from these conditions by identifying the classic signs and symptoms described below.
- True Cushing syndrome also must be distinguished from other conditions that share some clinical presentations (as well as elevated plasma cortisol concentrations) such as depression, anxiety disorder, obsessive-compulsive disorder, alcoholism, obesity, uncontrolled diabetes, eating disorders, and physiologic stress—the so-called pseudo-Cushing states.

Signs and Symptoms (Percent Prevalence)

General appearance

- Weight gain and obesity, manifesting as truncal obesity (90%)
- Rounded and puffy face ("moon facies") (75%)
- Dorsocervical ("buffalo hump") and supraclavicular fat accumulation
- Hirsutism (75%)

Skin changes from atrophy of dermis and connective tissue

- Thin skin
- Facial plethora (70%)
- Skin striae ("stretch marks" that are usually red or purple in appearance and greater than 1 cm) (50%)—not common in patients older than 40 years of age
- Acne (35%)
- Easy bruising (40%)
- Hyperpigmentation—typically with ectopic ACTH syndrome

Metabolic

- Hyperglycemia that can range from impaired glucose tolerance (75%) to diabetes mellitus (20%–50%)
- Hyperlipidemia (70%)
- Polyuria (30%)
- Kidney stones (15%–50%)
- Hypokalemic alkalosis (from mineralocorticoid effect of cortisol)

Cardiovascular

- Hypertension (from mineralocorticoid effect of cortisol) (85%)
- Peripheral edema

Genitourinary

- Menstrual irregularities (typically amenorrhea) (70%)
- Erectile dysfunction (85%)

Other

- Psychiatric changes such as depression, emotional lability, psychosis, euphoria, anxiety, and decreased cognition (85%)
- Sleep disturbances
- Osteopenia (80%) and osteoporosis—usually affecting trabecular bone
- Linear growth impairment in children
- Proximal muscle weakness (65%)
- Avascular necrosis (more common in iatrogenic cases)
- Glaucoma, cataracts
- Impaired wound healing and susceptibility to opportunistic infections
- Hypothyroidism

Laboratory Tests

- Diagnosis is often complex and generally requires the involvement of endocrinologists and specialized testing centers.
- Initial screening tests are listed in **Table 46–5**.[1,21] Typically, a combination of two screening tests is used to establish the preliminary diagnosis.
- After the diagnosis is confirmed, additional tests (eg, midnight serum cortisol or combined dexamethasone suppression plus CRH test) can be performed to determine the etiology or rule out false positive/negative results.

Other Diagnostic Tests

Imaging studies and inferior petrosal sinus sampling may be needed to distinguish between pituitary, ectopic, and adrenal tumors.

Table 46–4

Etiologies of Cushing Syndrome[1,15-17]

ACTH Dependent
- ACTH-secreting pituitary tumor (Cushing *disease*)—70% of endogenous cases
- ACTH-secreting nonpituitary tumors (ectopic ACTH syndrome)— 15% of endogenous cases; usually from small cell lung carcinoma and bronchial carcinoids; also from pheochromocytoma, or from thymus, pancreatic, ovarian, or thyroid tumor. The tumor is usually disseminated (difficult to localize)
- CRH-secreting nonpituitary tumors (ectopic CRH syndrome)—rare

ACTH Independent—15% of endogenous cases
- Unilateral adrenal adenoma
- Adrenal carcinoma
- Bilateral nodular adrenal hyperplasia—rare (< 1%)

Drug-Induced Cushing Syndrome (ACTH independent)—most common cause of Cushing syndrome
- Prescription glucocorticoid preparations (most routes of administration)
- Nonprescription and herbal products with glucocorticoid activity (eg, nonprescription anti-itch products with hydrocortisone, herbal products with magnolia bark or those claiming to contain adrenal cortex extracts, or other byproducts)
- Other drugs with glucocorticoid activity (eg, megestrol acetate, medroxyprogesterone)

ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone.

Table 46–5

First-Line Screening Tests in Patients with Characteristics of Cushing Syndrome[1,21]

Test	Test Procedure and Measurement	Rationale	Typical Finding in Cushing Syndrome	Comments
24-hour urinary free cortisol	Collect urine over 24 hours and measure unbound cortisol excreted by kidneys	Urinary cortisol is elevated in hypercortisolic states	Elevated urinary free cortisol (value depends on the assay used)	• Easy to perform but should not be used alone since sensitivity and specificity depend on assay used • To exclude periodic hypercortisolism, two or more samples should be obtained (with urinary creatinine measurement to assess completeness of collection) • Distinguishes the effects of Cushing syndrome (elevation) from obesity (no elevation). However, false positive in other pseudo-Cushing states, physiologic stress, if fluid intake ≥ 5 L/day, or taking carbamazepine or fenofibrate (if measured by HPLC) • False negative if moderate to severe renal function, or subclinical hypercortisolism
Overnight dexamethasone suppression test (DST)	Give 1 mg oral dexamethasone at 11 PM, then measure plasma cortisol at 8–9 AM the next morning	Dexamethasone administration suppresses morning plasma cortisol in normal individuals	Plasma cortisol < 1.8 mcg/dL (50 nmol/L) is not suggestive of Cushing syndrome	• Simple to perform and inexpensive • Can be used in conjunction with, or instead of, the urinary free cortisol test • False positive if pseudo-Cushing states, physiologic stress, pregnancy, estrogen treatment (including contraceptives), uremia, taking inducers of dexamethasone metabolism (phenytoin, alcohol, etc), or decreased dexamethasone absorption • False negative if subclinical hypercortisolism, slow metabolism of dexamethasone (eg, CYP3A4 inhibitors), or liver or renal impairment • In pseudo-Cushing states, the 48-hour 2-mg DST (administer 0.5 mg dexamethasone every 6 hours for 48 hours then measure serum cortisol at 8 or 9 AM after the last dose) is preferred
Late-night salivary cortisol	Collect salivary cortisol concentration at 11 PM	Loss of circadian rhythm of cortisol secretion (no nadir at night) in Cushing syndrome but not in pseudo-Cushing states	Elevated late-night salivary cortisol	• Easiest screening test to perform (sample can be collected at home by patient) • To exclude periodic hypercortisolism, two or more samples (on two separate evenings) should be obtained • False positive possible with cigarette smoking, chewing tobacco, licorice ingestion, in pseudo-Cushing states • Adjust collection time in shift workers and others with bedtime significantly after midnight

CYP, cytochrome P450; HPLC, high-performance liquid chromatography.

Patient Encounter 2

A 45-year-old man presents to a clinical pharmacist for asthma education. His medical history is significant for hypertension, hyperlipidemia, and asthma. He complains of insomnia, fatigue, and erectile dysfunction. Physical examination reveals an obese (BMI 39 kg/m^2) man with truncal obesity, dorsocervical fat, and facial plethora. His current medications include valsartan, atorvastatin, fluticasone/vilanterol inhaler, and albuterol inhaler. His fluticasone/vilanterol inhaler dose has increased over the last 2 years in the setting of asthma exacerbations. He has had several walk-in clinic visits this year for asthma exacerbations and was treated with a high-dose prednisone protocol each time. The clinical pharmacist suggests evaluation for possible Cushing syndrome.

Which findings are suggestive of Cushing syndrome?

Aside from Cushing syndrome, what are some major differential diagnoses for clinical presentation?

The patient is diagnosed with drug-induced Cushing syndrome after evaluation and diagnostic testing by the endocrinologist. What patient education points should be provided?

hormone secretion and inhibition of epiphysial cartilage development in long bones.[14,20]

Treatment

The goal of treatment in patients with Cushing syndrome is reversal of hypercortisolism and management of the associated comorbidities, including the potential for long-term sequelae such as cardiac hypertrophy. **KEY CONCEPT** Surgical resection is considered the treatment of choice for Cushing syndrome from endogenous causes if the tumor can be localized and if there are no contraindications. The treatment of choice for Cushing syndrome from exogenous causes is gradual discontinuation of the offending agent.

▶ *Nonpharmacologic Therapy*

Transsphenoidal pituitary microsurgery is the treatment of choice for Cushing disease. Removal of the pituitary tumor can bring about complete remission or cure in 78% to 97% of cases. HPA axis suppression associated with chronic hypercortisolism can result in prolonged adrenal insufficiency lasting for months after surgery and requiring exogenous glucocorticoid administration. Pituitary irradiation or bilateral adrenalectomy is usually reserved for patients who are not surgical candidates or for those who relapse or do not achieve complete remission following pituitary surgery. Because the response to pituitary irradiation can be delayed (several months to years), concomitant treatment with cortisol-lowering medication may be necessary. Bilateral adrenalectomy is also used for the management of adrenal carcinoma and in patients with poorly controlled ectopic Cushing disease in whom the ACTH-producing lesion cannot be localized. Bilateral laparoscopic adrenalectomy achieves an immediate and total remission (nearly 100% cure rate), but these patients will require lifelong glucocorticoid and mineralocorticoid supplementation.[5,22] Nelson syndrome may develop in nearly 20% to 50% of patients who undergo bilateral adrenalectomy without pituitary irradiation. This condition presumably results from persistent hypersecretion of ACTH by the intact pituitary adenoma, which continues to grow because of the loss of feedback inhibition by cortisol. Treatment of Nelson syndrome may involve pituitary irradiation or surgery.[4]

The treatment of choice in patients with adrenal adenomas is unilateral laparoscopic adrenalectomy. These patients require glucocorticoid supplementation during and after surgery due to atrophy of the contralateral adrenal gland and suppression of the HPA axis. Glucocorticoid therapy is continued until the recovery of the remaining adrenal gland is achieved. Patients with adrenal carcinomas have a poor prognosis, with a 5-year survival of 20% to 58%, because of the advanced nature of the condition (metastatic disease). Surgical resection to reduce tumor burden and size, pharmacologic therapy, or bilateral laparoscopic adrenalectomy are the treatment options commonly utilized to manage this condition.[1,5]

▶ *Pharmacologic Therapy*

KEY CONCEPT Pharmacotherapy is indicated when the ectopic ACTH-secreting tumor cannot be localized; to control hypercortisolism to prepare for surgery; in patients who (a) are not surgical candidates; (b) have failed surgery or had a relapse after surgery; or (c) have Cushing disease awaiting the onset of effect of pituitary radiation.[23] The drugs used are classified according to their mechanism and site of action (Table 46–6[22-30]). The most widely used therapeutic class is the adrenal steroidogenesis inhibitors, which can improve hypercortisolism by inhibiting enzymes involved in the biosynthesis of cortisol.[23] Because of their potential to cause adrenal suppression, temporary glucocorticoid replacement, and in some cases mineralocorticoid supplementation, may be needed during and after treatment.

KEY CONCEPT In drug-induced Cushing syndrome, discontinuation of the offending agent is the best management option. However, abrupt withdrawal of the glucocorticoid can result in adrenal insufficiency or exacerbation of the underlying disease.[15] **KEY CONCEPT** Glucocorticoid doses less than 7.5 mg/day of prednisone or its equivalent for less than 3 weeks generally would not be expected to lead to the suppression of the HPA axis.[5,25] However, in patients receiving pharmacologic doses of glucocorticoids for prolonged periods, gradual tapering to near physiologic levels (5–7.5 mg/day of prednisone or its equivalent) should precede drug discontinuation. Administration of a short-acting glucocorticoid in the morning and use of alternate-day dosing may reduce the risk of adrenal suppression. Testing of the HPA axis may be useful in assessing adrenal reserve. In some cases, supplemental glucocorticoid administration during excessive physiologic stress may be needed for up to 1 year after glucocorticoid discontinuation.[15] Table 46–7 lists strategies to prevent the development of hypercortisolism and hypocortisolism.

Outcome Evaluation

- Monitor patients receiving surgical, medical, or radiation therapy for the resolution of the clinical manifestations of hypercortisolism. Symptoms often improve immediately after surgery and soon after initiation of drug therapy. However, it may take months for symptoms to resolve following radiation therapy.
- Monitor for normalization of serum cortisol concentrations.
- Patient Care Process discusses additional evaluation strategies.

Table 46–6

Pharmacologic Treatments for Cushing Syndrome[22-30]

Drug	Mechanism of Action	Dosage[a]: Initial, Usual, Maximum, Dosing Adjustment for Renal and/or Hepatic Failure	Common and/or Major Adverse Reactions	Comment
Inhibitors of Adrenal Steroidogenesis				
Ketoconazole[b] (oral administration)	Inhibits several CYP enzymes, including 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase. Also inhibits cholesterol synthesis	*Adults*: 400–1600 mg/day; every 6–8 hour dosing Extensively metabolized by liver and dosing adjustment should be considered in severe liver disease. Dosing adjustment not needed in renal disease	Generally well-tolerated. Symptoms of adrenal insufficiency (eg, nausea, vomiting, decreased appetite, fatigue) Gynecomastia, decreased libido, and impotence (due to inhibition of testosterone synthesis). Hepatotoxicity	• Effective in a majority of causes; rapid clinical improvement seen • Monitor efficacy with urinary cortisol • Monitor liver transaminases for hepatotoxicity • Useful in women with hirsutism and patients with hyperlipidemia • Requires gastric acidicity for dissolution and absorption, therefore not useful in patients with achlorhydria and those taking proton pump inhibitors or round-the-clock antacids or histamine-2 receptor blockers • Is a CYP3A4 substrate and a strong CYP3A4 inhibitor. Also has other CYP interaction potential. Coadministration with certain medications can lead to QT prolongation and dysrhythmia
Metyrapone[b] (oral administration)	Inhibits 11β-hydroxylase. Also suppresses aldosterone synthesis	*Adults*: 500 mg/day to 6 g/day; every 6–8 hour dosing Dosages in special populations (liver and kidney disease, elderly patients) have not been established	Generally well-tolerated Hirsutism, acne, adrenal insufficiency, GI intolerance, rash, hypokalemia, edema, hypertension	• Used in Cushing disease, ectopic ACTH syndrome, and adrenal carcinoma • Also used as a test to diagnose adrenal insufficiency
Osilodrostat (oral administration)	Inhibits 11β-hydroxylase	*Adults*: Starting dose: 2 mg twice daily. Maximum 30 mg twice daily	Generally well-tolerated. Symptoms of adrenal insufficiency (eg, nausea, vomiting, headache, fatigue, edema)	• FDA-approved in 2020 for adults with Cushing disease for whom pituitary surgery is not an option or has not been curative • Hypocortisolism-related adverse events occurred mainly during dose titration and were considered manageable • There are a number of ongoing clinical trials that will include evaluating long-term effects • Substrate of CYP3A4, CYP2B6, CYP2D6, and UDP-glucuronosyltransferases • Inhibitor of CYP1A2, CYP2C19, CYP2D6, and CYP3A4/5
Etomidate[b] (intravenous infusion administration)	Inhibits 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase	*Adults*: Bolus and adjust dose based on serum cortisol level (typically a loading dose of 3–5 mg followed by 0.01–0.1 mg/kg/hour) Extensively metabolized in the liver to inactive metabolites. Because of changes in protein binding, dosing adjustment may be needed in kidney and liver disease	Injection site pain, nausea, vomiting, myoclonus, hypotension	• Is a general anesthetic and requires careful monitoring in an intensive care unit • Generally reserved for patients with more severe symptoms and in emergency settings

Adrenolytic Agent				
Mitotane (oral administration)	Inhibits steroidogenesis at lower doses and is adrenolytic at higher doses. Inhibits 11β-hydroxylase and cholesterol side-chain cleavage. Reduces aldosterone synthesis	*Adults*: Starting dose: 250 mg; 500 mg/day to 8 g/day. Elderly patients may require a dose decrease Primarily metabolized by the liver and dosing adjustment may be needed in liver disease	GI intolerance (high incidence), fatigue, dizziness, somnolence, gynecomastia Hyperlipidemia requiring lipid-lowering treatment Adrenal insufficiency requiring glucocorticoid replacement therapy	• FDA-approved for treatment of inoperable adrenal cortical carcinoma. Can be used in other types of Cushing syndrome • Efficacy takes several weeks • Lower rate of relapse when used with pituitary radiation. Also enables lower doses and therefore lower rate of adverse reactions • Hypocortisolism (if occurs) may persist several weeks/months after discontinuation as drug is stored in fatty tissues • Strong inducer of CYP3A4
Peripheral Glucocorticoid Antagonist				
Mifepristone (RU 486) (oral administration)	Antagonizes glucocorticoid receptors	*Adults*: 300–1200 mg/day Maximum 300 mg/day with concomitant strong CYP450 inhibitors Do not exceed 600 mg/day in renal impairment or mild-to-moderate hepatic impairment. Do not use in severe hepatic impairment	Nausea, fatigue, headache, hypokalemia, arthralgia, vomiting, peripheral edema, hypertension, dizziness, decreased appetite, endometrial hypertrophy, prolonged QT interval. Has abortifacient and embryotoxic properties	• FDA-approved for control of hyperglycemia secondary to hypercortisolism in adult patients with endogenous Cushing syndrome who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or are not candidates for surgery • Increases cortisol and ACTH levels via antagonism of negative feedback of ACTH secretion • Requires cautious use since limited clinical experiences and cannot use cortisol or ACTH levels to monitor efficacy of treatment • Quicker effectiveness compared to other drug treatment options • Is a CYP3A4 substrate. Also inhibits CYP3A and has other CYP interaction potential
Somatostatin Analog				
Pasireotide (subcutaneous injection)	Binds to somatostatin receptor subtype 5 overexpressed in corticotroph tumor cells resulting in the inhibition of ACTH secretion	*Adults*: 0.6–0.9 mg twice daily Moderate hepatic impairment (Child Pugh B): initial 0.3 mg twice a day, maximum 0.6 mg twice a day. Avoid in severe hepatic impairment (Child Pugh C). No dosage adjustment needed in renal impairment	Hyperglycemia, GI pain, nausea, diarrhea, headache, fatigue, bradycardia, QT prolongation, liver test elevations, cholelithiasis, pituitary hormone (other than ACTH) inhibition	• FDA-approved for treatment of adult patients with Cushing disease for whom pituitary surgery is not an option or has not been curative • Measure response based on 24-hour urinary free cortisol level and/or improvement in signs and symptoms

[a] Dosing guidelines (including age ranges) and safety for children have not been definitively established.

[b] These medications do not have FDA-approved indications for the treatment of Cushing syndrome in either adults or children.

ACTH, adrenocorticotropic hormone or corticotropin; CYP, cytochrome P450; FDA, Food and Drug Administration; GI, gastrointestinal.

Table 46–7

Principles of Glucocorticoid Administration to Avoid Hypercortisolism or Hypocortisolism

To Prevent Hypercortisolism and Development of Cushing Syndrome

- Give the lowest glucocorticoid dose that will manage the disease being treated and for the shortest possible duration
- If feasible, give glucocorticoid via administration routes that minimize systemic absorption (such as inhalation or dermal)
- If feasible, administer glucocorticoid treatment every other day (calculate the total 48-hour dose and give as a single dose of intermediate-acting glucocorticoid in the morning)[4]
- Avoid concurrent administration of drugs that can inhibit glucocorticoid metabolism

To Prevent Hypocortisolism and Development of Adrenal Insufficiency or Adrenal Crisis

- If the patient requires discontinuation from chronic treatment with supraphysiologic doses of glucocorticoid, the following discontinuation protocol can be used:[4]
  - Gradually taper the dose to approximately 20 mg of prednisone or equivalent per day, given in the morning, and then
  - Change glucocorticoid to every other day administration, in the morning
  - Stop the glucocorticoid when the equivalent physiologic dose is reached (20 mg/day of hydrocortisone or 5–7.5 mg/day of prednisone or equivalent)
  - Understand that recovery of the HPA axis may take up to a year after glucocorticoid discontinuation during which the patient may require supplementation therapy during periods of physiologic stress
- Evaluate patients at risk for adrenal insufficiency as a result of treatment(s) of Cushing syndrome and initiate glucocorticoid and mineralocorticoid replacement therapy as appropriate
- Avoid concurrent administration of drugs that can induce glucocorticoid metabolism
- Educate patients about:
  - The need for replacement or supplemental glucocorticoid and mineralocorticoid therapy
  - How to administer parenteral glucocorticoid if unable to immediately access medical care during an emergency
  - Need to wear or carry medical identification regarding their condition (eg, card, bracelet)

HPA, hypothalamic–pituitary–adrenal.

Patient Care Process: Cushing Syndrome

Collect Information:

- Perform a medication history of prescription and nonprescription medications.
- Identify allergies.
- Review the medical history and physical assessment findings.
- Identify lifestyle habits, health goals, and socioeconomic factors that affect care.

Assess the Information:

- Determine whether the patient is taking any glucocorticoids (from prescription or herbal/dietary supplement sources) that may have induced Cushing syndrome.
- Review relevant lab tests (eg, 24-hour urinary free cortisol, overnight dexamethasone suppression test [DST], late-night salivary cortisol).
- Establish diagnosis and etiology based on diagnostic testing.

Develop a Care Plan:

- Evaluate patient for appropriateness of surgery, radiation, and/or pharmacologic therapy depending on etiology.
- If etiology is exogenous administration of glucocorticoid, attempt taper.
- If etiology is endogenous, determine if patient is an appropriate candidate for surgical resection of the tumor or has contraindications to surgical resection such as advanced disease (metastatic adrenal carcinoma).
- Assess response and complications associated with surgery including[22]:
  - Measuring plasma cortisol postsurgery to determine if the patient displays persistent hypercortisolism (surgical-treatment failure) or hypocortisolism (adrenal insufficiency requiring steroid replacement therapy).
  - In patients demonstrating hypocortisolism:
    i. Monitor for signs and symptoms of glucocorticoid withdrawal (headache, fatigue, malaise, myalgia).
    ii. Monitor for signs and symptoms of adrenal insufficiency and develop a treatment plan.
    iii. Monitor morning cortisol or response to ACTH stimulation every 3 to 6 months to assess for HPA axis recovery. Discontinue glucocorticoid replacement therapy when cortisol concentrations are greater than 19 mcg/dL (524 nmol/L) on either test.
    iv. Monitor cortisol, ACTH, low-dose dexamethasone suppression, or other tests to assess for risk of relapse of hypercortisolism.
- If surgical resection does not achieve satisfactory disease control or is not indicated, evaluate the patient for pituitary radiation or bilateral adrenalectomy with concomitant pituitary radiation.
- Evaluate patients with adrenal adenomas for unilateral adrenalectomy.

(Continued)

Patient Care Process: Cushing Syndrome (*Continued*)

- Give glucocorticoid and mineralocorticoid replacement (permanently in the case of bilateral adrenalectomy).

Implement the Care Plan:

- Educate patient and caregivers on causes and possible sequelae of Cushing syndrome, how to recognize clinical manifestations, and the need to notify all healthcare providers of condition.
- Inform patients on how to reduce modifiable cardiovascular and metabolic complications.
- Review advantages and disadvantages of treatment options, including possible adverse consequences.
- Highlight the importance of adherence to therapy.
- Discuss the need for glucocorticoid and mineralocorticoid replacement after treatment, if appropriate.

Follow-up: Monitor and Evaluate:

- Monitor for response to therapy, need for dose adjustments, and the presence of adverse drug reactions.
- Once disease control is achieved, continue to monitor biochemical markers and patient for development of complications of Cushing syndrome, as relapse may occur.
- Monitor patients treated with surgery or pituitary radiation for development of pituitary hormone deficiency.

Abbreviations Introduced in This Chapter

ACTH	Adrenocorticotropic hormone or corticotropin
AIDS	Acquired immunodeficiency syndrome
BUN	Blood urea nitrogen
CRH	Corticotropin-releasing hormone
CT	Computed tomography
CYP	Cytochrome P450
DHEA	Dehydroepiandrosterone
DHEA-S	Sulfated form of dehydroepiandrosterone
DST	Dexamethasone suppression test
FDA	Food and Drug Administration
GI	Gastrointestinal
HIV	Human immunodeficiency virus
HPA	Hypothalamic–pituitary–adrenal
HPLC	High-performance liquid chromatography
IM	Intramuscular
IV	Intravenous or intravenously
MRI	Magnetic resonance imaging

Pituitary Gland Disorders

Christina M. Polomoff, Devra K. Dang,
and Judy T. Chen

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the mediators and primary effects of pituitary hormones.
2. Identify clinical features of patients with acromegaly.
3. Discuss the role of surgery and radiation therapy for patients with acromegaly.
4. Select appropriate pharmacotherapy for patients with acromegaly based on patient-specific factors.
5. Identify clinical features of children and adults with growth hormone (GH) deficiency and select appropriate pharmacotherapy for these patients.
6. Recommend monitoring parameters necessary to assess therapeutic outcomes and adverse effects in patients receiving GH therapy.
7. List common etiologies of hyperprolactinemia.
8. Identify clinical features of patients with hyperprolactinemia.
9. Select appropriate pharmacologic and nonpharmacologic treatments for patients with hyperprolactinemia based on patient-specific factors.

PHYSIOLOGY OF THE PITUITARY GLAND

The pituitary, referred to as the "master gland," is a small endocrine gland located at the base of the brain and is responsible for the regulation of many other endocrine glands and body systems. Growth, development, metabolism, reproduction, and stress homeostasis are among the functions influenced by the pituitary. Functionally, the gland consists of two distinct sections: the anterior pituitary lobe and the posterior pituitary lobe. The pituitary receives neural and hormonal input from the inferior hypothalamus via blood vessels and neurons.

The posterior pituitary is innervated by nervous stimulation from the hypothalamus, resulting in the release of specific hormones to exert direct tissue effects. The hypothalamus synthesizes two hormones, oxytocin and vasopressin. These hormones are stored and released from the posterior pituitary lobe. The anterior pituitary lobe is under the control of several releasing and inhibiting hormones secreted from the hypothalamus via a portal vein system. It synthesizes and secretes six major hormones. Figure 47–1 summarizes the physiologic mediators and effects of each of these hormones.

Hormonal Feedback Regulatory Systems

The hypothalamus is responsible for the synthesis and release of hormones that regulate the pituitary gland. Stimulation or inhibition of the pituitary hormones elicits a specific cascade of responses in peripheral target glands. In response, these glands secrete hormones that exert negative feedback on other hormones in the hypothalamic–pituitary axis (see Figure 47–1). This negative feedback serves to maintain body system homeostasis. In general, high circulating hormone concentrations inhibit the release of hypothalamic and anterior pituitary hormones.

Damage and destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, growth hormone (GH) deficiency, hypoprolactinemia, or panhypopituitarism. A tumor (adenoma) located in the pituitary gland may result in excess secretion of a hormone or may physically compress the gland and suppress adequate hormone release. The type, location, and size of a pituitary tumor often determine a patient's clinical presentation. This chapter discusses the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, GH deficiency, and hyperprolactinemia. The following hormones are discussed elsewhere in this textbook: adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), antidiuretic hormone (or vasopressin; ADH), and oxytocin.

GROWTH HORMONE (SOMATOTROPIN)

Somatotropin or GH, the most abundant hormone produced by the anterior pituitary lobe, is regulated primarily by the hypothalamic–pituitary axis. The hypothalamus releases GH–releasing hormone (GHRH) to stimulate GH synthesis and secretion, whereas somatostatin inhibits it.[1] Release of GH into the circulation stimulates the liver and other peripheral target tissues to produce insulin-like growth factors (IGFs). These IGFs are the peripheral GH targets. There are two types of IGFs, IGF-I and IGF-II. IGF-I is responsible for growth of bone and other tissues, whereas IGF-II is primarily responsible for regulating fetal growth. High concentrations of IGF-I inhibit GH secretion through somatostatin, thereby inhibiting GHRH secretion at the hypothalamus.[1] The hypothalamus also may stimulate the release of somatostatin to inhibit GH secretion. The effects of IGF-I in peripheral tissues are both GH dependent and GH independent.[2]

FIGURE 47–1. Hypothalamic–pituitary–target-organ axis. The hypothalamic hormones regulate the biosynthesis and release of eight pituitary hormones. Stimulation of each of these pituitary hormones produces and releases trophic hormones from their associated target organs to exert their principal effects. These trophic hormones regulate the activity of endocrine glands. Subsequently, increased serum concentration of the trophic hormones released from the target organs can inhibit both the hypothalamus and the anterior pituitary gland to maintain homeostasis (negative feedback). Inhibin is produced by the testes in men and the ovaries in women during pregnancy. Inhibin directly inhibits pituitary production of follicle-stimulating hormone (FSH) through a negative feedback mechanism. Melanocyte-stimulating hormone (MSH) produced by the anterior pituitary is not illustrated in the figure. (–), inhibit; (+), stimulate. GH is an anabolic hormone with direct "anti-insulin" metabolic effects. By stimulating protein synthesis and shifting the body's energy source from carbohydrates to fats, GH promotes a diabetic state (Table 47–1).[2] GH controls somatic growth and has a critical role in the development of normal skeletal muscle, myocardial muscle, and bone.

Table 47–1

Effects of Growth Hormone[2]

	Effect(s)
Lipid metabolism	Increases breakdown of fat (lipolysis) Increases circulating fatty acid concentrations Increases lean body mass
Protein metabolism	Increases muscle mass
Carbohydrate metabolism	Decreases glucose utilization Increases insulin resistance Hyperglycemia Increases hepatic glucose output

In healthy individuals, GH is secreted in a pulsatile manner with several short bursts occurring mostly during the night. The amount of GH secretion fluctuates throughout a person's lifetime. Secretion of GH is the lowest during infancy, increases during childhood, peaks during adolescence, and then declines gradually during the middle years.[1] These changes are parallel to an age-related decline in lean muscle mass and bone mineral density.

Growth Hormone Excess

▸ *Epidemiology and Etiology*

Acromegaly affects both genders equally, and the average age of presentation is 44 years. Approximately 125 to 295 people per 1 million are affected, with an estimated annual incidence of five cases per 1 million people.[3] In more than 95% of cases, overproduction of GH is caused by a benign pituitary adenoma, whereas malignant adenomas are rare. Most pituitary adenomas occur spontaneously as a result of a sporadic genetic mutation acquired during life.[4] Depending on tumor size, pituitary adenomas are classified as (a) microadenomas if they are 10 mm or less in diameter; or (b) macroadenomas if they are greater than 10 mm.[4] Although these tumors can produce GH, they more commonly secrete GHRH resulting in excessive GH and IGF-I production.

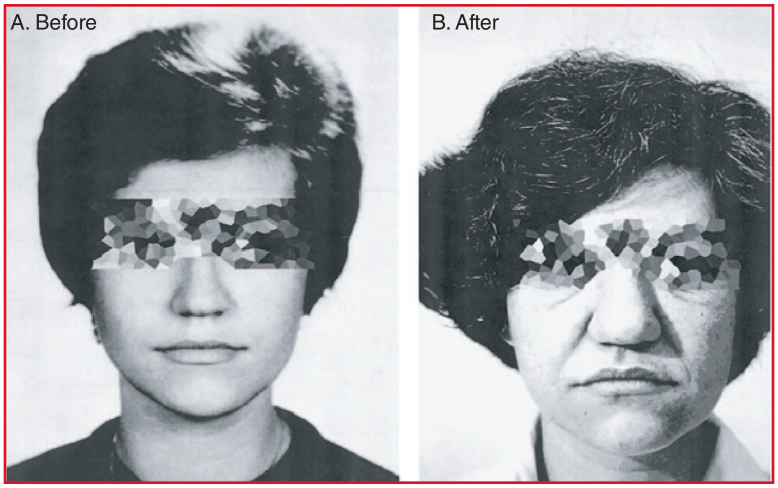

FIGURE 47–2. Before and after photographs of a patient with acromegaly. Compare the photographs **(A)** before the onset of acromegaly and **(B)** after approximately 20 years when the diagnosis was well established. Notice the coarsening of facial features, with an enlarged nose, lips, and forehead.

▶ *Pathophysiology*

Acromegaly is a rare disorder that manifests gradually over time and typically occurs after fusion of the epiphyses (growth plates) of the long bones.[5] The facial and hand features of an acromegalic patient are depicted in Figures 47–2 and 47–3. Gigantism refers to GH excess that occurs during childhood before epiphyseal closure and results in excessive linear growth. Because the signs and symptoms of acromegaly are insidious, diagnosis of this disorder is often delayed for up to 10 years after the initial presentation of symptoms.[5] Therefore, it is important for practitioners to be vigilant in identifying this disease in the early stages.

Diagnosis of acromegaly is based on both clinical and biochemical findings. Because GH fluctuates throughout the day, a single random measurement is never a reliable diagnostic tool to evaluate GH excess.[1] Serum IGF-I concentrations correlate positively with mean GH concentrations and are relatively stable, thus making elevations in IGF-I concentrations an ideal and reliable biochemical marker to monitor disease activity and response to therapy.[5,6] IGF-I serum concentrations are often represented as age- and sex-matched population values.[6] In addition to an elevated serum IGF-I concentration, an oral glucose tolerance test (OGTT) is recommended to confirm the diagnosis.[7] Under normal circumstances, GH is suppressed to less than 1 ng/mL (mcg/L) after administration of a 75-g oral glucose challenge because postprandial hyperglycemia inhibits secretion of GH. However, in patients with acromegaly, there is lack of suppression of GH following an oral glucose load.[7] Therefore, the diagnosis of acromegaly is confirmed if a patient has a random GH concentration greater than 1 ng/mL (mcg/L) or has nadir GH concentration greater than 0.4 ng/mL (mcg/L) 2 hours after the test.[7,8]

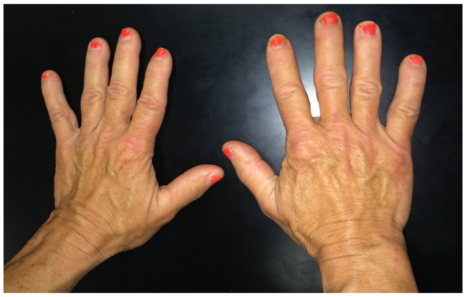

FIGURE 47–3. Photograph of hands from a patient with acromegaly. Soft-tissue swelling and enlargement of the hand in a woman with acromegaly resulting in increased ring and glove size.

▶ *Treatment*

Desired Outcomes Patients with untreated acromegaly experience a two- to threefold increase in mortality rate primarily because of cardiovascular, cerebrovascular, and pulmonary diseases,[5,7] with cancer reported as a cause of death in recent years.[6,8,10] **KEY CONCEPT** Prolonged exposure to elevated GH and IGF-I can lead to serious complications in patients with acromegaly.[10] Comorbid conditions such as hypertension, diabetes, dysrhythmias, coronary artery disease, and heart failure should be aggressively managed to prevent cardiovascular, pulmonary, metabolic, respiratory, musculoskeletal, and neuropathic complications.[6-8,10] Normalization of GH and IGF-I concentrations also normalizes mortality rate and improves overall life expectancy.[10] Goals of therapy are as follows:[5-8]

- Reduce fasting morning GH and IGF-I concentrations as close to normal as possible.
- Reduce tumor size to relieve tumor mass effect.
- Prevent tumor recurrence.
- Preserve normal pituitary function.
- Improve clinical signs and symptoms.
- Alleviate significant morbidities.
- Reduce mortality rates to those of the general population.

It is recommended for patients to receive treatment at the Pituitary Tumor Centers of Excellence to benefit from multimodal management of care with a multidisciplinary team of experts who can offer integrated acromegaly management and utilize the best and most cost-effective care with a personalized approach to treatment.[6,8]

Surgical Treatment According to the Endocrine Society[7] and the American Association of Clinical Endocrinologists (AACE) treatment guidelines for acromegaly,[5] **KEY CONCEPT** surgical resection of the pituitary tumor through transsphenoidal pituitary microsurgery is the treatment of choice for most patients with

Clinical Presentation and Diagnosis of Acromegaly[5-7,9]

General

The patient will experience slow development of soft-tissue overgrowth affecting many body systems. Signs and symptoms may gradually progress over 7 to 10 years.

Symptoms

- Headache and visual disturbances (loss of peripheral vision and blurred vision) caused by the actual tumor mass and its close proximity to the optic structures.
- Weakness, low blood sugar, or weight loss caused by the disruption of adrenal function (ie, ACTH deficiency) by the effect of tumor mass on the pituitary.
- Fatigue and weight gain caused by the disruption of thyroid function (ie, TSH deficiency) by the effect of tumor mass on the pituitary.
- Absence of regular menstrual periods (amenorrhea), impotence, and decreased libido caused by the disruption of the gonadotropin secretion (ie, LH and FSH).
- Excessive sweating, joint pain, nerve pain, and abnormal neurologic sensations (paresthesias) related to elevated GH and IGF-I concentrations.

Signs

- Coarsening of facial features
- Increased hand volume
- Increased ring and shoe size
- Increased spacing between teeth
- Increased acne or oily skin
- Enlarged tongue
- Deepening of voice
- Thick, irregular, and patchy skin discoloration
- Enlarged nose, lips, and forehead (frontal bossing)
- Abnormal protrusion of the mandible (prognathia) and bite abnormalities
- Inappropriate secretion of breast milk (galactorrhea)
- Abnormal enlargement of various organs (organomegaly) such as liver, spleen, and heart
- Carpal tunnel syndrome caused by nerve compression from the swollen tissue

Laboratory Tests

- Elevated IGF-I concentration compared with age-matched control values.
- OGTT: lack of suppression of GH to less than 1 ng/mL (mcg/L) or nadir GH concentration greater than 0.4 ng/mL (mcg/L) following documented hyperglycemia during an OGTT.
- Loss of other hormonal functions caused by tumor mass compression of the anterior pituitary.
- Measuring prolactin concentration in all patients because prolactin cosecretion is common.
- Impaired glucose tolerance and type 2 diabetes mellitus develop in 30% to 50% of patients.

Additional Clinical Sequelae

- Cardiovascular diseases: hypertension, coronary heart disease, cardiomyopathy, left ventricular hypertrophy, and arrhythmia.
- Osteoarthritis and joint damage develop in up to 90% of patients.
- Respiratory disorders and **sleep apnea** occur in up to 80% of patients.
- Vertebral fractures affect up to 60% of patients.
- Increased risk for the development of esophageal, lung, colon, stomach, kidney, and thyroid cancer.

Other Diagnostic Tests

- Perform magnetic resonance imaging (MRI) examination of the pituitary to locate the tumor and validate the diagnosis.
- Obtain serum prolactin concentrations to assess for hyperprolactinemia and **hypopituitarism**.
- Without obvious pituitary tumor but proven acromegaly, measurement of GHRH may be helpful to detect ectopic tumors.

GH-producing pituitary adenomas. When performed by experienced surgeons, greater than 85% of patients with microadenomas and greater than 40% of patients with macroadenomas achieve biochemical remission.[7] Complete resection of a macroadenoma may be difficult if the tumor has already invaded the surrounding nerves and tissues. In such cases, debulking of the tumor along with adjunctive radiation and/or pharmacotherapy may improve treatment outcome. Infrequent surgical complications include meningitis, serious visual impairment, spinal fluid leakage, diabetes insipidus, and hypopituitarism.[7] Relative contraindications to surgery include patient frailty, acromegaly-associated comorbidities, and medically unstable conditions such as airway difficulties, severe hypertension, or uncontrolled diabetes.

Pharmacologic Therapy Pharmacologic therapy is often necessary for patients in whom surgery is not an option (Figure 47–4).[8] Somatostatin analogs, GH-receptor antagonists, and dopamine agonists are the primary pharmacologic therapies used for the management of acromegaly (Table 47–2).[1,5,7,8,11-14] Pharmacologic therapy avoids hypopituitarism and other surgical risks.

Somatostatin Analog (GH-Inhibiting Hormone) KEY CONCEPT Somatostatin analogs are the mainstay of pharmacotherapy for the treatment of acromegaly when surgery is not appropriate, or as an adjuvant therapy until patients achieve a sustained response to radiation therapy.[7,8] These agents mimic endogenous somatostatins and bind to somatostatin receptors in the pituitary to cause potent inhibition of GH, insulin, and glucagon secretion. Long-term treatment can sustain GH suppression, alleviate soft-tissue manifestations, and reduce tumor size. The long-acting preparations of somatostatin analogs (octreotide or lanreotide) are considered the cornerstone of therapy because of improved patient

Patient Encounter 1, Part 1

A 45-year-old man presents to your clinic for the first time, as requested by his primary care provider who has concerns that the side effects of his medications are causing bothersome symptoms. The patient complains of weakness, fatigue, excessive sweating, and joint pain. He states he recently scheduled an appointment to see the ophthalmologist because of his worsening blurry vision. The patient has noticeably large facial features, a very deep voice, and oily skin.

PMH: Heart failure, type 2 diabetes mellitus, sleep apnea

FH: Positive for heart disease in father and hypertension in mother

Allergies: No known drug allergies

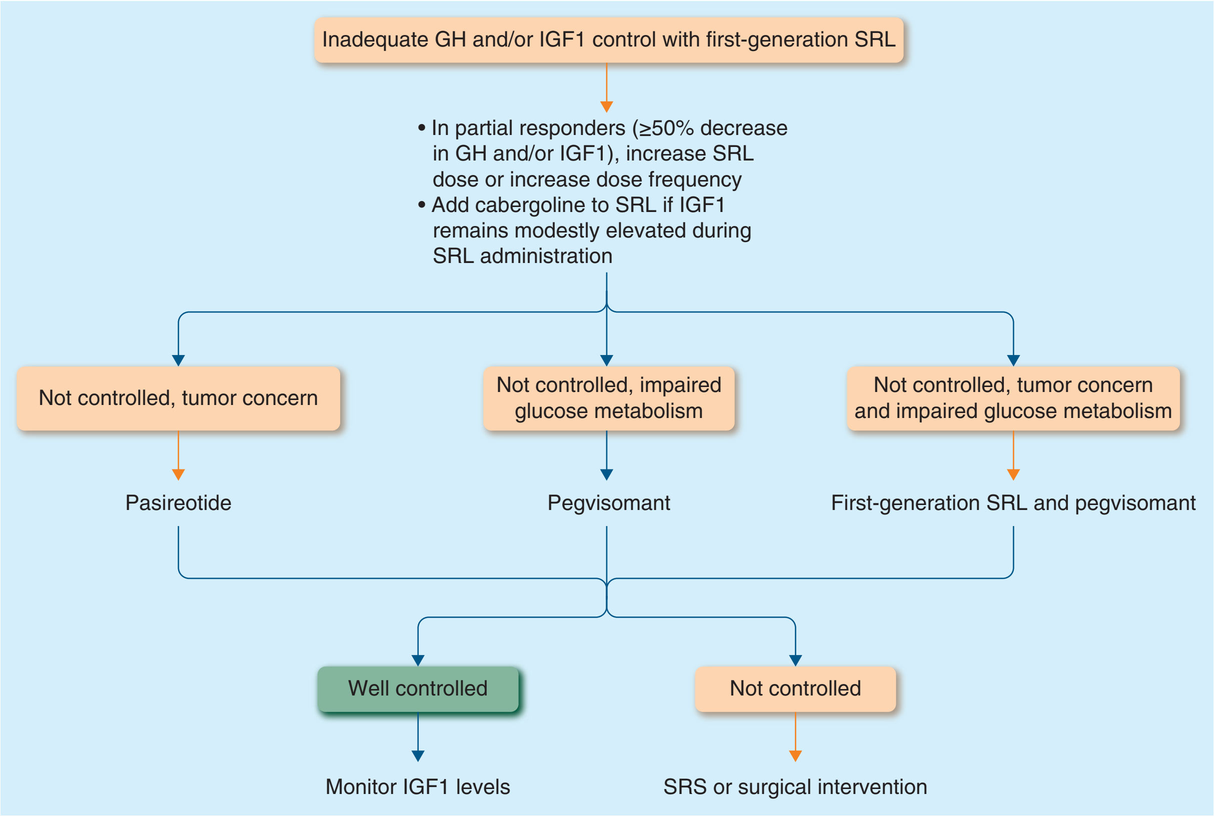
SH: Janitor at an elementary school

Meds: Atorvastatin 40 mg daily, lisinopril 20 mg daily, metoprolol succinate 25 mg daily, furosemide 40 mg daily, metformin 1000 mg twice daily, liraglutide 1.8 mg daily, empagliflozin 25 mg daily, gabapentin 600 mg three times daily, aspirin 81 mg once daily, lidocaine cream 4% applied three to four times daily to affected area

Based on the information available, what signs and symptoms are suggestive of acromegaly?

What comorbidities are present in this patient as a result of untreated acromegaly?

What diagnostic tests should be performed to confirm the patient's diagnosis of acromegaly?



Inadequate GH and/or IGF1 control with first-generation SRL
• In partial responders (≥50% decrease in GH and/or IGF1), increase SRL dose or increase dose frequency
• Add cabergoline to SRL if IGF1 remains modestly elevated during SRL administration
Not controlled, tumor concern
Not controlled, impaired glucose metabolism
Not controlled, tumor concern and impaired glucose metabolism
Pasireotide
Pegvisomant
First-generation SRL and pegvisomant
Well controlled
Not controlled
Monitor IGF1 levels
SRS or surgical intervention

FIGURE 47–4. Medical management of patients with acromegaly.[8] The proposed algorithm presents treatment of acromegaly in patients inadequately controlled with first-generation somatostatin receptor ligands (SRL), lanreotide Autogel and octreotide long-acting release. In partial responders (greater than or equal to 50% decrease in growth hormone [GH] and/or insulin-like growth factor 1 [IGF1]), increase SRL dose and/or dose frequency. If IGF1 remains modestly elevated during SRL administration, add cabergoline to SRL. If disease control is not achieved, patients should be switched to the second-generation SRL pasireotide if there is a clinically relevant residual tumor on imaging and/or clinical concern of tumor growth (tumor concern). Patients with impaired glucose tolerance should be switched to the GH antagonist pegvisomant. Patients with impaired glucose tolerance and tumor concern should be treated with a combination of a first-generation SRL and pegvisomant. Those who remain uncontrolled despite second-line medical therapy should be considered for stereotactic radiosurgery (SRS) or surgical intervention (Reprinted by permission from Creative Commons Attribution License: Melmed S, Bronstein, MD, Chanson P, et al. A Consensus Statement on acromegaly therapeutic outcomes. Nat Rev Endocrinol. 2018;14:552–561. (Licensed under a CC BY 4.0 license. Link available at https://creativecommons.org/licenses/by/4.0/.)

Table 47–2

Comparison of Various Drugs Within Drug Classes for Treatment of Acromegaly[1,5,7,8,11-14]

	Dopamine Agonist	Somatostatin Analog						GH-Receptor Antagonist
Medication	**Cabergoline**	**Octreotide (Sandostatin)**	**Octreotide (Mycapssa)**	**Octreotide LAR (Sandostatin LAR)**	**Lanreotide SR**	**Lanreotide Autogel (Somatuline Depot)**	**Pasireotide (Signifor LAR)**	**Pegvisomant (Somavert)**
Starting dose	1 mg/week orally	50 mcg SC thrice daily	20 mg PO twice daily	20 mg IM every 4 weeks	60 mg IM every 2 weeks	90 mg deep SC every 4 weeks[a]	40 mg IM every 4 weeks	10 mg SC daily after initial loading dose of 40 mg
Maximal dose	7 mg/week orally	100 mcg SC thrice daily	80 mg daily	40 mg IM every 4 weeks[b]	120 mg IM every 7 days	120 mg deep SC every 4 weeks	60 mg IM every 4 weeks	30 mg SC daily[c]
Dosage in hepatic insufficiency	Dosage reduction may be recommended for patients with severe hepatic failure	–	–	Cirrhosis: 10 mg IM every 4 weeks	Dosage reduction may be necessary; no guidelines available	Moderate-to-severe impairment: starting dose 60 mg every 4 weeks	Moderate impairment: starting dose 20 mg every 4 weeks, maximal dose of 40 mg every 4 weeks. Severe hepatic impairment: avoid use	Discontinue therapy if liver function tests are elevated at least five times the upper limit of normal or transaminase at least three times the upper limit of normal with any increase in serum total bilirubin
Dosage in renal failure	None	Dialysis dependent: adjustment may be necessary; no guidelines available	Initial dose in ESRD: 20 mg PO daily	Dialysis-dependent renal impairment: 10 mg IM every 4 weeks	Dosage reduction may be necessary; no guidelines available	Moderate-to severe-impairment: starting dose, 60 mg every 4 weeks	None	None
Side effects	Nausea, GI cramps, headache, drowsiness, dizziness, fatigue	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones	Nausea, GI cramps, diarrhea, hyperglycemia, fatigue, gallstones, abdominal pain	Headache, fatigue, GI cramps, abnormal liver enzymes, injection-site reactions, sweating
Monitoring suggestions	GH, IGF-I, and prolactin concentration 4–6 weeks after each dose change	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	GH and IGF-I 2 weeks after dose initiation or change, thyroid function tests and blood glucose	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose	Liver function tests (serum transaminase, total bilirubin, alkaline phosphatase) monthly for 6 months, then biannually for the next year; MRI every 6 months, then yearly if no growth; IGF-I (not GH) after the first year, then yearly

[a] In the United States, initiate lanreotide at 90 mg every 28 days for 3 months and then titrate accordingly based on response.

Different labeled dosing guidelines exist for the United Kingdom and Canada.

[b] Product labeling recommends a maximum of 30 mg IM every 4 weeks.

[c] Although higher doses have been used in patients with persistently elevated IGF levels, doses > 30 mg/day are not approved and recommended.[8]

ESRD, end-stage renal disease; GH, growth hormone; GI, gastrointestinal; IGF-I, insulin-like growth factor-I; IM, intramuscularly; LAR, long-acting release; MRI, magnetic resonance imaging; PO, per os (by mouth); SC, subcutaneously; SR, slow release.

Adapted from AACE Medical Guidelines for Clinical Practice for the diagnosis and treatment of acromegaly. Endocr Pract. 2004;10:213–225 by permission of publisher, American Association of Clinical Endocrinologists (AACE) Corp.

adherence and acceptability over the first-generation octreotide. Somatostatin analogs normalize GH and IGF-I concentrations in approximately 55% of patients[5] and modestly reduce pituitary tumor size in more than half of patients with acromegaly.[7] Optimal dose titration of somatostatin analogs is important in disease control.[7] Patients with inadequate biochemical control can benefit from titrating to higher doses with more frequent dosing.[8] The long-acting release (LAR) formulation of pasireotide has been demonstrated to provide superior efficacy compared to octreotide or lanreotide in achieving clinical and biochemical control[11] and is recommended as the second-line therapy in patients with inadequate control with LAR lanreotide or octreotide.[8] The delayed-release oral octreotide is the first and only oral somatostatin analog approved for patients who previously responded to and tolerated octreotide or lanreotide injections.[12-14] The Pituitary Society integrates oral octreotide into the treatment algorithm for those who have demonstrated complete or partial biochemical response on octreotide or lanreotide injections, and recommends initiating it at the time of the previously scheduled injection.[14] While the oral somatostatin analog may improve patient acceptance due to its preferred route of administration, oral octreotide is less effective compared to the long-acting injectable preparations.

Because somatostatin analogs can achieve substantial relief of clinical symptoms with significant reduction in tumor size,[15] it is important to monitor patients for tumor recurrence if treatment is discontinued.[5,7] Use of somatostatin analogs before surgery is not routinely recommended due to insufficient data to suggest additional benefits over surgery alone.[16]

Somatostatin analogs are generally well tolerated. Transient gastrointestinal (GI) disturbances are common but usually subside within the first months of therapy.[17] Somatostatin analogs inhibit gallbladder contractility and decrease bile secretion; therefore, their major adverse effect is development of biliary sludge and asymptomatic gallstones (cholelithiasis).[17] Somatostatin analog–induced gallstones are generally asymptomatic; therefore, prophylactic therapy or routine abdominal ultrasound monitoring is usually not needed.[7,17] Additionally, somatostatin analogs may alter the balance of counterregulatory hormones (ie, glucagon, insulin, and GH), resulting in either hypoglycemia or hyperglycemia. Higher incidence of hyperglycemia and diabetes has been reported with pasireotide compared to other somatostatin analogs;[11] therefore, its use is not recommended in patients with uncontrolled diabetes.[6,8] Somatostatin analogs also may suppress pituitary release of TSH, leading to decreased thyroid hormone secretion and subsequent hypothyroidism. Proactive monitoring of thyroid function and glucose metabolism is recommended. Sinus bradycardia, conduction abnormalities, and arrhythmias have been reported with the use of somatostatin analogs. Because of the potential adverse effects of the somatostatin analogs, concomitant use with insulin, oral hypoglycemic agents, β-blockers, or calcium channel blockers may require careful dosage adjustment. Somatostatin analogs may also alter the bioavailability and elimination of cyclosporine, and monitoring of cyclosporine serum concentration is necessary.

GH-Receptor Antagonist The advent of a GH-receptor antagonist represents a novel approach to the treatment of acromegaly. Pegvisomant is the only genetically engineered GH-receptor antagonist that blocks the action of GH. Pegvisomant is indicated for the treatment of acromegaly in patients who have an inadequate response to surgery or radiation therapy. The effects of pegvisomant work independently of tumor characteristics, somatostatin, and dopamine receptors. To date, pegvisomant is the most effective agent in normalizing IGF-I concentration in acromegaly; it achieved this in 89% to 100% of patients in initial clinical trials, and in 73% in more recent cohorts.[18,19] Long-term safety and efficacy of pegvisomant (10 year follow up) from an ongoing postmarketing surveillance registry (ACROSTUDY) suggest a reasonable benefit/risk balance.[14,20] Pegvisomant therapy has favorable effects on glucose tolerance and insulin sensitivity and should be considered as a treatment option if patients have partial or no response to first-line medical therapy and also present with uncontrolled diabetes.[6] However, use of pegvisomant is associated with significant dose-dependent increases in GH despite declining IGF-I concentrations. The dose-dependent increase in GH is troubling because it has been suggested that persistent elevation of GH concentration may be indicative of tumor growth. Given the incidence of pituitary tumor enlargement is 6.8%, careful monitoring with periodic imaging scans is warranted.[20] **KEY CONCEPT** Pegvisomant is recommended in patients who have inadequate response to somatostatin analogs, or as an adjuvant for patients who have only a partial response to somatostatin analogs.[5,7,8] Patients at risk of visual damage from large tumors impinging on the optic chiasm may consider alternative pharmacologic therapy.[7]

The long-term use of pegvisomant appears to be well tolerated with a low incidence of adverse effects, including self-limiting injection-site reactions (3.1%) and elevated liver enzymes (3%).[20] Although elevations of liver enzymes often are self-limiting and not associated with symptoms,[5,7] hepatotoxicity has been reported in clinical trials, particularly in patients receiving combined pegvisomant and somatostatin analogs.[18] Therefore, serum transaminases, total bilirubin, and alkaline phosphatase should be assessed before initiating therapy and periodically thereafter. Use caution when administering pegvisomant to patients with elevated liver function tests (LFTs), and therapy should be discontinued in patients who present with clinical signs and symptoms of hepatic injury.

Dopamine Agonists Dopamine is one of the neurotransmitters that can increase GH secretion in healthy adults. However, dopamine agonists administered to patients with acromegaly exert the opposite effect and suppress GH release from the tumor. The first dopamine agonist used for acromegaly, bromocriptine, achieved normal IGF-I concentrations in fewer than 10% of patients.[21] The large doses of bromocriptine required to achieve the desired response are often associated with dose-limiting toxicity such as GI discomfort and orthostatic hypotension. Cabergoline is the preferred dopamine agonist for the treatment of acromegaly due to its improved tolerability and extended duration of action. Cabergoline can effectively reduce GH and IGF-I concentrations in approximately 30% of patients but its efficacy appears to decrease over time.[7] Although orally administered dopamine agonists are the least expensive medical therapy for managing acromegaly, the major disadvantage is their relative lack of efficacy compared with existing therapeutic options. **KEY CONCEPT** Cabergoline may be considered for patients with the modest elevation of GH and IGF-I concentrations less than 2.5 times the upper limit of normal (ULN). It may also be used as adjunctive therapy in patients unresponsive to monotherapy with somatostatin analogs or pegvisomant.[7,8] Although cardiac valvular abnormalities have been observed in patients using higher doses of cabergoline for Parkinson disease, patients receiving treatment for acromegaly do not seem to carry increased risk of cardiac valve disease.[5,7,21,22] Nonetheless, echocardiographic monitoring for potential cardiac abnormalities is reasonable for patients who require prolonged, high-dose (> 2 mg/week) cabergoline therapy.[7]

Combination Therapy For patients who are resistant to monotherapy, combination therapies have been beneficial with improved efficacy and reduced side effects associated with individual medication. Addition of pegvisomant or cabergoline may be considered in patients with inadequate response to somatostatin analog.[7,14]

Radiation Therapy Radiation therapy is an important adjunctive therapy in patients with residual GH excess after surgery or pharmacologic therapy.[7] Treatment involves the use of radiation to destroy rapidly growing tumor cells and often results in a reduction in tumor size. A major complication of radiation therapy is hypopituitarism, requiring lifelong hormone replacement.[5] There is also the potential for optic nerve damage if the pituitary tumor is near the optic tracts. Radiation therapy may take 10 to 20 years before its full effects become evident.[5] Owing to this delay in the onset of effectiveness, pharmacologic therapy with a somatostatin analog often is indicated as bridge therapy.[5,7] Men and women who desire to have children should be warned that pituitary irradiation therapy may impair fertility because of subsequent gonadotropin deficiency.[5]

Management of Acromegaly in Pregnancy Due to limited safety data, use of pharmacologic therapy during pregnancy is reserved for tumor and headache control. Substitute long-acting formulation of somatostatin analogs and pegvisomant with short-acting octreotide approximately 2 months prior to conception.[7] Monitoring of IGF-I and GH level during pregnancy is limited in patients with acromegaly because conventional assays are not usually able to distinguish between the variant forms of GH.[7]

▶ *Outcome Evaluation*

- Lifelong biochemical assessment is critical for determining therapeutic outcomes.[19] Although some patients may experience a rapid decline in GH concentrations after surgery, stabilization of IGF-I concentrations usually occurs 3 months after surgery but rarely may be delayed for up to 12 months. Fully assess pituitary function at 12 weeks or later after surgery.[5] Monitor random GH and IGF-I concentrations every 3 to 6 months postoperatively to assess treatment response.[5] Obtain IGF-I concentrations annually in all postsurgical patients to monitor for potential pituitary tumor recurrence.[5,7,19] Measure nadir GH level after glucose load in patients with GH greater than 1 ng/mL (mcg/L).[7]
- Assess MRI at least 12 weeks after surgery to visualize residual tumor.[7]
- For patients treated with somatostatin analogs, assess baseline fasting blood glucose, thyroid function tests, and heart rate. Thereafter, periodically monitor patients for adverse reactions such as GI disturbances, glucose intolerance, signs and symptoms of thyroid abnormalities, bradycardia, and arrhythmias in patients receiving long-term somatostatin analogs. Reevaluate IGF-I and GH concentrations at 3-month intervals to determine therapeutic response and inquire about symptoms of gallbladder disease (eg, intermittent pain in the upper right abdomen) during follow-up appointments.[5,7] If normalization of GH and IGF-I concentrations is not fully achieved after 1 year, perform MRI 6 months later and annually thereafter to monitor tumor mass.[5]
- For patients treated with a GH-receptor antagonist, GH concentrations are not measured because pegvisomant is a modified GH molecule that is detected in commercial GH assays, resulting in falsely elevated GH concentrations. Therefore, monitor IGF-I concentrations to assess response to pegvisomant therapy. After appropriate dose titration, monitor IGF-I concentrations every 6 months.[5,7] Concern for tumor growth requires careful monitoring of tumor size; therefore, perform MRI every 6 months during the first year of therapy. If there is no evidence of growth, then monitor annually thereafter.[7] Because of the potential for hepatotoxicity with pegvisomant therapy, it is mandatory to monitor liver enzymes prior to initiation of therapy, monthly during the first 6 months, biannually thereafter.[7] More frequent monitoring of liver enzymes is warranted in patients with elevated liver enzymes at baseline.[5] Discontinue pegvisomant if LFT is more than threefold elevated.[7]
- For patients receiving dopamine agonists, the maximal suppression of GH and IGF-I concentrations may take up to 3 months to achieve. After stable control of biochemical markers is achieved with dopamine agonists or somatostatin

Patient Encounter 1, Part 2

PE:

VS: BP 142/86 mm Hg, P 87 beats/min, RR 19 breaths/min, T 36°C (96.8°F), Ht 193 cm (6′4″), Wt 106 kg (233 lb), BMI 28.4 kg/m^2

ROS: (+) fatigue, (+) weakness (+) deepening of voice, (+) decreased joint motion, (+) excessive sweating

HEENT: Visual field defects; head is elongated with bony prominence of the forehead, nose, and lower jaw; large fleshy nose

CV: RRR, normal S1 and S2; no murmurs, rubs, or gallops, 2^+ pitting edema of lower extremities, (–) chest pain, palpitation, orthopnea

Pulm: (–) SOB, (–) cough

GI: (–) Nausea, vomiting, and abdominal pain

Abd: Soft, nontender, nondistended; (+) bowel sounds, (–) hepatosplenomegaly

Neuro: A&O × 3. Normal reflexes

Psychiatric: Pleasant

Available Labs: Electrolytes and renal function are within normal limits. Fasting blood glucose concentration is 234 mg/dL (13 mmol/L), glycated hemoglobin A1c ($HgbA_{1c}$) is 8.5% (0.085; 69 mmol/mol Hb), (+) microalbuminuria. GH concentration 2 hours after an OGTT is 72 ng/mL (mcg/L). Elevated IGF-I concentration at 876 ng/mL (mcg/L). TSH 1.2 μU/mL (mU/L) and free thyroxine (FT_4) 1.4 ng/dL (18 pmol/L) are within normal range

MRI: (+) 7 mm benign pituitary adenoma extending toward the optic chiasm; no invasion into the cavernous sinus

Given the patient does not want surgery, what pharmacologic treatment options are available?

What factors need to be considered when choosing a pharmacologic treatment option?

Provide monitoring parameters to assess efficacy and safety to the patient starting on pegvisomant.

Patient Care Process: Acromegaly

Collect Information:

- Review the available diagnostic data to determine pituitary tumor size and location.
- Perform complete medication history. Identify allergies to medications and other substances.
- Determine treatment options the patient has tried in the past.
- Review the medical history, relevant laboratory tests, and physical assessment findings.
- Speak with patient and review records to identify signs and symptoms of acromegaly, preferences and beliefs, health goals, and socioeconomic factors or barriers that affect medication access and other aspects of care.

Assess the Information:

- Assess the patient's clinical signs and symptoms and biochemical disease markers to determine the severity of acromegaly.
- Determine if the patient has a coexisting prolactin-secreting tumor and the impact of the tumor on the optic tract.
- Assess the presence of acromegaly complications. Identify any significant comorbidity associated with acromegaly that requires immediate treatment or early diagnosis.
- Evaluate patient for the presence of surgical contraindications to transsphenoidal microsurgery. Determine if the patient is able or willing to undergo surgical intervention.
- Assess if the patient has any contraindication or allergy to therapies (see Table 47–2).

Develop a Care Plan:

- If surgical intervention does not achieve satisfactory disease control, select subsequent appropriate pharmacologic therapy based on patient-specific factors (see Figure 47–4).
- Determine if selected drug doses are optimal (see Table 47–2). Consider if the patient's therapy requires any dose adjustment.

Implement the Care Plan:

- Discuss potential effectiveness and disadvantages of existing treatment options.
- Address any patient concern about acromegaly, its management, and possible complications.
- Determine whether the patient has insurance coverage and preferred treatments covered.
- Educate patient about changes in drug therapy, proper medication administration techniques, potential new adverse effects, and how to manage and report adverse effects that occur.
- Discuss the importance of medication adherence and how to reduce the modifiable cardiovascular and metabolic risk factors.
- Use motivational interviewing and coping strategies to maximize adherence.

Follow-up: Monitor and Evaluate:

- Monitor patient's biochemical markers (GH and IGF-I concentrations) and complications to surgical intervention.
- Review adherence to treatment plan using multiple sources of information.
- Review physical examination, lab tests, and results of other diagnostic tests to assess changes in clinical status and complications.
- Evaluate safety and efficacy of pharmacologic therapy and the degree of disease control.
- Determine whether the patient is experiencing any adverse reaction or drug interaction.
- Routinely assess acromegaly complications; include blood pressure, glucose tolerance, fasting lipid profile, cardiac evaluations (if clinically indicated), colonoscopy, dual-energy X-ray absorptiometry (DEXA) scan (hypogonadal only), evaluation of residual pituitary function, and sleep apnea.

analogs, monitor GH and IGF-I concentrations annually.[5] Measure GH, prolactin, and IGF-I level 4 to 6 weeks after dose change.[5]

- Monitor GH and IGF-I annually 1 to 3 months after medication withdrawal to assess efficacy of radiation therapy.[7] Assess for hypopituitarism and replace any hormone deficit.[7]

Growth Hormone Deficiency

▸ *Epidemiology and Etiology*

An estimated 2% of the population can be characterized as having short stature, with only 1 in 4,000 primarily caused by GH deficiency.[9] Children may present with GH deficiency at any time during their developmental stages. The evaluation of GH deficiency in a child of short stature should be deferred until appropriate exclusion of other identifiable causes of growth failure, such as hypothyroidism, chronic illness, malnutrition, genetic syndromes, and skeletal disorders, has occurred. Several medications, such as somatostatin analogs, gonadotropin-releasing hormone (GnRH) agonists, methoxamine, phentolamine, isoproterenol, glucocorticoids, cimetidine, methylphenidate, and amphetamine derivatives, may induce GH insufficiency.[23]

▸ *Pathophysiology*

GH deficiency exists when GH is absent or produced in inadequate amounts. GH deficiency may be congenital, acquired, or result from disruption of the hypothalamus–pituitary axis. GH deficiency may be an isolated condition or occasionally be accompanied by another endocrine disorder (eg, panhypopituitarism). Because GH is frequently undetectable with random sampling, a stimulation or provocative test is usually performed to confirm the diagnosis. Historically, the gold standard for diagnosis of adults with GH deficiency has been the insulin tolerance test (ITT); however, because of safety limitations, this test has been used less frequently in recent years.[25,26] The glucagon stimulation test (GST) has become the more commonly used alternative test because of its reproducibility and safety with relatively few contraindications. The macimorelin test, approved in 2017, is a GH

Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Children[9,24]

General

The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and sex.

Signs

- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with GH-deficient or GH-insufficient short stature also may present with abdominal obesity, prominence of the forehead, and immaturity of the face.

Laboratory Tests

- Patients will exhibit a peak GH concentration of less than 10 ng/mL (mcg/L) after a GH stimulation test.
- Reduced IGF-I concentration may be present.
- Because GH deficiency may be accompanied by the loss of other pituitary hormones, hypoglycemia and hypothyroidism may be noted.

Other Diagnostic Tests

- Perform MRI of the hypothalamic–pituitary region to detect structural or developmental anomaly.
- Perform radiography of the left wrist and hand for children older than 1 year of age to estimate bone age (knee and ankle for children younger than 1 year of age).
